Environmental causes (Table 62–10) and an abnormal blink reflex are common causes of increased evaporative loss of tears and worsening of dry eye.

**Treatment**

** Desired Outcomes**
- Relief of the symptoms of dry eye
- Maintain or improve visual acuity
- Prevention of long-term adverse effects from dry eye

**General Approach to Treatment**

Dry eye is a chronic condition. Symptoms can be improved with treatment, but unless dry eye is secondary to a disease, it is not usually curable. Because of this, patient education is critical, and a periodic reassessment of the efficacy of the treatment is appropriate. If the patient is unresponsive to treatment, refer to an ophthalmologist for additional options. If the dry eye is secondary to a systemic disease, the disease should be managed by the appropriate medical specialist.

**Nonpharmacologic Therapy**

Behavioral and environmental modifications may significantly improve dry eye, especially in mild cases. Patients should be counseled to increase their frequency of blinking, use eyelid hygiene and warm compresses, and stop smoking. Reduce air drafts and consider adding a humidifier in low-humidity areas. Schedule regular breaks from computer work or reading. Lower
the computer screen to below eye level to decrease lid aperture. Evaluate medication profile and therapeutically substitute medications that do not exacerbate dry eye. Spectacle side shields or goggles may reduce tear evaporation.\(^{21,22}\)

- If pharmacologic and other therapies are not sufficient, punctal occlusion or lateral tarsorrhaphy may be an option.\(^{21,22}\) Punctal occlusion is the plugging of the punctal drainage sites with collagen or silicone plugs. Lateral tarsorrhaphy sutures portions of the lid margins together to decrease evaporative tear loss.

**Pharmacologic Therapy**

- The mainstay of treatment for dry eye is artificial tears. Artificial tears augment the tear film topically and provide symptom relief. If a patient uses artificial tears more than four times daily, or develops an allergy to ophthalmic preservatives, recommend a preservative-free formulation. Artificial tears are available in gel, ointment, and emulsion forms that provide a longer duration of relief. Ointment use is appropriate at bedtime.\(^{21}\)

- Preliminary data suggest dietary or supplemental intake of omega-3 fatty acids may be beneficial.\(^{22}\) Omega-3 fatty acids may block the production of inflammatory cytokines and pro-inflammatory mediators.\(^{21}\)

- Anti-inflammatory agents may be used in conjunction with artificial tears. The only approved agent is cyclosporine emulsion. Cyclosporine emulsion increases tear production in some patients. Fifteen minutes should elapse after instillation of cyclosporine before artificial tears are instilled.\(^{22}\) Use of topical corticosteroids for short periods (2 weeks) may suppress inflammation and ocular irritation symptoms.\(^{22}\)

- The oral cholinergic agonists pilocarpine and cevimeline are used for patients with Sjögren syndrome (combined dry eye and dry mouth) or severe dry eye. By binding to muscarinic receptors, the cholinergic agonists may increase tear production. Excessive sweating is a common side effect with pilocarpine and may limit its use (Table 62–11).\(^{22}\)

**Outcome Evaluation**\(^{22}\)

- Monitor patient for relief of symptoms and ocular damage.
- Periodically reassess the patient’s compliance with therapy and understanding of the disease.
- It may take 6 to 12 weeks before improvement is seen with pilocarpine therapy.\(^{21}\)

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the basic pathophysiology of allergic rhinitis (AR).
2. List the four typical symptoms of AR and identify the one that is usually the most troublesome.
3. List at least three reasons for referral to an allergy specialist.
4. Differentiate the categories of pharmacotherapy choices for treatment of AR.
5. Rank the pharmacotherapy choices for efficacy in treating the usual single most troublesome symptom of AR.
6. Describe an approach for treatment of mild AR with over-the-counter (OTC) drugs.
7. Create a therapy plan for treatment of moderate–severe AR.
8. Describe how to monitor patients treated for AR.
9. Identify the differences in approach to the treatment of AR for children, pregnant women, and the elderly compared with the routine approach in adults.

INTRODUCTION

Rhinitis is inflammation of the lining of the nose and contiguous parts of the upper respiratory tract.1–4 Allergy is only one of numerous causes of rhinitis.1–5 The most common causes of nonallergic rhinitis are shown in Table 63–1.1–5 Some patients suffer concurrently from both allergic rhinitis (AR) and one or more types of nonallergic rhinitis (NAR). This is sometimes called mixed rhinitis (MR).1,3 AR will be emphasized in this chapter, but some mention will be made of NAR. Because ocular symptoms frequently occur in association with AR, some sources use the term allergic rhinoconjunctivitis. This acknowledges involvement of the bulbar and palpebral conjunctivae in the allergic process.

KEY CONCEPT  AR is an allergen-induced, immunoglobulin E (IgE)-mediated inflammatory condition of the lining of the nose and upper respiratory tract.1,6–9 This pathophysiologic feature differentiates AR from NAR. AR has traditionally been categorized as either seasonal or perennial.7 Seasonal allergic rhinitis (SAR) is attributed to inhaled allergens (aeroallergens) that have a seasonal variation. These allergens are usually encountered outdoors and are most often grass, tree or weed pollens and substances from molds and fungi. Perennial allergic rhinitis (PAR) is attributed to aeroallergens that are present in the patient’s environment almost continuously throughout the year and are usually encountered indoors. Common perennial allergens are the house dust mite, indoor molds and fungi, insects (especially cockroaches), and companion animals (pets).7 Some patients are affected year round, but have seasonal exacerbations. These people are probably allergic to both seasonal and perennial aeroallergens. Other patients have only episodic manifestations. These people are probably allergic to aeroallergens that are only episodically encountered.

Because these traditional categories of seasonal and perennial AR are imperfect and help little with therapeutic management decisions, another system for categorizing AR has been suggested by the international group Allergic Rhinitis and its Impact on Asthma (ARIA).9 This alternative system categorizes the manifestations by a combination of frequency and severity. There are two divisions of frequency: intermittent and persistent. Intermittent frequency is defined as AR manifestations occurring less often than 4 days per week or for fewer than 4 consecutive weeks. Persistent frequency is defined as AR manifestations occurring for 4 or more days per week and for 4 or more consecutive weeks. Severity is categorized as either mild or moderate–severe. Mild manifestations are those that do NOT cause interference with sleep, daily activities, or work or school performance and that are not “troublesome.” Moderate–severe severity includes those patients with manifestations of AR that DO cause interference with sleep, impairment of daily activities, problems at work or school, or are “troublesome.” The ARIA document uses IAR (for intermittent) and PER (for persistent) for the two frequency categories. It is important to realize that IAR and PER are not synonymous with the classical categories of SAR and PAR, respectively. The ARIA system results in four categories: mild intermittent, mild persistent, moderate–severe intermittent, or moderate–severe persistent. The ARIA approach was updated in 2008 and again in 2010.9,10 See Table 63–2 for a summary of these categories of AR.

EPIDEMIOLOGY

AR affects up to 30% of adults and 40% of children in the United States, and there is evidence that the incidence is increasing.3,5 The total direct and indirect costs of AR in the United States were estimated to be about 11 billion dollars, annually, in 2005.11
The major risk factors for AR are a family history of atopy (AR, asthma, eczema, or food allergies); elevated serum IgE levels (especially before the age of 6 years); higher socioeconomic class; positive skin test results; exposure to particulate air pollution; maternal smoking; firstborn status; and emigration into a Western industrialized environment.  

Certain disorders commonly occur with AR. The most important example is asthma. While different percentages are reported, most patients with asthma have rhinitis symptoms (many of which are AR), and only somewhat fewer with AR have asthma. In fact, there is evidence that AR can predispose to the development and/or worsening of asthma. Other conditions that can occur with AR include allergic conjunctivitis, eczema, sinusitis, sleep disorders, otitis media with effusion, and the oral food allergy syndrome.

From Refs. 7 and 8.

AR is an IgE-mediated disorder of people who are allergic prone. Initial contact is required to sensitize the patient to subsequent exposures. Patients with an inherited tendency to allergic disorders produce T-helper lymphocyte type 2 (Th-2)-directed responses, including production of specific IgE antibodies, to one or more allergens. Many types of cells, mediators, and intermediate substances (including cytokines) are involved. In response to subsequent exposures to the trigger antigen(s), there is an early-phase and often a late-phase allergic response. This distinction has therapeutic implications.

During the early phase, the trigger allergen becomes bound to IgE that is fixed to mast cells in the nasal mucosa. This occurs within minutes of subsequent exposure to the antigen. Mast cells degranulate and release preformed mediators, the most important of which is histamine. This stimulates more mast cells, as well as macrophages, eosinophils, and basophils to produce more substances, including cysteine leukotrienes and prostaglandin D2. These mediators bind to receptors in the nose and facilitate many of the manifestations of AR. The resultant vasodilation, mucosal edema, and hypertrophy all contribute to nasal congestion. Clear, watery, and often profuse rhinorrhea is also characteristic in this early phase, a result of mucous secretion and increased vascular permeability. Sneezing and nasal itch are other prominent features of the early phase. Many patients also have ocular symptoms.

The late phase occurs in about 50% of AR sufferers. It can begin as soon as 2 hours after the early phase and usually peaks between 6 and 12 hours. The late phase involves a second release of many of the mediators of the early phase. In addition, the late phase is characterized by an inflammatory component caused by infiltration of several cell types into the nasal mucosa. The most significant manifestation during the late phase is nasal congestion that is often severe and long lasting.

A phenomenon known as the priming response or nasal hyperresponsiveness is also of importance. This means that prolonged and/or repeated allergen exposure makes it easier to stimulate mediator release and symptoms. A vicious cycle results in which smaller doses of allergen can create symptoms (ie, the threshold is lowered). Thus, even when pollen exposure is decreased, symptoms may continue. In some patients, the threshold is lowered to the degree that even irritant substances (eg, formaldehyde, tobacco smoke, perfumes, automobile exhaust, and other environmental pollutants) may cause symptoms, on a nonallergic basis.
Clinical Presentation and Diagnosis of Allergic Rhinitis

**Typical Symptoms**
- Rhinorrhea (usually clear and bilateral; primarily anterior but may be posterior [postnasal drip])
- Sneezing
- Itching (mostly nasal, but also palate, throat, eyes, ears)
- Nasal congestion (not in all patients, but when present, usually the most troublesome symptom)

**Other Symptoms**
- Ocular manifestations (itch, redness, tearing, chemosis, periorbital edema)
- Sleep disturbances often with fatigue, asthenia, malaise, and irritability
- Presenteeism (impaired performance at work or school)
- Absenteeism from work or school
- Quality of life impairment (including social function)
- Headache, mild facial or ear pain, or fullness
- Cough (especially in those with concurrent asthma)
- Children (especially): snorting, sniffling, clearing the throat, learning or attention problems, poor appetite

**Signs (Especially Common in Children)**
- Pale, boggy nasal mucosa
- Rubbing the nose upward (allergic salute; may create horizontal crease just above tip of nose)

**Diagnosis**
- Typical symptoms, confirmatory signs, especially in association with exposure to allergen triggers
- Other diagnostic testing usually optional, but may be necessary to rule out nonallergic causes or if immunotherapy is considered (appropriate physical examination, specific IgE antibody testing by either skin testing or in vitro serum testing, other specialized testing)
- Several sources particularly good for differential diagnosis of nonallergic rhinitis.\(^1,2,14\)
- Vasomotor rhinitis—sneezing and itching less common than AR; anosmia more common
- Unilateral symptoms—refer for possible obstruction, anatomic abnormality, tumor, CSF leak
- Atrophic rhinitis—older adults, history of nasal surgery

**TREATMENT**

**Desired Outcomes**

**KEY CONCEPT** The goals of treatment of AR are to minimize the frequency and severity of symptoms, prevent comorbid disorders and complications, improve the patient’s quality of life, improve work attendance and productivity and/or school attendance and performance, and minimize adverse effects of therapy. Until a cure is established, these are the only realistic goals.

**Nonpharmacologic Therapy**

**KEY CONCEPT** The general approach for treatment of AR is fourfold: avoidance of allergen triggers, pharmacotherapy, immunotherapy, and patient/family education.\(^8,12\) Immunotherapy could be considered a type of pharmacotherapy. However, even with availability of patient-administered sublingual immunotherapy (SLIT), referral for specific diagnostic testing is required. Therefore, immunotherapy will be discussed separately.

Avoidance of allergen triggers, to the extent they have been identified and to the extent such avoidance is possible, underlies the treatment for all patients with AR (Table 63–3).\(^7,8\)

Immunotherapy is almost always initiated by an allergist or otolaryngologist, after referral for specific allergen testing to determine individualized therapy. Historically, immunotherapy was considered for patients in three categories.\(^5\) The first were those with severe, complicated or worsening rhinitis. This was partly for additional diagnostic testing to rule out nonallergic causes of rhinitis. The second were those patients with AR who did not tolerate or responded poorly to appropriate pharmacotherapy. The third were those patients who had a single, or one major allergen identified, for which there was an immunotherapy product available for treatment. In addition, some patients requested immunotherapy, on the basis of superior and durable effectiveness. Currently, the role of any other health care provider is limited to referral of appropriate candidates. However, this may change in the future with the introduction of several products for sublingual self-administration. As of April, 2014, three products have been approved for administration as sublingual immunotherapy (SLIT). Until that time, only subcutaneous immunotherapy (SCIT) had been available as an approved therapy in the United States.\(^15,18\) The major advantage of SLIT over SCIT is ease of administration. The first dose is given in the prescriber’s office, for purposes of safety. Subsequent doses are self-administered by the patient. Questions remain, however, about comparative efficacy and the details of optimal dosage, frequency of administration, and duration of therapy. The current cumulative wisdom is that SCIT is somewhat more effective than SLIT, but that SLIT is somewhat safer and easier to administer than SCIT.\(^15,18,23\)

Education of the patient and the patient’s support system is essential.\(^7\) All parties need to understand the potential seriousness of AR (including complications such as asthma) and the chronic, recurrent nature of AR. All should be told about the treatment options, including their relative advantages and disadvantages. Proper understanding and use of current medication in the patient’s regimen should be assured. A better educated patient and support system will result in a better relationship with health care providers and hopefully will optimize patient outcomes.

**Pharmacologic Therapy**

Guideline documents have been published on AR.\(^7,9,10,14\) They provide some of the basis for the summary that follows.
Table 63–3

Allergen Avoidance Measures

Allergen avoidance underlies all other treatments of AR. There are several limitations to allergen avoidance:

- Allergen(s) must be identified.
- Literature support for a clinically significant improvement in symptoms from allergen avoidance is meager.
- Quality of life may be negatively impacted by forced removal of a pet from the household.

Outdoor plant pollen and mold/fungi parts:
- Limit outdoor exposure, especially during high pollen conditions (warm sunny days with wind and low humidity) and during mold/fungi spore release (shortly after rains).
- Wear a face mask during activities that disturb soil and decaying vegetation.
- Keep windows and doors closed.
- Use air conditioning, but maintain clean equipment.

Indoor allergens (house dust mite, mold/fungi, cockroaches, and pets):
- Use air-conditioning, but maintain clean equipment.
- Maintain humidity below 50%, and maintain clean equipment.
- Clean frequently to prevent mold growth (dilute bleach with detergent).
- Avoid exposed food and garbage to deter insects.
- Clean kitchen frequently.
- Use roach traps that facilitate their removal.
- Vacuum frequently, and use a high-efficiency particulate air (HEPA) (filter).
- Cover bedding (pillows, mattresses, box springs) with allergen-proof, zippered cases.
- Launder bedding frequently, in hot water (> 130°F or 54°C) to kill mite ova.
- Consider acaricide (eg, benzyl benzoate) treatment of carpets to kill mites and ova.
- Put items that cannot be laundered (eg, soft toys) in a plastic bag and freeze.
- Keep pets out of bedroom and bathe cats weekly, if possible.

Irritants:
- Avoid, as possible, all exposure to smoke, chlorine fumes, formaldehyde fumes, and other substances identified as irritant triggers (eg, perfumes, newspaper ink).
- Quality of life may be negatively impacted by forced removal of a pet from the household.

Evelyn M, a regular customer in your community pharmacy, asks your advice about helping her 8-year-old son, Aaron. He has a diagnosis of “mild” asthma that is primarily exercise induced. His symptoms are usually well controlled by prophylactic use of an albuterol metered-dose inhaler. Both of his parents told the doctor that they do not want Aaron to be treated with “steroids.” However, a new issue is that in recent months, he has also had frequent trouble with runny nose, sneezing, and “throat” itching.

What additional information should you get before making any suggestions?

Although guideline documents are highly regarded by many, the patients enrolled in the randomized clinical trials that are a major basis for their conclusions and recommendations are not always representative of patients in a primary practice population. Other sources provide additional information for the treatment of AR. The recommended approaches begin with allergen avoidance, emphasize patient/family education and pharmacotherapy, and include immunotherapy as an option in selected patients.

Routine first-line agents for the treatment of AR are intranasal corticosteroids and oral (or possibly intranasal) antihistamines. Secondary agents, each of which may have a first-line role in selected patients, include oral (and rarely intranasal) decongestants, the intranasal mast cell stabilizer cromone (cromolyn), the oral leukotriene receptor antagonist (LTRA) (montelukast), the intranasal antimuscarinic (ipratropium), and intranasal saline irrigation. In all cases, therapy must be individualized, in cooperation with the patient. Considerations include frequency and severity of specific symptoms, realistic avoidance measures, patient age, patient preferences for route of administration, tolerance of side effects, adherence issues, comorbid disorders, and concurrent therapy. See Table 63–4 for intranasal and oral medications for the treatment of AR.

Table 63–4

Intranasal and Oral Medications for AR

Corticosteroids
- Intranasal (budesonide, beclomethasone, ciclesonide, flunisolide, fluticasone furoate, mometasone, OTC: triamcinolone, fluticasone propionate)
  - Oral (rarely used)

Antihistamines
- Intranasal (azelastine, olopatadine)
  - Oral (first-line agents)
  - First generation/sedating (cautious use in selected patients) (most OTC depending on strength: diphenhydramine, chlorpheniramine, clemastine, and others)
  - Second generation/low- or nonsedating (desloratadine, levocetirizine; OTC: loratadine, cetirizine, fexofenadine)

Combination antihistamine/corticosteroid
- Intranasal (azelastine and fluticasone propionate)

Mast cell stabilizer/cromone
- Intranasal (OTC: cromolyn)
- Oral (montelukast)

Antimuscarinic
- Intranasal (ipratropium)

Decongestant
- Intranasal (short-term use) (tetrahydrozoline; OTC: phenylephrine, naphazoline, oxymetazoline)
  - Oral (OTC: phenylephrine; BTC: pseudoephedrine)

*First-line choices.
*Some products combine an antihistamine with a decongestant, sometimes with other ingredients.
*Behind the counter (OTC plus other requirements necessary; see the Decongestants section of text).

From Refs. 7 and 8.
Patient Encounter 1, Part 2

Additional history from both Evelyn and Aaron reveals the following information. Aaron does have eye symptoms, including bilateral itching, watering, and redness. He thinks all his nose and eye symptoms are worse in the spring when plants are blooming. Both Evelyn and her husband have “hay fever.” Aaron’s symptoms have occurred most days of the week for the last 6 to 8 weeks, but he does not think they are “bad or troublesome.” He denies unilateral nasal symptoms, significant decreased smell, significant nasal congestion, cough, frequent nighttime awakenings, facial pain, and ear symptoms. Evelyn is not aware of significant changes in Aaron’s school performance. The family does not have any animal companions (pets). Aaron has not been given any medications for these new nasal symptoms.

You notice bilateral allergic shiners, and Aaron does rub his nose and snuffle frequently during your encounter. You are not able to examine his nasal mucosa or throat.

**Explain the reasons for how you would classify Aaron’s presumed allergic rhinitis.**

**What recommendations would you make for initial management of Aaron’s presumed AR?**

One publication includes an action plan for AR, similar to that used for asthma. The entire article, with a sample Rhinitis Action Plan, is available for universal access on the following website: http://www.aaaai.org/Aaaai/media/MedicalLibrary/PDF%20Documents/Practice%20and%20Parameters/rhinitis2008-diagnosis-management.pdf. Many patients will benefit from having an AR action plan.

► **First-Line Agents**

**Corticosteroids** Corticosteroids are usually administered by the intranasal route for the treatment of AR. Occasionally, a short course of oral therapy (burst and taper) is necessary. Oral corticosteroids are best applied to overcome severe nasal congestion, particularly that due to rhinitis medicamentosa (see the section on Decongestants). Parenteral administration of corticosteroids for AR is discouraged due to side effects.

Intranasal corticosteroids (INCSs) provide very good relief for sneezing, itching, and rhinorrhea, and even nasal congestion and ocular symptoms. Nasal congestion is often the most bothersome symptom of AR, and the most difficult to control. This is probably because it results from inflammation that predominates in the late phase of the allergic response. **KEY CONCEPT** Intranasal corticosteroids (INCSs) are the most effective therapy for AR, especially for nasal congestion. They are first-line agents for severe manifestations and are also used for those with moderate disease not controlled with oral and/or intranasal antihistamines. Their anti-inflammatory mechanism of action probably contributes to this superiority. The majority of contemporary literature suggests that INCSs are superior to intranasal antihistamines, to oral antihistamines even when combined with a leukotriene antagonist, and to a leukotriene antagonist alone.

There are currently eight intranasal corticosteroid products available in the United States, including two different salt forms of fluticasone. Most (budesonide, ciclesonide, fluticasone furoate, mometasone, and triamcinolone) are used once daily. However, fluticasone propionate may be given either once or twice daily; beclomethasone is usually given twice daily, and flunisolide is given two or three times daily. There is no good evidence that any single product is superior in efficacy. INCSs are best given regularly, as the onset of action usually takes up to 12 hours and the maximum effects may be delayed up to 14 days. In some people the onset is within 3 to 4 hours, so these agents may even be used on an as needed basis. When nasal congestion is severe, intranasal administration may not be effective due to limited exposure to the nasal mucosa. Short-term use of intranasal decongestants may facilitate better exposure. There have been some recent additions to the marketed ICNSs. Two agents are formulated as HFA metered-dose aerosols: beclomethasone (Qnasl) and ciclesonide (Zetonna). They may be better tolerated. There is a fixed-dose intranasal combination of fluticasone propionate with azelastine (an antihistamine). Two OTC products are now available. See Table 63–5 for intranasal corticosteroid products.

The correct technique for administration of intranasal medication is important for optimum efficacy. Consult the individual product labeling for specific instructions. Also see Table 63–6 for general instructions for the optimal administration of intranasal solutions. The technique described maximizes exposure of the drug to the nasal mucosa to optimize efficacy and minimizes both exposure to the nasal septum and loss of medication down the esophagus.

Most patients tolerate intranasal corticosteroids very well. Local side effects include nasal burning, irritation, and dryness, which may occur in 2% to 10% of patients. Also, 2% to 12% of patients may experience mild epistaxis. This may be partly due to administration technique. Perforation of the nasal septum is very rare. This can be minimized by proper administration technique (see Table 63–6), specifically, directing the spray laterally and away from the (medial) nasal septum.

The older intranasal corticosteroids (beclomethasone, flunisolide, and budesonide) have significant absorption, whereas, among the newer products, fluticasone and mometasone, have bioavailability of less than 2%. The decreased absorption minimizes systemic side effects. However, there is still some concern for hypothalamic–pituitary–adrenal (HPA) axis suppression (growth suppression), osteoporosis, and ocular effects (glaucoma, cataracts). There is no confirmation that intranasal corticosteroids cause posterior subcapsular cataracts, increased intraocular pressure, or decreased bone density; however, those with risk factors for these conditions should be monitored carefully for their development. Ultimately, patient preference for a specific intranasal corticosteroid may be determined more by cost, availability, and formulation differences that affect odor and aftertaste.

**Antihistamines** Antihistamines used for AR treatment are administered by either the oral or the intranasal route. These agents interact with the H1 (histamine type 1) receptor. They are technically inverse agonists, not competitive antagonists; however, there may be little clinical significance to the difference. These drugs bind H1 receptors, keeping them in the inactive state. This downregulation of H1 receptor activity results in a decrease in end organ effects.

Activation of H1 receptors in the nose, upper airway mucosa, and the eye produce the common manifestations of AR (sneezing, itching, rhinorrhea, nasal congestion, and ocular symptoms). The antihistamines are very effective for the sneezing, itching, and rhinorrhea. There is some improvement of nasal congestion, but less so than for the other symptoms. There is also...

mcg, micrograms; yo, years old; HFA, hydrofluoroalkane (propellant); MDP, metered-dose pump.
Note: All products are FDA Pregnancy category C except budesonide, which is B.
*available OTC.
From Refs. 25 and 27.

Table 63–6
Administration Instructions for Intranasal Solution Medications (Not HFA MDP Products)

1. Clear the nose of mucus and debris.
2. Consult product labeling for preadministration instructions (eg, shaking the container, priming the spray pump).
3. Do not tilt head backward. This increases drug lost down the esophagus. This decreases efficacy and increases the potential for systemic absorption and thus systemic side effects.
4. Bend the head forward (flex the chin onto the chest) so that the nose is the lowest portion of the head. This is best for nasal sprays. If possible, lie down with the stomach on a flat surface or kneel down. Then, flex chin onto neck, so that the open nostrils are pointing upward, toward the ceiling. This position may be best for nose drops (more volume than sprays). An alternate position is to lie supine on a flat surface or kneel down. Then, flex chin onto neck, so that the open nostrils point upward toward the ceiling.
5. Use the contralateral hand to insert the spray nozzle or dropper into one nostril (ie, the left hand for right nostril).
6. Use the other hand to occlude the opposite nostril (the one not being medicated).
7. Aim the spray or drops toward the outer (lateral) inside surface of each nostril and away from the nasal septum.
8. Breath in slowly but deeply through the medicated nostril.
9. Repeat this procedure to apply medication to the other nostril.
10. Consult the product labeling for instructions on cleaning the device.
11. See the text for information about preparation and use of saline irrigation.

HFA, hydrofluoroalkane (propellant); MDP, metered-dose pump.
From Refs. 2, 6, and 8.

Benefit for the ocular symptoms (eg, itching, redness, tearing). Intranasal administration is more effective than oral administration for the nasal congestion, but less effective for the ocular symptoms. The onset of action by oral administration is usually within 1 to 2 hours, and for intranasal administration within 15 minutes.⁷,²⁵,₂⁷ Antihistamines probably provide better relief when used continuously during symptomatic periods, but they are also effective used only when needed.

The herbal agents are divided into first- and second-generation drugs. The first-generation agents are distributed among six chemical classes, including the more sedating ethanolamine class (eg, diphenhydramine) and the least sedating alkylamine class (eg, chlorpheniramine). Most sources now discourage the routine use of the first-generation agents for AR. This is due to their CNS and antimuscarinic side effects. The CNS effects are primarily sedation and impairment of cognitive function and performance of tasks. Decision making and driving or work performance are impaired even when the patient is unaware of any overt effects.⁷,²⁵ There is also evidence of decreased performance at school and impaired learning among pediatric patients.²⁵ The major antimuscarinic effects include blurred vision, dry mouth, urinary retention, and constipation. The only possible advantage of the antimuscarinic properties is an additional effect to decrease rhinorrhea. Another disadvantage of the first-generation antihistamines is that most are administered three to four times daily. Patients who take other sedative substances may have an additive effect from the antihistamine. Those taking any other medications with antimuscarinic properties may experience additive effects from the antihistamine. The elderly are, in general, more sensitive to both types of adverse effects.

Currently available oral second-generation H₁ antihistamines are cetirizine, levocetirizine, loratadine, desloratadine, etc.
fexofenadine, and acrivastine. All except acrivastine are available as a single agent, and some are marketed in combination with the decongestant pseudoephedrine. As of August, 2014, cetirizine, loratadine, and fexofenadine are available OTC. The second-generation antihistamines have less antimuscarinic activity than the first-generation agents. Based on current literature, no single \( H_1 \) antihistamine (first or second generation) is clearly superior in efficacy; however, very few head-to-head comparative studies have been conducted. Individual variation is likely, and patients may need to try more than one product to realize optimal benefit. The oral second-generation antihistamines are effective for the sneezing, itching, and rhinorrhea of AR, but less effective for the nasal congestion. They also improve ocular symptoms. Intranasal antihistamines are somewhat better for nasal congestion.

Fexofenadine has virtually no sedative effects, even at doses higher than recommended. Loratadine and desloratadine are not sedative at recommended doses but can be at higher doses. Cetirizine, levocetirizine, and acrivastine have some sedative effects, even at recommended doses. All the oral second-generation agents require some dosage reduction with impaired renal function, but specific recommendations vary with creatinine clearance. Most of the oral second-generation antihistamines can be administered once daily (except for the lower dosage forms of fexofenadine and the acrivastine combination product).

There are only two intranasal antihistamine products available in the US market as of August, 2014. Both azelastine and olopatadine are considered second-generation agents, although they also have anti-inflammatory effects. Both are available only by prescription. The most common side effect of these products is a bitter taste. This is more common with the original formulation of azelastine (Astelin) and less common with olopatadine. A newer formulation of azelastine (Astepro) has less bitter taste. Also, there is enough systemic absorption to cause sedation in some patients using azelastine (about 10%) and perhaps somewhat fewer on olopatadine. See Table 63–7 for the single-agent second-generation antihistamine products.

Note: Acrivastine is available only with pseudoephedrine and so is not included in this table.

<sup>a</sup>Available OTC.

<sup>b</sup>Available in combination with pseudoephedrine (consult labeling for pediatric dosage).

From Refs. 25 and 27.

**KEY CONCEPT** Second-generation antihistamines are first-line agents, and are often effective alone, especially for mild or intermittent AR. They are preferred over first-generation antihistamines because of fewer side effects. Although effective for most symptoms of AR, they are less effective than intranasal corticosteroids for nasal congestion. Intranasal administration is more effective than oral administration for nasal congestion. Most patients can use oral second-generation products. Others may prefer the intranasal route of administration, but they require a prescription. If nasal congestion is not relieved, addition of a decongestant is reasonable, either alone or as a combination product (see Decongestant section). Perhaps even the combination of an oral with an intranasal antihistamine is reasonable for some patients, depending on their preferences. Other pharmacologic agents can be combined with oral and/or intranasal antihistamines, as necessary for optimal control of symptoms. The new intranasal combination product of azelastine and fluticasone (Dymista) may be appropriate for some patients.

**Adjunctive or Secondary Choice Agents**

### Decongestants

Decongestant drugs are useful only for nasal congestion. This results from their \( \alpha_1 \)-adrenergic agonist action, which constricts the nasal mucosa, thereby decreasing the size of the nasal passages. Other actions include bronchodilation and vasoconstriction in the skin. However, the effects in the lower respiratory tract are not as significant as those in the upper respiratory tract. Decongestant products are available OTC in select countries. They are available in different dosage forms (Table 63–8) and contain different active ingredients that differ in their duration of action and the intensity of their effects. They are available as single-agent preparations or in combination products with antihistamines.

**Table 63–8**

Note: Phenylephrine and naphazoline are available OTC. Neosynephrine and Scopine require a prescription.

**KEY CONCEPT** Due to their potential for rebound nasal congestion and systemic side effects, decongestants should be used only for short-term relief (generally no more than 5 days).
activity, which causes vasoconstriction in the nasal mucosa. They provide no benefit for the sneezing, itching, rhinorrhea, or the ocular manifestations. Decongestants can be given alone, either by the oral or by the intranasal route. Also, numerous combination products are available, consisting of a decongestant with an antihistamine (and sometimes other ingredients). There are some special considerations for use of decongestants in pediatric and pregnant patients (see the Special Populations section).

Oral decongestant products are currently limited to pseudoephedrine and phenylephrine.\(^5\,25\,27\) Pseudoephedrine has been changed from truly OTC to a more controlled “behind the counter” (BTC) status because it is an ingredient in the illicit manufacture of methamphetamine. Some manufacturers changed the ingredients of their products by replacing pseudoephedrine with phenylephrine to maintain shelf presence in the OTC area. However, much controversy surrounds the efficacy of oral phenylephrine. Most contemporary literature suggests that the currently recommended adult dose is minimally effective as a nasal decongestant.\(^5\,25\,27\)

The side effects of orally administered decongestants most often affect cardiovascular function or the CNS. The side effects are primarily due to sympathetic stimulation and are usually dose related. Some elevation of blood pressure may occur, but in normotensive and well-controlled hypertensive patients, the elevation is usually small. It is not of clinical significance in most situations, especially considering that these drugs are most appropriately used only briefly or intermittently. Insomnia, nervousness, irritability, and anxiety are relatively common CNS side effects. Some patients may have decreased appetite, tremors, headache, and even hallucinations. Men with benign prostatic hyperplasia (BPH) and other patients with disorders causing bladder outlet obstruction may have increased urinary retention due to \(\alpha\) stimulation of the urethral sphincter.

The intranasal agents currently available include the OTC products phenylephrine, oxymetazoline, and naphazoline. Intranasal application of decongestants provides rapid and effective relief of nasal congestion. This therapy may provide relief for nasal congestion, even for those patients already on intranasal corticosteroids.\(^\text{25,27}\) However, the continuous use of intranasal decongestants often causes a paradoxical rebound phenomenon of persistent nasal congestion, called rhinitis medicamentosa.\(^\text{5,25,27}\) Although some patients do not develop rhinitis medicamentosa, even after several weeks of continuous use of intranasal decongestants, the usual recommendation is to use them for no more than 3 consecutive days.\(^\text{2,7}\) Intranasal decongestants can cause local side effects, including stinging, burning, dryness, and even sneezing. These are usually mild and well tolerated. Due to very limited absorption, the intranasal route rarely causes systemic side effects.\(^\text{5,7}\) Administration technique should be optimized as described in Table 63–6. Should rhinitis medicamentosa occur, the best management is first to discontinue the decongestant, possibly with a taper to minimize worsening the situation. However, the response to withdrawal is often delayed for days. Therefore, it may be necessary to start intranasal corticosteroids and/or begin a short course of oral corticosteroid.\(^\text{32}\)

**Patient Encounter 1, Part 3**

About 6 months later, Aaron and his mother Evelyn come back to speak with you. Aaron tried using saline irrigations but he did not like the “messiness” it created, so he stopped them. He tried cetirizine but it made him sleepy during the day. Loratadine and fexofenadine just did not seem to work well. His parents still object to trying INCSs, despite your explanation. Montelukast seemed to help the AR symptoms, and even the exercise induced asthma to some extent. However, Aaron’s doctor became concerned when Aaron complained of increased sleep disturbance while taking montelukast. The doctor wanted it stopped for what he called “safety” reasons. Ophthalmic ketotifen does help the ocular symptoms, but not the nasal symptoms, which he thinks are actually becoming more frequent and bothersome. They ask your advice.

What suggestions would you offer for control of Aaron’s symptoms, now?

---

**Cromolyn**

Cromolyn is the only cromone that is approved in the United States for treatment of AR. It is available as an OTC intranasal product. The mechanism of action in AR is mast cell stabilization. The drug binds to mast cells and prevents release of the mediators of AR that would otherwise result from allergen exposure. The drug is moderately effective, but less so than both intranasal corticosteroids and oral or intranasal antihistamines. It does have effects on both early and late phases of AR. Its effects begin within 4 to 7 days of use but may not be maximal for up to 2 weeks.\(^\text{2}\) However, it can be used effectively on an as needed basis for episodic exposures to allergen.\(^\text{2,27}\) Cromolyn is very well tolerated. The most common side effects are mild local stinging and/or burning, sneezing, unpleasant taste, and possibly nose bleeds. A disadvantage is the frequency of administration. At least initially, it should be used four times daily. Some patients may need only two or three daily doses when used continuously after the first few weeks at four times daily. It is most useful for patients with mild or intermittent symptoms, especially in the pediatric population and in pregnant women.

**Leukotriene Receptor Antagonist (LTRA)**

Leukotrienes are involved in the pathophysiology of AR and in particular contribute to the nasal congestion in the late phase.\(^\text{1,5–9,12,13}\) There is some difference of opinion about benefits of LTRAs. Most sources indicate good benefit for nasal congestion and rhinorrhea, some benefit for ocular symptoms, but less for nasal itch and sneezing compared to INCSs and antihistamines.\(^\text{5,25,27}\) Montelukast is the only LTRA approved for treatment of AR. It is marketed as oral granules and as both chewable and regular tablets. The combination of montelukast with an oral antihistamine shows improved efficacy over either agent alone, according to some sources, however, even the combination is probably not better than intranasal corticosteroids.\(^\text{5,25}\) The onset of action of montelukast is delayed for a day or more.\(^\text{2}\) The drug is usually considered to be very well tolerated. However, there are case reports of neuropsychiatric events, including sleep disturbances, depression and suicidal ideation, as
well as headache, GI disturbances, skin rash, and Churg-Strauss syndrome.\textsuperscript{12,25,27} It is administered once daily, considered safe (FDA Pregnancy Category B and indicated for children as young as 6 months of age), and particularly well suited to those patients who also have asthma. It may have some benefit in vasomotor (idiopathic, autonomic) rhinitis.\textsuperscript{4}

\textbf{Antimuscarinic Agent}\textsuperscript{5,7,12,25,27} Ipratropium is currently the only antimuscarinic agent indicated for treatment of AR. Systemic absorption is minimal. It is available by prescription as an intranasal spray. Its use is limited to those patients whose rhinorrhea has not been controlled by other therapy (antihistamines and/or INCSs). There are two strengths available. The 0.03% product is approved for AR in children as young as 6 years of age. This agent may be particularly helpful for patients who have vasomotor (idiopathic, autonomic) rhinitis, or those who may have a mixed etiology.\textsuperscript{5,25} Local side effects are usually limited to nasal and oral dryness, throat irritation, and mild epistaxis.\textsuperscript{27}

\textbullet {} Saline Nasal administration of saline is an alternative for treatment of AR.\textsuperscript{5,7,25,33,34} This therapy may benefit any patient with rhinitis, including those with vasomotor rhinitis.\textsuperscript{5} Saline may be administered as drops or a spray, but the irrigation mode of administration is popularly known by several terms, including neti pot, nasal wash, nasal douche, nose bidet, and as nasal irrigation. Although less effective than intranasal corticosteroids, it has been shown to improve sneezing and nasal congestion. It can be used either alone or as add-on therapy. The formula provided by the American Academy of Allergy, Asthma and Immunology (AAAAI) should be followed for those making their own saline nasal irrigation solution.\textsuperscript{34} Iodized salt is not recommended as it may be irritating. Hypertonic saline seems to have no advantage over 0.9% sodium chloride. Administration can be accomplished while the patient is in the shower or leaning over a sink. The head is bent forward and downward, then tilted to the side opposite the treated nostril. Then, with a bulb syringe or similar device, slowly introduce about 4 oz (118 mL) of the warm saline solution into one nostril. Soon, the solution will run out of the opposite nostril. The position of the head should be adjusted as necessary to avoid the solution running into the ears or down the throat.

Nasal irrigation is one delivery method, although the optimal method (spray, drops, nebulizer, or irrigation) is not known. Optimal frequency of administration is also not known. Nasal irrigation is usually given twice daily, but use of smaller volumes as spray products may be given up to four times daily. Side effects are usually limited to minor local nasal irritation, but nausea has been reported.

\textbf{Omalizumab}\textsuperscript{7,25,35} Omalizumab is a monoclonal antibody that binds to IgE. The product is approved for asthma, but not for AR as of August, 2014. It is administered by subcutaneous injection. Dosage is determined by the patient’s circulating IgE levels. The cost is high compared with that of other modes of therapy. Investigational use has demonstrated efficacy in AR, although relative efficacy is unknown. Its use is best limited to those with concurrent asthma and AR.

\textbf{Complementary and Alternative Medicine Therapy} Complementary and alternative therapy for AR has been reviewed.\textsuperscript{25,36} Consistent evidence for efficacy has not been established, and there are some safety concerns.

**Special Populations**

\textbullet {} **Children** Generally speaking, the treatment of AR in children is the same as it is for adults. There are, however, limitations in terms of FDA-approved products for different age groups.

---

**Patient Encounter 2, Part 1**

Mrs. AL presents to your place of work to ask some questions. She is 32 years old, married, with no children. She does not work, but volunteers at several nonprofit organizations. This occupies several hours of her day, 4 days each week. Her husband works full time for a landscaping business. Her only chronic illness is allergic rhinitis that is caused by what her doctor calls “bad pollen allergies.” She complains of “attacks” of repeated sneezing; copious watery runny nose; itchy nose and throat; often accompanied by itchy, watery eyes. Her only medications are Dymista (combination azelastine/fluticasone propionate) intranasal spray and oral fexofenadine 180 mg once daily. The dosage of Dymista is supposed to be one spray into each nostril twice daily. However, since starting it about 3 months ago, she has figured out that it makes her sleepy. She often skips the morning dose, especially, if she is volunteering that day.

\textbf{What additional information do you need to better evaluate Mrs AL’s problem?}

\textbf{What preliminary suggestions would you make?}

---

Also, depending on the age of the patient, there may be administration issues with some products. Most children affected by AR are older than 2 years, because usually, several years of antigen exposure is required to establish sensitization.\textsuperscript{41} Children who have rhinitis before the age of 2 should be evaluated for other etiologies.\textsuperscript{2,25}

There has been concern about use of combination cough and cold products (many contain an antihistamine and a decongestant) in children due to side effects. Most negative outcomes have resulted from inadvertent overdosage, often by giving the same drug from more than one product concurrently. These products are discouraged in children younger than 4 years.\textsuperscript{37}

First-generation H\textsubscript{1} antihistamines are discouraged for children as they are for adults, due to the possible detrimental effects on school performance and learning. They may also cause paradoxical CNS stimulation in the very young (< 2 years old).\textsuperscript{25} Second-generation (less sedating) H\textsubscript{1} antihistamines (primarily for mild or intermittent symptoms) or intranasal corticosteroids (for moderate–severe or persistent manifestations) are first-line modes of therapy. Antihistamines may need to be used even for more severe and/or persistent symptoms in those children who have difficulty with use of intranasal products. If necessary, these two classes can be combined.

See Table 63–7 for dosages of second-generation antihistamines by age groups for which they are indicated. Special care should be given to avoid administration of the same medication from different (especially combination) products. The side effects of second-generation antihistamines in children are similar to those for adults.

See Table 63–5 for dosages of intranasal corticosteroids by age groups. The consensus of opinion about intranasal corticosteroids and systemic side effects, especially delay in growth, is that most products are safe. Three INCSs, mometasone, fluticasone furoate, and triamcinolone, are FDA approved for children as young as 2 years of age.\textsuperscript{25,27} Seven local side effects of intranasal corticosteroids are the same in children as for adults.

Other therapy options may be worth consideration for some pediatric patients. Montelukast provides an oral alternative, especially for those who are too young to cooperate with...
intrasal administration of corticosteroids. It may be used in combination with an oral antihistamine for additional efficacy. Another option for mild or intermittent symptoms is intranasal cromolyn, primarily due to its excellent safety. This OTC product is labeled for use in children 2 years of age and older. Intranasal ipratropium is indicated for patients 6 years of age or older and may benefit unresponsive rhinorrhea.

Pregnant Women Women who have AR may suffer an exacerbation of symptoms during pregnancy. However, only minor changes in the routine approach to therapy are necessary as a result of the pregnancy. Nasal saline irrigations are safe, effective, and improve the response to most other modes of therapy. They can be the foundation of AR therapy for pregnant patients. Physical exercise increases vasoconstriction of the nasal mucosa, decreasing congestion, and rhinorrhea. External adhesive strips can be used to help keep the nares open, especially during sleep. Second-generation antihistamines are generally considered safe, based on an increasing number of studies and experience. The same generalization applies to intranasal corticosteroids. While budesonide is the only product which is FDA pregnancy category B, no evidence exists of fetal harm from either INCSs or inhaled corticosteroids used for asthma. Cromolyn is also FDA Pregnancy Category B and is considered safe. The disadvantages are frequent administration and less efficacy than antihistamines and INCSs. Montelukast is also FDA Pregnancy Category B, but some recommend it primarily in those with concurrent asthma or who have demonstrated a good response prior to pregnancy. Ipratropium is FDA Pregnancy Category B and is useful for troublesome rhinorrhea. Oral decongestants are best avoided, especially in the first trimester. If nasal congestion is severe enough to warrant a decongestant, the intranasal route of administration is preferable, due to decreased systemic exposure. Limiting the duration of use to 2 to 3 days is wise.

Breast-Feeding Women One source has information about the relative safety of AR medication use in breast-feeding women. Budesonide is probably the safest INCS and loratadine is probably the safest antihistamine. Intranasal cromolyn is also considered safe. Nasal saline irrigation could also be considered as a safe alternative in breast-feeding women.

Elderly AR in elderly patients is treated generally as it is in younger adults. Therefore, first-line agents are primarily INCSs and second-generation oral or possibly intranasal antihistamines. Older patients may also have a component of atrophy of nasal tissues that can result in more nasal congestion. Most will benefit from regular nasal saline irrigation. The elderly are more sensitive to the sedative and antimuscarinic effects of (especially first-generation) antihistamines and to the cardiovascular and CNS-stimulant effects of decongestants. These drugs should be used cautiously if at all. An increase in cholinergic activity may result in more rhinorrhea. This may respond well to ipratropium.

Ocular Symptoms Several products are available for instillation directly into the eyes for those patients with predominant or unresponsive ocular manifestations. They may be appropriate for occasional moderate—severe flares or episodic AR when other modes of therapy are not optimally effective. The combination (antihistamine and mast cell stabilizing) agents may be the most effective, and they have the advantages of rapid onset of action and (usually) only twice daily administration. Ketotifen is in this category and because it is available OTC, it can be an appropriate initial agent. See Table 63–8 for these products.

Summary of Treatment Once an agent appropriate for initial therapy is chosen, ongoing management requires repeated checks to ascertain response and freedom from intolerable or adherence limiting side effects. Either “step-up” or “step-down” therapy may be appropriate, depending on individual response. See Table 63–9 for a summary of the approach to treatment of AR. Table 63–10 attempts

NSAID, nonsteroidal anti-inflammatory drug; yo, years old.
*Available OTC.
From Refs. 7, 27, 40, and 41.
Also, see Chapter 62, Ophthalmic Disorders for more details.
Table 63–9

Routine Approach to Therapy of AR

All patients should practice avoidance of identified allergens

Mild intermittent

First line:
Oral antihistamine (OTC, initially; preferably second generation)

Adjunctive/secondary (may use more than one; no specific order intended):
Add nasal saline (eg, as irrigation)
Consider intranasal cromolyn, especially preexposure for episodic AR
Consider OTC INCS for refractory symptoms
Consider intraocular medications, as needed for ocular symptoms (See Table 63–8)
Consider OTC oral decongestant for nasal congestion
Consider OTC intranasal decongestant for refractory nasal congestion (not > 3 days)
Consider prescription therapy for inadequate response (see below)
Possibly consider referral for immunotherapy

Persistent or moderate–severe

First line:
Intranasal corticosteroid (could try OTC product first)
Add oral antihistamine for possible additional benefit if necessary

Adjunctive/secondary (may use more than one):
Add nasal saline (eg, as irrigation)
Consider intraocular medications, as needed for ocular symptoms (See Table 63–8)
Consider OTC oral decongestant for nasal congestion
Consider short-term intranasal decongestant for refractory nasal congestion
Consider replacement of one first-line agent, if poorly tolerated, with montelukast
Consider ipratropium for inadequately controlled rhinorrhea
Consider intranasal antihistamine
Consider combination intranasal antihistamine with corticosteroid
Consider referral for immunotherapy

Episodic (no order of preference intended)
Oral antihistamine (OTC, initially; preferably second generation)
Consider addition of or replacement with intranasal cromolyn (OTC) or intranasal antihistamine or intranasal corticosteroid

Special situations (children, pregnant women, elderly, ocular symptoms)
See Special Populations section of text

From Refs. 2,5–10,12,14,25,29,33, and 34.

Note: The information in this table is a composite from numerous sources. There are different opinions about some of the rankings, partly due to inadequate study. Individual variation may create different relative efficacy in some patients. Higher number equals greater activity.

Some products in these classes are available OTC.

Intranasal decongestants are best used for severe, unresponsive nasal congestion, or to facilitate mucosal contact of other intranasal medications, but in either case, should usually be limited to no more than 3 days.

From Refs. 2,5–10,12,14,25,29,33, and 34.
Patient Encounter 2, Part 2

Mrs. AL returns in 2 weeks. She took your advice. She continued the fexofenadine. She replaced Dymista with OTC triamcinolone intranasal spray. And, she tried saline nasal irrigations. Formal allergy skin testing done by her doctor showed that she is allergic to “…just about every tree and flower that blossoms…” in this area! However, she is not allergic to animals, molds, fungi, house dust mite, or cockroaches! Her doctor made some suggestions for allergen avoidance, mostly to stay indoors, keep doors and windows closed, and use an air conditioner. She has noticed some improvement with the new regimen. She does not feel quite as sleepy, having stopped the Dymista. She thinks both the saline irrigations and the triamcinolone help. However, she still has significant symptoms while in her house, during the evening and often during the night.

Additional information gathered at this visit follows.

She is unaware of her family history. They have lived in the same city for more than 15 years. She moved to another part of town when she got married six years ago. Her current home has some plants in the yard, but her husband does all the yard upkeep. Her AR symptoms started as a child, but seem quite a bit worse in the last 5 years or so. She is not exposed to animal dander. She does not think her home is a source of mold or cockroaches. She does have symptoms during the night (while in her bedroom), but she also has symptoms in every other room of the house (see below).

She admits to some nasal congestion and mouth breathing especially at night. Other symptoms include some difficulty sleeping due to “attacks” in the evenings and even during the night. Overall, she considers her symptoms, troublesome. She has AR symptoms virtually every day even with her current regimen. Therefore, she probably has ARIA category moderate-severe persistent AR.

She thinks that her symptoms are worse when she is home and better when she is at the nonprofit organizations where she volunteers at least half a day, 4 days each week.

Before the allergy testing was done, she did not know what specific pollens she was allergic to. She had noticed more frequent and severe symptoms when plants are blooming. Now she knows what she is allergic to (see above). Curiously, however, she has symptoms both indoors and outdoors.

She tried Benadryl several years ago. It made her sleepy and caused dry mouth, so she gave up.

She has an IUD in place. It is called Mirena, which is replaced every 5 years. A new one (her third) was placed about 1 year ago. Since having this IUD, she notices that her menses are a bit lighter, although she is very regular. Her last menses started 7 days ago, and lasted the usual 2 days. She also has fewer problems with cramping. She and her husband have no plans to have children at this time.

Explain the rationale for your plan at this time.

Patient Encounter 2, Part 3

After the second visit with Mrs. AL (Patient encounter 2, part 2), you had an uneasy feeling. Later that evening, you began to wonder about some of the elements in her story. You formulate a theory about the source of her symptoms, and plan to phone Mrs. AL to ask more specific information. If your theory is correct, you may be able to significantly improve her symptom control.

What is the theory about Mrs. AL’s symptoms?

Presuming the theory is correct, what specific plan could be suggested?

Patient Encounter 3, Part 1

EM presents to your place of business to ask your advice about his “nose and eye” symptoms. EM is a 50-year-old man, who works as a tax accountant. About 25 years ago, he moved from New England to the Southwest, for employment reasons. The environment was much warmer than he was used to, but like the local people said, it was “…a dry heat!” Within a few months of the move, he began having problems with watery, sometimes profuse runny nose. At that time, the only other symptom he had was a decrease in his sense of smell.

He thought he had allergies to the new plants in the area, but the doctor he saw said that by examination his nose, throat, and ears looked normal. The doc called it “non-allergic rhinitis.” He was given a prescription for intranasal flunisolide spray and told to use it three times a day. Over the years, it seemed to work sometimes, but not always. And, he always had problems remembering to use it regularly. He added an OTC oral antihistamine years ago, but it did not help much, and it caused so much sleepiness that he couldn’t work. He stopped it, and just continued irregular use of the flunisolide.

More recently, in the last year, he notices even more symptoms, including some sneezing, some nasal itch, and some eye symptoms (redness, wateriness, and itchiness). EM denies all other chronic illnesses and he takes no other medications on a regular basis. He asks your advice for treatment options for his current symptoms.

How would you characterize EM’s problem?

What are your recommendations for his therapy?
Patient Encounter 3, Part 2
EM returns 2 weeks later. He took most of your advice. He tried saline irrigations, but found them difficult to do twice every day. He switched from intranasal flunisolide to triamcinolone, which was easier to use and more effective. He tried oral cetirizine, but it seemed to make him tired, so he stopped. The major remaining problems are relatively persistent, and sometimes profuse, watery nasal discharge and itchy eyes.

What additional advice can you suggest?

OUTCOME EVALUATION

- Confirm the patient’s understanding of the disorder (see Clinical Presentation and Diagnosis).
- Confirm the patient’s understanding about allergen avoidance measures (see Table 63–3).
- Assess the patient’s symptom response, tolerance, and adherence.
- Assess the patient’s administration technique with intranasal products.
- Recommend second-generation oral antihistamine therapy for most patients with mild or intermittent symptoms (see Clinical Presentation and Diagnosis and Table 63–9).
- Recommend intranasal corticosteroid therapy for moderate–severe or persistent symptoms (two products are OTC). Suggest additional therapy for those with incomplete control (see Clinical Presentation and Diagnosis and Table 63–9).
- Consider step-up therapy for exacerbations or incomplete response.
- Consider step-down therapy if symptoms are minimal or stable for several months.
- Consider referral to rule out nonallergic causes of rhinitis in nonresponding patients or those with an atypical presentation (see Clinical Presentation and Diagnosis).
- Consider referral for patients who request immunotherapy.
- Consider referral for patients with comorbid conditions, especially asthma.

Patient Care Process

Patient Assessment:

- Determine that the patient probably does not have a nonallergic type of rhinitis (see Table 63–1)
- Determine extent and severity of patient’s signs and symptoms of AR. This should be done by combination of History of Present Illness (HPI), Past Medical History (PMHx) and appropriate physical assessment
- Assessment of HPI includes seven elements, using eg, the acronym LOQSSAM (location; onset; quality; quantity; setting; associated symptoms; modifying factors) (see Clinical Presentation and Diagnosis box)
- Appropriate PMHx should include conditions associated with AR and its complications (see Epidemiology section)
- Appropriate physical assessment is usually limited to observation of the patient, and sometimes examination of the nasal mucosa and oropharynx (see Clinical Presentation and Diagnosis box)
- This assessment should be expressed in terms of the frequency and severity of AR, as defined by the ARIA system (see Table 63–2)

Therapy Evaluation:

- Determine what modes of therapy the patient has already tried (allergen avoidance, pharmacotherapy, immunotherapy).
- Assess theroprietnness of current therapy, relative to the clinical response.
- If the clinical response is inadequate or suboptimal, determine first, if poor adherence and/or administration technique (ie, with intranasal agents) are involved. See Table 63–6.
- If nonadherence and poor technique do not explain a suboptimal response, consider alternative therapeutic modes. See Table 63–9.
- If specific patient features exist (female who is currently or may become pregnant, woman who is breast-feeding, child, or elderly), see Selected Populations section.

Care Plan Development:

- Advise allergen avoidance to the degree possible. See Table 63–3.
- Educate and counsel about optimal administration technique and adherence.
- Base subsequent, specific recommendations for therapy on symptom pattern (nasal congestion, rhinorrhea, ocular manifestations, concurrent asthma), previous response to therapy and availability (OTC, Rx, referral).

Follow-up Evaluation:

- Follow up weekly at first, especially during worse times or seasons.
- When optimal control is approached, increase duration between follow-up visits (eg, monthly, every 2–3 months, or less frequently).
LEARNING OBJECTIVES

Upon completion of this chapter, the reader will be able to:

1. Discuss the etiology and risk factors of psoriasis.
2. Describe the pathophysiology and clinical presentations of psoriasis.
3. Evaluate the assessment strategies of patients with the disease state.
5. Develop appropriate treatment and care plan for psoriasis patients.
6. Recommend appropriate monitoring parameters for a patient with psoriasis.
7. Propose patient education and counseling information for patients and caregivers as part of the care plan.

INTRODUCTION

Psoriasis is a chronic inflammatory condition that exhibits a normal pattern of relapse and remission. There is currently no cure for the disease and treatment is aimed toward management of signs and symptoms associated with the condition. Remission may last years in some patients, whereas in others, exacerbations may occur every few months. Things known to exacerbate the condition are stress, seasonal changes, environmental factors, life crises, and certain medications. The severity of the condition ranges from mild and moderate to severely disabling. Depression, alcohol-related problems, cardiovascular diseases, metabolic syndrome, and skin cancers are select comorbidities associated with the severe form of the disease. Thus, management of patients with psoriasis is long term and management modalities may change according to the severity of illness at the time. Treatment should be individualized to meet patient needs. The disease may precipitate emotional distress that requires empathy and a caring attitude.

EPIDEMIOLOGY AND ETIOLOGY

Psoriasis is a chronic common inflammatory skin disorder with a population prevalence of 2% to 3% worldwide. The prevalence is found in Americans and Canadians in a range of 4.6% to 4.7%. African, African American, and Asian populations have an estimated 0.4% to 0.7% prevalence of the disease. Male patients tend to die at least 3.5 years earlier and females 4.5 years earlier than nonpsoriasis patients normalized for differences in mortality by gender. The disease may present at any age, but peaks between age 15 and 30 and again from 50 to 60 years. Types of psoriasis manifest as plaque, flexural (aka inverse or intertriginous), erythrodermic, pustular, guttate, nail, and psoriatic arthritis (PsA). Eighty to ninety percent of psoriatic patients present with plaque psoriasis. Plaque psoriasis presents with red-pink lesions of varying sizes covered with silvery scales. Up to 42% of patients with psoriasis have been reported to also have PsA. PsA is mostly limited to joints, ligaments, and tendons, and manifests in the presence of psoriasis disease. Clinical presentations include pain, stiffness, swelling, and tenderness. PsA progresses from mild symptoms to the destruction of joints affecting quality of life for patients. Some patients may have deforming PsA without cutaneous involvement. Recent research has shown that psoriatic patients have an increased risk of cardiovascular diseases, especially myocardial infarction. The risk is increased in patients with both mild and severe psoriasis, with the highest risk in younger patients with severe disease. These findings persist even when corrected for other cardiovascular risk factors.

Even though study results are inconclusive, genetic association has been documented for both psoriasis and psoriatic arthritis. The histocompatibility complex region of chromosome 6 (HLA-Cw*06) has been suspected in the disease. Even though the linkage to HLA-Cw*06 has long been known, there is further support for this linkage in recent studies. Studies have also shown that HLA-A2, B8, B17, and B44 are involved. Women exposed to tobacco smoke have a higher risk of psoriasis than their male counterparts with the same exposure. Four life events: divorce, death of a close friend, death of a family member, and change in work environment can increase the risk of developing psoriasis. First-degree relatives with psoriasis is another risk factor, affecting males more than females. Risk is also found to be higher in urban settings versus rural settings. Additional factors exacerbating psoriasis include drugs such as lithium, NSAIDs, antimalarials, β-adrenergic blockers, and withdrawal of corticosteroids. Cytokines such as interleukins and tumor necrosis factor α (TNF-α), T cells, and keratinocytes play significant roles in the inflammatory process that constitutes the disease mechanism.

The emotional and psychological impact of psoriasis may not correlate with the severity of the skin presentation, and it is
important to always evaluate the psychosocial effects of psoriasis on the patient.8,9

**PATHOPHYSIOLOGY**

- The pathogenesis of psoriasis involves multiple components of the immune system. Cytokines, T cells, and keratinocytes are central to the inflammatory process associated with psoriasis. Additionally, it has been found that when keratinocytes are perturbed, the release of antimicrobial peptide LL-37 takes place. This peptide binds with DNA and RNA. This complex potentially leads to the activation of plasmacytoid and myeloid dendritic cells. These activated dendritic cells secrete interleukin IL-12 and IL-13. The production of these two interleukins eventually results in IL-17 and T helper cell type 1 differentiation. The T cells then release Interleukin IL-17A, IL-17F, IL-22, and IL-23 as mediators which then subsequently activate keratinocytes. This process then generates a complex cascade including proinflammatory cytokines such as TNF-α, interferon (IFN-α and IFN-γ), and interleukin (IL-1β and IL-6). The entire process then leads to alteration of the immune system and chronic inflammation that manifests in the skin causing vascular changes and formation of psoriatic lesions. Keratinocyte proliferation is central to the clinical presentation of psoriasis. Keratinocytes are skin cells producing keratin, which act as a skin barrier. Hyperkeratosis that results from immune derangements causes the characteristic thick, scaly skin lesions seen in patients with psoriasis. The pathologic pathway of psoriatic arthritis is the same, except that the changes that occur as a result of T-cell mediators happen in the synovial fluid within the joints. Osteoclast activation, osteolysis, and bone resorption produces the damage that occurs within the joints.2

**CLINICAL PRESENTATION AND DIAGNOSIS**

**KEY CONCEPT** Diagnosis of psoriasis is usually based on recognition of the characteristic plaque lesion and is not based on lab tests.

“The severity of the disease is classified as mild/limited disease, moderate, or severe disease based on body surface area (BSA) involvement (Table 64–1).” Additionally, classification may be based on assessment tools used such as the Psoriasis Area and Severity Index (PASI) and the Dermatology Life Quality Index (DLQI).15,16

**TREATMENT**

**Desired Outcomes and Goals**

**KEY CONCEPT** Given its manifestations, inflammation, involvement of multiple areas of the affected skin, and the chronic nature of psoriasis, treatment goals must be well targeted. The goals of treatment

**Patient Encounter, Part 1**

AD is a 52-year-old woman who has noticed dark, red, and smooth lesions covering the majority of her upper body. When questioned, the patient says her skin has been relatively clear, until about a month ago. Since then, the lesions have been becoming more uncomfortable, spreading from her back and abdomen to her arms. She is feeling self-conscious about what is happening and does not know what to do.

*What type of psoriasis is AD experiencing?*

---

### Clinical Presentation and Diagnosis of Plaque Psoriasis

**General characteristics**

Small, discrete lesions to generalized confluent lesions over a large BSA.

**Symptoms**

Severe itching.

**Signs**

- Raised lesion red to violet or silvery in color (commonly known as plaques).
- Sharply demarcated borders lesions, except where confluent.
- Lesions are loosely covered with silvery-white scales, which if lifted off, show small pinpoints of bleeding (Auspitz sign).
- Plaques show on the elbows, knees, scalp, umbilicus, and lumbar areas, and often extend to involve the trunk, arms, legs, face, ears, palms, soles, and nails.
- Nail involvement presents as pitting, discoloration (“oil spots”), crumbling, splinter hemorrhages, growth arrest lines, or tissue buildup around the nails.

**Clinical Presentation and Diagnosis of Other Types of Psoriasis**

- Flexural psoriasis:
  - Appears in intertriginous area
  - Scaling is minimal
- Guttate psoriasis:
  - Sudden eruption of small, disseminated erythematous papules and plaques
  - Often preceded by a streptococcal infection (2–3 weeks prior)
- Pustular psoriasis:
  - May be localized or generalized
  - May be an acute emergency requiring systemic therapy.
    - The others are given physical descriptions, but this one is not
- Generalized pustular psoriasis:
  - Disseminated deep-red erythematous areas and pustules
  - May merge to become “lakes of pus”
- Erythrodermic psoriasis: generalized, life-threatening condition
  - Erythema, desquamation, and edema
  - May require life support measures as well as systemic therapy.
General Approach to Treatment

Management of the disease must be structured to target the type of psoriasis. Plaque, guttate, flexural, pustular, and erythrodermic are the types that currently manifest clinically in patients, with plaque psoriasis being the most common. General treatment modalities must include location, the extent of BSA involvement, and lifestyle modifications. Additionally, the choice of management approach must take into consideration whether the disease is mild, moderate, or severe.

For PsA, the goal of treatment is to keep the patient pain free, reduce swelling, retard or minimize joint damage and keep the joints functioning. The goals to achieve for patients living with this skin condition are significant improvement of skin appearance and ensuring that unpleasant side effects of drugs are fairly minimized. Patients are managed with both pharmacologic and nonpharmacologic approaches (Figure 64–1).

Nonpharmacologic Management

Several effective nonpharmacologic options are available to patients with psoriasis. However, considering the nature of the disease, these treatments may be used as adjunctive treatments to therapeutic agents when appropriate.

Stress reduction techniques such as psychotherapy, guided imagery, and relaxation techniques have been shown to improve the extent and severity of psoriasis. Oatmeal baths in tepid water may help soothe the itching associated with psoriasis. Nonmedicated moisturizers (occlusive agents, humectants, and/or emollients) help the skin to retain moisture and reduce the scaling of the skin lesions. Aloe vera is a common emollient used to help manage skin dryness. These can be applied multiple times during the day to prevent skin dryness. Patients with skin sensitivities should consider the use of fragrance-free products. Harsh soaps, detergents, and other skin irritants must be prohibited as they may worsen the skin condition. Skin cleansing is appropriate; however, it should be done with lipid-free cleansers. Trauma to the skin must always be avoided. Psoriasis can manifest around sites of skin trauma including surgery. The use of sun protection factor (SPF) of 30 or less is recommended to prevent sunburns, as they can induce disease flare-ups. Loose-fitting clothes are desired to help reduce skin irritation.

Pharmacologic Therapy

The pathogenesis of the disease involves a complex mechanism that disturbs the immune system, causes vascular changes, and the development of skin lesions. It is paramount that therapeutic agents that antagonize these processes are well represented in the treatment of psoriasis. These agents are anti-inflammatory, anticytokines, and biologic therapies. They are classified into topical, phototherapy, conventional systemic therapy, and biologics.

Topical Treatment

“These agents are marked as first-line treatment for mild to moderate psoriasis (Table 64–2 and 64–3). They are specifically known for their anti-inflammatory, antiproliferative, and anti-immunologic properties. They are classified as corticosteroids, vitamin D analogues, retinoids, calcineurin inhibitors, anthralin, and salicylic acid derivatives. Different dosage forms are available such as creams, lotions, gels, foams, ointments, shampoos, oil solutions, tapes, and sprays. The choice of specific dosage form or vehicle is dependent on several factors such as the surface area involved, location, thickness of the lesions, and the appearance of the plaques. Ointments are recommended for dry and thick lesions to enhance absorption and reduce loss of skin moisture. Creams are indicated for acute, but moist appearing, lesions that do not require ointment-based products. Solutions and gels are recommended for scalp lesions and foams and sprays are usually used for lesions in genital areas. Vehicle selection is an important consideration and may vary from one body part to another. Ointments and tapes provide occlusion, enhancing drug penetration to improve efficacy. Creams and lotions are easier to spread, especially in hairy areas. Gels may have drying and cooling effects, in addition to easy spreadability. Foams may have enhanced drug delivery and/or efficacy compared to lotions or creams that can become cosmetically elegant liquids upon skin contact, providing good patient acceptance. Shampoos incorporating tar distillates or salicylic acid are useful for scalp psoriasis. Pastes, such as Lassar’s paste, have an inherent stiffness, minimizing the spread of medication, and are useful for incorporating drugs such as anthralin, which, especially in higher concentrations used in short-contact methods, may cause skin irritation and burning if in contact with normal skin. It is important to remember that changing to a different vehicle may significantly alter drug potency. For example, a tape formulation (highly occlusive) is much more potent than a cream formulation. Ultimately, the optimal vehicle may be the vehicle that the patient is willing to use. Occlusive ointments may be too
FIGURE 64–1. Treatment algorithm for psoriasis.5,8,21,22,24,27

aReview appointment at 4 weeks for efficacy. bRelapse < 50% over 3 months, move to systemic therapy; cyclosporine: no more than 1 year.

cDiscontinue by 16 weeks if adequate response not met.

dDiscontinue by 12 weeks if adequate response not met.

eContinue treatment beyond 10 weeks if patients shows adequate response.

greasy and cosmetically unappealing, resulting in poor compliance. Sometimes using a cream formulation during the day and an ointment at night may be the best option.18 Keratolytic agents, such as salicylic acid, are often added to bath oil or shampoos (typically 3%-4%) for scalp psoriasis.16,21,22 Salicylic acid can also be added to topical corticosteroid preparations to enhance steroid penetration (salicylic acid breaks down keratin).15,23

Diagnostic Assessment

Efficacy measurements are guided by three main instruments described as Physicians Global Assessment (PGA) scale, National Psoriasis Foundation-Psoriasis Score (NPF-PS), and PASI with PASI being the most common. Unfortunately, these tools are used predominately in clinical trials and infrequently in clinical practice. The PASI is a scoring instrument that ranges from 0 (absence of disease) to 72 (most severe form of the disease). This tool is commonly used because it takes into consideration severity of the disease and the BSA affected. Effective response to treatment in patients with psoriasis is indicated by a 75% reduction in PASI score.17

The National Institute for Health and Care Excellence (NICE) clinical guidelines on psoriasis outline other qualitative measures to be used in assessing the holistic approach to disease management.1 It emphasizes evaluating the physical, psychological, and social impact of the disease on the patients’ quality of life. The impact of psoriasis on the patients’ daily living activities should be assessed. Depending on how the patient is coping, advice and support may be needed in the overall treatment plan for

</table>

Phototherapy and photochemotherapy are generally used in the management of moderate to severe disease. Systemic therapies are used for patients with extensive or moderate to severe disease. To minimize drug toxicities or increase efficacy, systemic therapies are sometimes used in conjunction with topical or phototherapy. Phototherapy is traditionally done by using ultraviolet B (UVB) radiation. It can be used as monotherapy or in combination with topical or systemic agents. The UVB disrupts the synthesis of proteins and nucleic acids in skin, which reduces epidermal keratin proliferation. Education should be provided to all patients and include information about the importance of wearing goggles for eye protection. Dosing is administered by the Fitzpatrick skin type, which deals with the skin tones of the patient. Phototherapy may be administered during pregnancy and is considered a first-line therapy.

Photochemotherapy is the administration of phototherapy together with topical or systemic agents. UVA has a long wavelength, and therapy with UVA is always combined with psoralens (eg, methoxsalen or trioxsalen), which are used as photosensitizers to increase efficacy. The use of psoralens + ultraviolet A (PUVA) for psoriasis causes two types of reaction: (a) an anoxic reaction that affects cellular DNA that inhibits the proliferation of epidermal cells and induces cell death (apoptosis), and (b) an oxygen dependent reaction that gives rise to the formation of free radicals and reactive oxygen that may damage membranes by lipid peroxidation.

PUVA (psoralen ultraviolet A therapy) applies to a group of therapies utilizing psoralens to sensitize cells to UVA light. Bath PUVA, topical PUVA, and oral PUVA regimens are available. Oral PUVA consists of 8-methoxypsoralen, but in Europe 5-methoxypsoralen is more common. 5-methoxypsoralen is less toxic, but not approved in the United States. Bath PUVA involves soaking in a bath of psoralens (trimethylpsoralen) liquid for 15 minutes prior to UVA treatment and is commonly used in Scandinavian countries for generalized psoriasis to reduce systemic toxicities from psoralens. Topical PUVA uses psoralens directly on the skin, then followed by UVA therapy. Psoralens act much more on cells that are actively dividing than on resting cells. This explains why they are effective only in the active stage of scleroderma and not in the fibrotic stage. Their action on actively dividing or activated immune cells, especially on T cells, explains their action in immune-mediated diseases like psoriasis.

Patient Encounter, Part 2

Additional relevant information was obtained from the patient, including the following history:

FH: Father has psoriasis. Mother passed away 6 months ago from a stroke at the age of 65. Younger sister has Stage I HTN and hyperlipidemia

SH: AD is married with three children: ages 5, 3, and 1. She owns her own landscaping business and tries to join her team in the yards as often as possible. She is an occasional drinker (one to two glasses of wine per week) and admits to smoking when she has “a particularly difficult client”

Meds: Lisinopril 10 mg daily; ibuprofen 400 mg every 8 hours as needed (headaches)

PE:

Gen: She appears very distressed about the lesions

VS: BP 134/87 mm Hg, P 88 beats/min, RR 18 breaths/min, T 37.0°C (98.6°F), Ht 5’ 5” (165 cm), Wt 175 lb (79.4 kg)

Abd: Soft, NTND; (+) bowel sounds; lesions on abdomen

Exts: Within normal limits; no joint pains; lesions spreading onto arms

Skin: Dark red lesions on abdomen, back, and arms

Labs: All within normal limits, including lipids, renal function tests, and LFTs

What risk factors does she have for psoriasis?
Systemic Therapy

Systemic therapies are usually recommended for moderate to severe psoriasis. These oral agents are classified into immunosuppressants, oral retinoids, T-cell activation inhibitors, cytokine modulators, TNF-α inhibitors, and interleukin 12 and 23 blockers. See Tables 64–4 and 64–5.

Acitretin is an oral retinoid that is likely safer than methotrexate or cyclosporine since potentially serious adverse effects can usually be minimized by appropriate patient selection, careful dosing, and monitoring. Acitretin given concurrently with phototherapy, acitretin + ultraviolet B (ReUVB) or oral retinoid + PUVA (RePUVA), has a synergistic treatment effect. Acitretin monotherapy is usually given for 14 days before instituting UVB or PUVA. The ultraviolet light dose should be reduced by 30% to 50%.

ReUVB and RePUVA are well-established treatment regimens for psoriasis. Acitretin is teratogenic (Pregnancy Category X) and contraindicated in women of childbearing potential. Pregnancy must be avoided during or for 3 years after discontinuation of therapy. Acitretin can transform spontaneously or be converted by ethanol (transesterification) into etretinate, which may take up to 3 years for body clearance. Abstinence from alcoholic beverages should be observed during therapy and for at least 2 months after acitretin is discontinued. Common side effects of acitretin include mucocutaneous dryness and hyperlipidemia. Long-term continuous use has caused diffuse idiopathic skeletal hyperostosis (DISH) and periungual pyogenic granulomas. Drug interactions include vitamin A (due to the increased risk of hypervitaminosis A), and drugs that interfere with cytochrome P-450 metabolism or have significant plasma albumin binding, which should be used with caution.

Methotrexate is a folic acid antagonist that interferes with purine synthesis and thus inhibits DNA synthesis and cell replication. In addition to the antimitotic effect, it has a specific activity of T-cell suppression and, in low doses, anti-inflammatory and antiproliferative effects. Compared with cyclosporine, methotrexate has a more modest effect but can be used continuously for years, with durable benefits. Folic acid is added to the treatment with methotrexate to reduce gastrointestinal symptoms. It may take up to 4 weeks to see a clinical response after a dose increase. Methotrexate is contraindicated in pregnancy, renal impairment, hepatitis, cirrhosis, alcoholics, unreliable patients, and patients with leukemia or thrombocytopenia.

Cyclosporine is an immunosuppressant that specifically inhibits helper T cells and keratinocyte activation and proliferation. Cyclosporine is efficacious in both inducing remission and in maintenance therapy for patients with moderate to severe plaque psoriasis and is also effective in treating pustular, erythrodermic, and nail psoriasis.

Mycophenolate mofetil was found useful in patients with cyclosporine-induced nephrotoxicity as a switch-over agent. Although PASI increased, patients’ renal function improved. As adjunctive or monotherapy, there are a few studies in relatively small groups of patients with moderate to severe psoriasis that showed some benefit (at least a 50% reduction in PASI). For PsA, the systemic drugs used for rheumatoid arthritis are commonly used. This may include NSAIDS, aspirin, but also methotrexate, retinoids, corticosteroids (oral or intrasynovial injection), and cyclooxygenase inhibitors (COX-2s). Biologic Response Modifiers

Biologic response modifiers (BRMs) are currently recommended for consideration as first-line therapies alongside traditional systemic agents for moderate to severe disease. These are agents employed in the treatment of psoriasis that act by inhibiting various molecular signaling steps of the immunological signaling cascade that are key determinants of the pathogenesis of psoriasis. The following agents are recommended for chronic plaque psoriasis:

1. Inhibitors of TNF, which includes biologic agents such as etanercept, adalimumab, infliximab
2. Inhibitors of interleukin which includes ustekinumab and secukinumab

Their safety profile in comparison with other systemic agents and relatively good acceptability by patients are all positive factors. However, due to a significant cost difference, biologic agents are often reserved for cases in which traditional systemic agents provide inadequate control or for patients with comorbidities such as depression or diabetes (eg, in a patient with PsA or for whom traditional systemic agents may be inappropriate due to potential adverse effects).

Oral apremilast is one of a class of “small molecule” systemic BRMs specifically approved for PsA. It inhibits phosphodiesterase 4 (PDE4) which controls part of the inflammatory actions within cells via CAMP to decrease nitric oxide synthase, TNF-α and interleukin (IL) 23 and increase IL-10. Other BRMs may also be used.

### Patient Encounter, Part 3

The diagnosis is that the patient has erythrodermic psoriasis. Patient expresses to you at this time that she “does not have the best insurance,” but she wants something that will take care of her psoriasis.

**What nonpharmacologic alternatives are appropriate for this patient?**

**What pharmacologic agents are appropriate for this patient?**

### Patient Encounter, Part 4

The patient was started on methotrexate and has been doing well for 18 months. She reports that her condition was well controlled during this time, but recently, she and her husband have been fighting more frequently and she has noticed the lesions have reappeared. She continued her methotrexate regimen, even after the fighting had stopped and has seen no improvement.

**Current Meds:** Nonmedicated moisturizer after bathing and ad lib; methotrexate 2.5 mg every 12 hours for a total of three doses per week

**What is your main treatment goal for this patient?**

**What pharmacologic treatments would be appropriate for this patient at this time?**

**What are the monitoring parameters of your proposed treatment?**

**Natural Health Products and Treatments**

Some patients with psoriasis are inclined to use nonmedical and synthetic preparations, such as those containing natural substances. The choice in many cases is motivated by the unwanted side effects and contraindications of conventional medications. These preparations are either used alone or in combination with the medication prescribed by the physician. The following products have clinical evidence in the literature that is inconclusive to support their use in patients with psoriasis. Examples of these products are aloe vera, oil of avocado, and Oregon grape (*Mahonia aquifolium*). Some products have been tested in animal studies but their efficacy has not yet been validated in humans. Examples are capsaicin, chamomile, indigo, and *naturalis*. A short list of plants and plant products with purported efficacy against psoriasis appears in Table 64–6.

**Investigation Drugs**

There are several agents including topical, oral and biologic modifiers under investigation at various levels including the combination of topical corticosteroids with vitamin D analogues. Micellar paclitaxel, voclosporin, and pioglitazone are among the oral agents currently being studied. Biological agents such as IL-11 inhibitor daclizumab, IL-10, protein kinase blocker AEB071, IL-12 and 23 monoclonal antibodies are all in the pipeline under various stages of investigations.

**OUTCOME EVALUATION**

- Monitor for clearance of skin lesions. Depending on the agent(s) used and site of lesions, it may take 2 to 6 weeks or longer to see a response. Complete clearance may not be achieved for all patients.

- Monitor for specific adverse effects and drug interactions, depending on agent(s) used.

- Methotrexate: Monitor CBC and liver function tests at baseline and on a regular basis. Consider liver biopsy prior to treatment and again at a cumulative dose of 1.5 g for high-risk patients.

- Cyclosporine: Monitor serum creatinine, blood urea nitrogen, serum lipids, magnesium, and blood pressure at baseline. Reassess biweekly for at least 12 weeks or until drug levels stabilize then adjust doses accordingly.

- Acitretin: Monitor serum lipids, liver function tests and perform pregnancy testing.

- Topical corticosteroids: Monitor for skin thinning, irritation telangiectasias, and possible hypothalamic–pituitary–adrenal axis suppression.

- Total clearance of skin disease is not impossible during periods of remission; remissions may be days, months, years, and even decades in length with patients being weaned from their medications entirely or have them reduced to a low maintenance dose.

**DISCUSSION**

- Several factors must be taken into consideration in identifying the right therapy for a patient with psoriasis. Some of these factors are the affected area of the disease, cost, availability of medication, and the preferred lifestyle of the patient. Full patient history including allergies must be collected to make therapeutic approach a success. Topical agents are recommended for mild to moderate disease due to the low cost and fewer adverse effects of the products. Low potency corticosteroids are used as first line for mild conditions. If the condition persists, it is recommended to switch to a very high potency steroid in combination with vitamin D analogue or topical retinoids. In general, a patient disease surface area should be less than 5% to qualify for topical therapy. A general recommendation after unsuccessful treatment with topical agents is to add phototherapy. PUVA was found to be more effective that UVB in the treatment of patients with moderate to severe psoriasis. The traditional systemic agents should be the next in line for patients with severe diseases. Clinical trials indicate that immunosuppressants are more effective than oral retinoids. Due to the cost associated with biological agents, they are reserved as a last resort for patients with severe diseases not responding to traditional systemic agents or intolerant to the side effects of these agents. Biologics are known for their fewer adverse effects. The choice of biologic agents depends on the patient’s preference. Infliximab and adalimumab are more effective than alefacept or etanercept. A disease affecting more than 5% of the BSA should be the justification for initiating systemic therapy. For patients with liver disease, kidney dysfunction, and skin cancer, it is recommended to avoid methotrexate, cyclosporine, and PUVA treatment, respectively.

SUMMARY

It should be recognized that psoriasis is a chronic disease with no current cure but requires lifelong management of the disease state. No two cases of psoriasis are identical and treatment modalities must be tailored to the patient with the help of a dermatologist. The disease can severely impact the patients’ quality of life by affecting their physical, psychological, and social well-being. The NICE guidelines recommend a holistic approach in assessing all areas of life in caring for patients that live with this disease.

ACKNOWLEDGMENTS

The authors and editors wish to acknowledge and thank Dr. Rebecca Law, the primary author of this chapter in the 3rd edition of this book. Additionally, the current authors would like to acknowledge the student research assistants that contributed to this chapter, Sarah Anderson, Rebecca Kyper, Heather Rose, and Rebecca Widder from Cedarville University School of Pharmacy.

Abbreviations Introduced in This Chapter

- BB-UVB: Broadband ultraviolet B
- BRM: Biologic response modifier
- BSA: Body surface area
- cAMP: Cyclic 3’-5’-adenosine monophosphate
- DISH: Diffuse idiopathic skeletal hyperostosis
- IF-γ: Interferon-γ
- IL-2: Interleukin-2
- IL-10: Interleukin-10
- IL-12/23: Interleukin-12 and interleukin-23
- LFT: Liver function test
- NSAIDs: Nonsteroidal anti-inflammatory drugs
- PASI: Psoriasis Area and Severity Index
- PPD: Purified protein derivative
- PUVA: Psoralen ultraviolet A therapy
- Q: Every
- PsA: Psoriatic arthritis
- RePUVA: Oral retinoid + PUVA
- ReUVB: Acitretin + ultraviolet B
- TNF: Tumor necrosis factor
- UVB: Ultraviolet B

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of common skin disorders.
2. Assess the signs and symptoms of common skin disorders in a presenting patient.
3. List the goals of treatment for patients with common skin disorders.
4. Select appropriate nonpharmacologic and pharmacologic treatment regimens for patients presenting with common skin disorders.
5. Identify adverse effects that may result from pharmacologic agents used in the treatment of common skin disorders.
6. Develop a monitoring plan that will assess the safety and efficacy of the overall disease state management of common skin disorders.
7. Create educational information for patients about common skin disorders, including appropriate self-management, available drug treatment options, and anticipated therapeutic responses.

INTRODUCTION

Several thousand skin disorders are currently documented, and many patients seek the assistance of a health care provider when a complication with their skin develops. Others will utilize self-care to effectively treat their symptoms. This chapter discusses acne vulgaris, contact dermatitis (irritant and allergic), and diaper dermatitis; other common skin and soft tissue infections and superficial fungal infections are discussed in Chapters 73 and 83, respectively. Providing patients with appropriate therapy options, as well as patient education on treatment and prevention, will assist the successful management of many common skin disorders.

ACNE VULGARIS

Acne vulgaris is an inflammatory skin disorder of the pilosebaceous units of the skin. Although most commonly seen on the face, acne can also be present on the chest, back, neck, and shoulders (Figure 65–1). Acne is not just a self-limiting disorder of teenagers. The clinical course of acne can be prolonged or recur, resulting in long-term physical complications such as extensive scarring and psychological distress.

EPIDEMIOLOGY AND ETIOLOGY

With an estimated 40 to 50 million people affected, acne vulgaris is the number one skin disease in the United States. Acne affects approximately 85% of adolescents and adults aged 12 to 25 years, with severity of acne correlating with pubertal maturity. Additionally, acne may persist beyond puberty and has been found to affect 64% and 43% of individuals into the 1920s and 1930s, respectively. Acne is more likely to occur in males during adolescence and females during adulthood. Individuals with a positive family history of acne have been shown to develop more severe cases of acne at an earlier age. Prevalence of acne among ethnic groups is similar.

While the link between diet and acne has continued to be controversial, there is evidence to suggest that high glycemic load diets may exacerbate acne. Local irritation from occlusive clothing or athletic equipment, oil-based cosmetics or beauty products, prolonged sweating or environments of high humidity, and a variety of medications may also worsen acne.

PATHOPHYSIOLOGY

The development of acne lesions results from four pathogenic factors: excess sebum production, keratinization, bacterial growth, and inflammation.

The pilosebaceous unit of the skin consists of a hair follicle and the surrounding sebaceous glands. An initial acne lesion, called a comedo, forms when there is a blockage in the pilosebaceous unit. Sebum is released by the sebaceous glands and naturally maintains hair and skin hydration. Increased androgen levels, especially during puberty, can cause an increased size of the sebaceous gland and production of abnormally high levels of sebum within those glands. This excess sebum can result in plugged follicles and acne formation.

Keratinization, the sloughing of epithelial cells in the hair follicle, is also a natural process. In acne, however, hyperkeratinization occurs and causes increased adhesiveness of the sloughed cells. Accumulation of these cells clogs the hair follicle, blocks the flow of sebum, and forms an acne lesion called an open comedo or “blackhead.”
Propionibacterium acnes (P. acnes), an anaerobic organism, is also found in the normal flora of the skin. This bacteria proliferates in the mixture of sebum and keratinocytes and can result in an inflammatory response producing a closed comedo or “whitehead.” More severe acne lesions such as pustules, papules, and nodules also form with inflammatory acne and result in significant scarring if treated inadequately.

**TREATMENT**

**Desired Outcomes and Goals**

Although traditionally thought of as a self-limiting disorder, acne can have patterns of recurrence. Because acne cannot be cured, proper treatment must involve both short-term and long-term strategies. Goals of therapy are to (1) Reduce the number and severity of existing lesions, (2) Prevent the development of new lesions, and (3) Prevent long-term disfigurement and permanent scarring. Acne can cause psychological symptoms of stress, anxiety, frustration, embarrassment, and even depression. Evaluating both physical and psychological aspects of acne is imperative.

**General Approach to Treatment**

Acne treatment regimens should be based on acne severity and type of acne lesion. Other factors such as response to previous treatment, patient preference, cost and adherence should also be considered. Topical therapy is considered first line for mild acne with oral therapies added to topical therapy in moderate to severe acne. Optimal management includes induction and maintenance therapy. Improvement of symptoms following induction therapy occurs gradually, sometimes taking 6 to 8 weeks for results to be physically apparent. Patients need to be educated on continual treatment compliance during this time and should not get discouraged if acne lesions appear to worsen before getting better. Maintenance therapy should begin after 12 weeks of induction therapy and continues for 3 to 4 months.

**Nonpharmacologic Therapy**

There is significant variance in the clinical benefit of many nonpharmacologic interventions for acne vulgaris. Patients should be counseled to avoid aggressive skin washing and to use a mild, noncomedogenic facial soap twice daily. Furthermore, discourage the use of abrasive cleansers and manipulating or squeezing

**Clinical Presentation and Diagnosis of Acne**

Acne lesions are most often seen on the face, but can also present on the chest, back, neck, and shoulders and are described as either noninflammatory or inflammatory. Severe inflammatory lesions may lead to scarring and hyperpigmentation.

**Noninflammatory Lesions**

Open comedo or “blackhead”: A plugged follicle of sebum, keratinocytes, and bacteria that protrudes from the surface of the skin and appears black or brown in color. Although dark in color, blackheads do not indicate the presence of dirt, but rather, an accumulation of melanin.

Closed comedo or “whitehead”: A plugged follicle of sebum, keratinocytes, and bacteria that remains beneath the surface of the skin. Closed comedos usually appear as small white bumps about 1 to 2 mm in diameter.

**Inflammatory Lesions**

Papules: Solid, elevated lesion less than 0.5 cm in diameter

Pustules: Vesicles filled with purulent fluid less than 0.5 cm in diameter

Nodules: Lesions greater than 0.5 cm in both width and depth

Cysts: Nodules filled with a fluid or semisolid that can be expressed

**Scars**

Inflammatory acne can result in permanent scarring that ranges from small depressed pits to large elevated blemishes.

**Hyperpigmentation**

Inflammatory acne may result in hyperpigmentation of the skin that can last for weeks to months.

**Diagnosis**

The diagnosis of acne vulgaris is clinical. Lesion cultures may be warranted when treatment regimens fail to rule out other skin infections.

**Assessment**

No standard acne grading scale has been identified. While several grading scale exist, most clinicians describe acne as mild (few noninflammatory lesions), moderate (many inflammatory lesions) or severe (numerous severe inflammatory lesions and evidence of scarring).
lesions to minimize scarring. Use of an oil-free, noncomedogenic moisturizer may improve the tolerability of topical drug therapy.7

Pharmacologic Therapy
» Topical Agents

Benzoyl Peroxide Benzoyl peroxide is easy to use and is recommended as an alternative to or in combination with topical retinoids or topical antibiotics in the treatment of acne of all severities.2,9 Benzoyl peroxide has a comedolytic effect that increases the rate of epithelial cell turnover and helps to unclog blocked pores. It also has antibacterial activity against P. acnes, which appears to be the main reason for its effectiveness.11,12

Benzoyl peroxide is available with or without a prescription and remains the most commonly purchased over-the-counter topical treatment for acne.7 Some data suggests that lower strengths offer similar efficacy to higher strengths. Beginning benzoyl peroxide treatment regimen with the lowest strength and titrating to higher effective strengths over several weeks, if needed, will reduce the incidence of localized adverse effects. Newer formulations of benzoyl peroxide are combined with moisturizers to help decrease skin redness and irritation.11,12

A typical regimen for benzoyl peroxide is to apply the product to clean, dry skin no more than two times a day. The strength and dosage form selected may vary from patient to patient depending on acne severity and the sensitivity of the patient’s skin. Gel preparations are the most potent dosage form. Patients with dry or overly sensitive skin should try a cream, lotion, or facial wash first.6 If severe irritation or an allergic reaction develops, benzoyl peroxide should be discontinued. Table 65–1 describes available products and adverse effects.

Retinoids Highly effective in the treatment of acne, retinoids stimulate epithelial cell turnover and aid in unclogging blocked pores. Retinoids also exhibit anti-inflammatory properties through the inhibition of neutrophil and monocyte chemotaxis.11 Due to the ability to target multiple pathogenic features of acne, topical retinoids are recommended as first-line therapy for induction and maintenance regimens in all forms of acne. Although success is seen with monotherapy, using topical retinoids in combination with benzoyl peroxide or topical antibiotic agents is preferred for inflammatory acne lesions.2,9

Available topical retinoids include tretinoin, adapalene, and tazarotene. Adapalene is considered the drug of first choice because it has similar efficacy and a lower incidence of adverse effects.9,11 Newer formulations involving a microsphere gel (Retin-A Micro) or prepolyolprepolymer-2 gel or cream (Avita) gradually release the active ingredient over time and may also cause less initial skin discomfort.13 Table 65–1 describes available products and adverse effects of topical retinoids.

Topical retinoids should be applied once daily at bedtime, beginning with a low-potency formulation. Increased strengths are then initiated according to treatment results and tolerance. Patients should be advised that a worsening of acne symptoms generally occurs in the first few weeks of therapy, with lesion improvement occurring in 3 to 4 months.14,15 The use of topical retinoids should be avoided in children younger than 12 years and in pregnant women.15

Antibacterials Topical antibacterials directly suppress P. acnes and are first-line agents used in combination with benzoyl peroxide, topical retinoids or azelaic acid for the treatment of mild to moderate inflammatory acne. To reduce the likelihood of bacterial resistance, topical antibiotics should never be used as monotherapy or as long-term maintenance therapy.2,9

Clindamycin and erythromycin preparations, applied once or twice daily for 3 months, have similar effects and are the most commonly prescribed topical antibacterial agents.2,9,11 These agents are available in various formulations and combinations with benzoyl peroxide and retinoids. Table 65–1 describes the strengths, formulations, and adverse effects of the available antimicrobial agents.

Azelaic Acid With antibacterial and anti-inflammatory properties, and the ability to stabilize keratinization, azelaic acid is an effective alternative in the treatment of mild to moderate acne in patients who cannot tolerate benzoyl peroxide or topical retinoids.2,9,13 It can also even out skin tone and may prove effective in patients who are prone to postinflammatory hyperpigmentation resulting from acne.3,15 Azelaic acid 20% cream should be applied twice daily, with improvement of symptoms seen in 4 weeks.15

Dapsone Dapsone gel, a sulfone drug, has antimicrobial and anti-inflammatory properties.17 Although approved for the treatment of mild to moderate acne, due to the lack of comparative efficacy trials, current guidelines do not comment on the place of dapsone in the treatment of acne.2,9

Dapsone 5% (Aczone) is a gritty gel that should be applied in a thin layer to the affected areas twice daily. If no improvement is seen after 12 weeks, treatment should be reevaluated.18

Keratolytics Sulfur, resorcinol, and salicylic acid are not as effective as other topical agents, but can be used as second-line therapies in the treatment of mild to moderate acne.2,7

Although these agents may cause less skin irritation than benzoyl peroxide or the topical retinoids, several disadvantages exist. Sulfur preparations produce an unpleasant odor when applied to the skin, whereas resorcinol may cause brown scaling. And although rare, the possibility of salicylism exists with continual salicylic acid use.2,15

» Oral Agents

Antibacterials Moderate to severe acne can be effectively treated with oral antibiotics, especially when treatment with topical therapy has failed.2,9 Because of the ability to decrease P. acnes colonization, oral antibiotics can prevent acne lesions from developing. Use of oral antibiotics should be limited to short periods of time, ideally 3 months or less. Assessment of response to oral antibiotics after 6 to 8 weeks of therapy is recommended. As with topical antibiotics, oral antibiotics should never be used as monotherapy or as long-term maintenance therapy. Additionally, the use of topical antibiotics in combination with oral antibiotics is should be avoided.2

Tetracycline, doxycycline, and minocycline are the most commonly prescribed oral antibiotics for acne. Erythromycin, azithromycin, and trimethoprim (± sulfamethoxazole) are appropriate second-line agents for use when patients cannot tolerate or have developed resistance to tetracycline or its derivatives. Although effectiveness is similar to the tetracyclines, erythromycin use is often limited due to potential adverse outcomes and increased bacterial resistance.19 (See Table 65–2 for antibiotic dosing guidelines and adverse effects.)

Isotretinoin Isotretinoin works on the four pathogenic factors that contribute to acne development and can produce acne remission rates of up to several years. Oral isotretinoin is Food and Drug Administration (FDA) approved for patients with severe recalcitrant nodular acne unresponsive to other topical and oral treatment regimens. Although studies are lacking, expert clinicians suggest that oral isotretinoin may be useful in treatment resistant acne of lower severity.2,9 Contrary to some expert clinicians, the 2012 European Guidelines suggest that oral

</table>
isotretinoin therapy may be used as first-line therapy in patients with severe nodular acne due to clinical effectiveness, prevention of scarring, and quick improvements in patient quality of life. Adverse effects with the use of isotretinoin are frequent and generally dose related. Table 65–2 lists common isotretinoin adverse effects and management strategies for those symptoms. Because isotretinoin is teratogenic and classified as Pregnancy Category X, the FDA mandates an online registry program called iPLEDGE to ensure that females do not become pregnant while taking isotretinoin. Wholesalers, pharmacies, doctors, and patients must be registered in the iPLEDGE computer-based system in order to control the distribution, prescribing, and dispensing of isotretinoin. Two negative pregnancy tests prior to initiating therapy and one negative pregnancy test each month thereafter must be obtained and confirmed in the system before a prescription can be dispensed to female patients of child-bearing potential. These patients must also commit to using two effective forms of birth control 1 month prior, during, and at least 1 month after discontinuation of isotretinoin therapy. Contact the program at their website: https://www.ipledgeprogram.com for further details.

Initial dose ranges for treatment are 0.5 to 1 mg/kg daily in two divided doses, with beneficial results generally reported at total daily doses of 120 to 150 mg/day. Treatment with oral isotretinoin should be continued for 6 months, but may be extended for patients with an insufficient response.

**Hormonal Agents** Oral contraceptives and antiandrogens (spironolactone and cyproterone acetate) are valuable second-line treatment options for moderate to severe acne in female patients. Hormonal agents primarily work by decreasing androgen production resulting in reduced sebum formation. Because sebum production occurs early in the pathogenesis of acne, it may take up to 3 to 6 months to see the full effect of hormonal agents. Although many contraceptives are effective, agents containing norgestimate with ethinyl estradiol, norethindrone acetate with ethinyl estradiol, and drospirenone with ethinyl estradiol (Yaz) have been FDA approved for the treatment of acne. Spironolactone at higher doses is effective for acne through antiandrogenic properties. While not approved for use in the United States, cyproterone acetate combined with an ethinyl estradiol containing oral contraceptive has demonstrated efficacy. (See Table 65–2 for hormonal agent dosing guidelines and adverse effects.)

**Other Agents** Although use is infrequent, several other agents are available as second- or third-line treatment options for acne when first-line therapies fail.

- Corticosteroids
- Chemical peels
- Surgical extraction
- Phototherapy/photodynamic therapy
- Laser treatments

Figure 65–2 shows useful algorithms for the effective treatment of the various stages of acne.

### OUTCOME EVALUATION

Depending on severity, complete resolution of acne lesions may take weeks to months. Monitor patients every 4 to 8 weeks during pharmacologic therapy to assess for efficacy.

- Decreased number of lesions
- Decreased severity of lesions

### Patient Care Process: Acne

**Patient Assessment:**
- Assess patient symptoms and acne lesions to determine acne severity: mild, moderate, or severe.
- Determine family history of acne, including severity.
- Evaluate skin care routine, including the use of cosmetics, facial washes, moisturizers, and other possible exacerbating factors.
- Conduct a medication history (nonprescription, prescription, and herbal medications). Identify previous acne treatment regimens.
- Identify any drug allergies.

**Therapy Evaluation:**
- If the patient is already receiving pharmacotherapy, assess whether active and/or previously tried therapies were effective, safe, and used as directed.
- If the patient is not well controlled, determine appropriate pharmacotherapy options for the patient’s acne severity (see Figure 65–2).
- Determine whether the patient has prescription medication coverage to identify possible recommendations included in the plan formulary.

**Care Plan Development:**
- Select nondrug and drug therapy likely to be effective and safe (see Tables 65–1 and 65–2).
- Address any patient concerns.
- Provide patient education on acne and its management:
  - What is acne and how does it develop?
  - Physical and psychological complications that can result from acne.
  - Proper administration technique. Topical acne therapy should be applied to acne prone areas and existing lesions.
  - Possible side effects of drug therapy.
  - Inform patient of possible initial worsening of acne and/or delay of therapeutic effectiveness of acne drug therapy.
  - Emphasize medication compliance and adherence to lifestyle modifications.

**Follow-up Evaluation:**
- Follow-up every 1 to 2 months to assess effectiveness and safety of nondrug and drug therapy (see Tables 65–1 and 65–2).
- If acne lesions do not respond after 3 months of drug therapy, consider an alternative acne regimen (see Figure 65–2).
- If the patient experiences resolution of acne symptoms, transition to maintenance drug therapy.

---

### Patient Encounter 1

A 15-year-old girl complains of “embarrassing zits.” She began getting a few lesions when she was 14 which have now increased in number. She is starting high school and is very anxious about her appearance. Visual examination reveals numerous noninflammatory lesions and several papules and pustules on her forehead, cheeks, and nose. She is frustrated because she thinks acne means she is not a “clean person” and nothing she has tried has “cured her acne.” She admits to washing her face at least three times a day with an over-the-counter face wash containing benzoyl peroxide. She also applies a salicylic acid 2% cream directly to her lesions once a day. She has never seen a dermatologist for her acne. The patient appears to be in good physical health.

**What reported symptoms support the diagnosis of acne?**
**What other information would you obtain from this patient before determining a treatment plan for her?**
**Describe your treatment goals for this patient.**
**What nonpharmacologic treatment options and lifestyle modifications would you suggest to this patient?**
**What pharmacologic treatment options are available for this patient?**

Given the information presented, develop a treatment regimen for this patient that includes the following:
(a) A statement of the drug-related needs and/or problem
(b) A patient-specific therapeutic plan
(c) Monitoring parameters to assess efficacy and safety

---

- Relief of pain/irritation
- Presence of scarring or pigmentation
- Psychological effects

If no improvement is reported after 6 weeks of drug therapy or if symptoms have worsened, patients should be reevaluated and a change to an alternative drug regimen may be necessary (see Figure 65–2).

Educate patients on potential adverse effects of drug therapy (see Tables 65–1 and 65–2). Consider changing therapy if a patient experiences effects that are not tolerated or are a compromise to their health.

---

### CONTACT DERMATITIS

Contact dermatitis is a condition in which exposure to an offending substance produces inflammation, erythema, and pruritus of the skin. More specifically, contact dermatitis can be divided into either irritant or allergic forms. **Irritant contact dermatitis (ICD)** results from first-time exposure to irritating substances such as soaps, plants, cleaning solutions, or solvents. **Allergic contact dermatitis (ACD)** is a delayed hypersensitivity reaction that occurs after an initial exposure to an allergen results in sensitization. With additional exposure, activation of the immune system results in dermatitis. Allergens that commonly cause ACD include poison ivy, latex, and certain types of metal. (Figures 65–3 and 65–4.) Table 65–3 lists agents commonly responsible for irritant and ACD. Although generally occurring on the exposed skin, such as the hands and face, contact dermatitis can appear anywhere on the body.

---

PATHOPHYSIOLOGY

Irritant contact dermatitis is not the result of an immunologic process, but rather occurs from direct injury to the skin. An irritating agent comes into contact with the skin, damages the protective layers of the epidermis, and can cause erythema, the formation of vesicles and pruritus. Symptoms occur within minutes to hours of exposure and begin to heal soon after removal of the offending substance.

Clinical Presentation and Diagnosis of Contact Dermatitis

Contact dermatitis is generally confined to the area of contact, but in a highly sensitive person, a widespread or even generalized eruption may occur. Contact dermatitis is divided into two forms—irritant and allergic. Both forms may include, but are not limited to:

- Erythema
- Pruritus
- Vesicles
- Papules
- Crusts
- Burning
- Pain

Irritant Form

The irritant form usually presents within hours of exposure and the rash is often localized. ICD may also result in fissuring and scaling.

Allergic Form

The allergic form can take several days to present and the condition may extend beyond the borders of the region exposed. ACD may cause intense itching and include oozing pustules and skin erosion.

Diagnosis

When the causative agent is known, the diagnosis of contact dermatitis is clinical. Patch testing is done if the allergens are unknown and is usually performed several weeks after the resolution of the original dermatitis.

TREATMENT

Desired Outcomes and Goals

- **Identifying the causative substance and eliminating its exposure is the initial treatment goal for contact dermatitis.** Although physical symptoms can develop almost immediately after contact, removal of the offending agent will improve existing symptoms and prevent further complications. Removing the offending agent includes washing the skin and any clothing or objects that may have come into contact with the agent to prevent reexposure. The second treatment goal is symptom relief. Since inflammation and pruritus, as well as lesion formation, are likely to result from contact dermatitis, appropriate selection of nonpharmacologic and pharmacologic agents for these symptoms is necessary.

Nonpharmacologic Therapy

In many cases, contact dermatitis may not require medical treatment. Nondrug therapy for contact dermatitis is aimed at relieving pruritus and maintaining skin hydration.

- Colloidal oatmeal baths
- Cool or tepid soapless showers
- Cool, moist compresses applied to the area for 20 to 30 minutes as often as needed
- Emollients applied to the area after bathing

Pharmacologic Therapy

- **Astringents**
  
  The drying effect of astringents will decrease oozing from lesions and relieve itching. Due to their ability to cause blood vessel constriction, astringents can also decrease inflammation. Aluminum acetate (Burow solution), aluminum sulfate/calcium acetate solution (Domeboro), calamine lotion, colloidal oatmeal baths/soaks, and witch hazel are safe and effective. Aluminum acetate or aluminum sulfate/calcium acetate may be applied as a compress for 30 minutes at least four times daily as needed. Colloidal oatmeal baths or soaks may be applied for 15 to 20 minutes at least twice daily.

- Adverse effects reported with these agents are minimal and include drying and tightening of the skin.

- **Topical Steroids**
  
  Erythema, inflammation, pain, and itching caused by ACD can be effectively treated with topically applied corticosteroids. The use of topical corticosteroids for the management of ICD is controversial, as patients with ACD generally respond better to therapy than those with ICD. With such a wide range of products and potencies, appropriate steroid selection is based on severity and location of lesions (see Table 65–4 for a list of topical steroids and potencies.) Higher potency preparations are used in areas where...

Penetration is poor, such as the elbows and knees. Lower potency products should be reserved for areas of higher penetration, such as the face, axillae, and groin. Low-potency steroids are also recommended for the treatment of infants and children.³⁴,³⁵

Adverse effects from topical steroids are usually related to the potency of the steroid, frequency of application, duration of therapy, and the site of application. Skin atrophy, hypopigmentation, striae, and steroid-induced acne are all possible side effects associated with long-term use.³⁰ Ointments, because of their occlusive properties, should be avoided on weeping lesions.²³,³⁶

Topical steroids are typically applied two to four times daily. As improvement begins, maintenance therapy should be limited to the lowest strength steroid that continues to control the condition. Once symptoms are completely resolved, use should be discontinued and should not exceed 1 to 2 weeks.³⁴

### Antihistamines
Whether due to their antihistaminic activity or their sedative side effects, pruritus caused by contact dermatitis can be relieved with the use of sedating oral antihistamines such as diphenhydramine or hydroxyzine. Topical antihistamines are available, but use is limited due to their high-sensitizing potential.²³,³⁴ In addition to sedation, many oral antihistamines can cause hypotension, dizziness, blurred vision, and confusion.

### Outcome Evaluation
With adequate treatment, most cases of contact dermatitis should improve within 7 days. Complete resolution of symptoms may take up to 3 weeks.²³ If patients experience severe symptoms associated with fever or difficulty breathing, they should be instructed to
**Patient Care Process: Contact Dermatitis**

**Patient Assessment:**
- Assess symptoms.
- Obtain a thorough patient history. Can the agent/exposure be identified? Has there been prior exposure to that agent? If so, what treatment regimens were used to alleviate symptoms?
- Obtain patient’s allergy status.

**Therapy Evaluation:**
- Determine whether the patient has ICD or ACD.
- Discuss testing needed to suggest or confirm the etiologic agent (patch testing).

**Care Plan Development:**
- Develop a treatment plan for ICD or ACD. In most cases, nondrug and nonprescription treatment options are most appropriate. If case is severe or if the patient has ACD, the plan may also include prescription therapy.
- Provide patient education on ICD or ACD and treatment:
  - Possible adverse effects of drug therapy
  - Symptoms that warrant physician referral?
  - Importance of treatment compliance.
- Educate on the recognition of agents that may cause contact dermatitis.

**Follow-up Evaluation:**
- Symptoms should improve within 2 to 3 days. If no improvement, the patient should be advised to follow-up with the provider.

**Patient Encounter 2**

A 25-year-old man presents to your pharmacy with complaints of intense itching and shows you a red, raised rash with papules on his arms. The patient tells you several days ago he spent the day clearing brush with his father on his family’s property. He states that he was wearing gloves and work boots, but had on a T-shirt and shorts. He suspects he came into contact with poison ivy, because his rash looks similar to the one he had before when he came into contact with poison ivy while camping. The patient indicates that he took a shower several hours after exposure, but hasn’t tried anything else to manage his symptoms. From the information he has presented, you conclude that he did likely come in contact with an agent while working that caused an allergic contact dermatitis to develop.

**What information supports the possibility of exposure to an allergic agent?**

**Describe the symptoms that support this diagnosis.**

**Determine what the patient has tried to relieve her symptoms.**

**Describe the differences between allergic and irritant contact dermatitis.**

**What are your treatment goals for this patient?**

**What nonpharmacologic and pharmacologic treatment options are available for this diagnosis?**

**Given the information presented, develop a treatment regimen for this patient that includes the following:**

(a) A statement of the problem
(b) A patient-specific therapeutic plan
(c) Monitoring parameters to assess efficacy and safety

**DIAPER DERMATITIS**

**EPIDEMIOLOGY AND ETIOLOGY**

Diaper dermatitis, more commonly known as diaper rash, is a form of ICD that affects the buttocks, upper thighs, lower abdomen, and genitalia of an estimated 7% to 35% of all infants. Onset of occurrence is usually between 3 weeks and 2 years of age, with the most cases reported between 9 and 12 months of age. The rise in the number of adults who use diapers for incontinence also increases the risk of developing diaper dermatitis.

**PATHOPHYSIOLOGY**

Although many factors contribute to diaper rash, it is most likely the result of prolonged contact of the skin with urine and feces in the diaper. If a diaper is not changed soon after urination or defecation, the protective layer of the skin can break down and make the area more susceptible to irritation and infection. Although most mild cases of diaper rash present as erythema, moderate to severe cases can result in the formation of papules, vesicles, and even ulceration. If these cases are not effectively treated, the likelihood of secondary fungal or bacterial infections developing is greatly increased.

**TREATMENT**

**Desired Outcomes and Goals**

- **The primary goal in the treatment of diaper rash is prevention and is most often accomplished through frequent diaper changes.**
- **When a diaper rash is already present, repairing the damaged skin, relieving discomfort, and preventing secondary infections from occurring are important factors to consider when developing an effective treatment regimen.**

**Nonpharmacologic Therapy**

Most mild cases of diaper rash can be resolved with the use of nonpharmacologic therapies. Keeping the diaper area clean and dry by changing diapers as soon as practically possible (at least every 2 hours or more frequently) is highly effective for treatment and prevention. Other nondrug options include:
Clinical Presentation and Diagnosis of Diaper Dermatitis

**Typical Symptoms**
- Erythema is the most common symptom presented with a diaper rash. The rash may begin as light to medium pink with poorly defined edges, but may become dark red and raised lesions with distinct edges.
- Rashes generally appear in the folds of the skin around the diaper area, thighs, genitals, and buttocks.
- Other typical symptoms include irritation and pruritus.

**Atypical Symptoms**
Patients presenting with the following symptoms may indicate the need for more aggressive antibiotic or antifungal therapy and should be referred to a physician for further evaluation:
- Rashes not responding to typical creams and concurrent nonpharmacologic treatment
- Rashes extending beyond the diaper region (upper abdomen, back)
- Formation of papules, bullae, and ulceration
- Excessive oozing
- Presence of genital discharge
- Concurrent fever
- Rashes appearing when diapers have not been used or rashes that fail to improve upon discontinuing diaper usage for extended periods of time (several days or more)
- Bleeding or open skin

**Diagnosis**
The diagnosis of diaper dermatitis is clinical. The presence of *Candida albicans* can be determined by KOH testing or culture, but is generally not necessary.

Pharmacologic Therapy

**Protectants**
Protectants form an occlusive barrier between the skin and moisture from the diaper. Cream and ointment preparations are effective in providing a sufficient barrier in mild, irritant, and noninfected diaper rashes. For more severe cases, a paste is the topical agent of choice. Pastes are thicker and often contain additional ingredients (petrolatum, moisturizers) to decrease discomfort and promote healing. Zinc oxide is one of the most commonly used topical protectants. In addition to forming an effective barrier against moisture, it has astringent and antiseptic properties that provide added symptom relief.

Protectants are generally applied to the affected area after every diaper change and can be discontinued when the rash resolves. Other available protectants that can be used alone or in combination for the safe and effective treatment of diaper rash include white petrolatum, Vitamins A and D, lanolin, and topical cornstarch. Many agents contain a combination of occlusive and protective agents such as Triple Paste and Calmoseptine.

**Topical Steroids**
Because of the increased permeability of their skin, infants are at risk for excessive absorption and toxicity from the use of topical steroids. Although effective in decreasing inflammation and relieving pruritus, steroid use in infants for the treatment of diaper dermatitis should be limited to only low-potency preparations. A thin layer of hydrocortisone cream (0.25%–1%) applied twice a day for no more than 2 weeks is an appropriate regimen. Use of higher potency steroids or use extending beyond 2 weeks should be at the discretion of a physician only.

**Antifungals**
- Diaper rashes lasting longer than 48 to 72 hours are at increased risk for the development of fungal infections. These complications are most frequently caused by *Candida albicans* and will require treatment with a topical antifungal. Adverse events with the use of topical antifungals are generally limited to local irritation at the site of application.
  - Nystatin, clotrimazole, and miconazole creams or ointments applied two to four times daily with diaper changes have all shown to be effective in the treatment of candidal diaper rash.
  - Although some of these products are available over the counter, parents and caregivers should be advised to initiate treatment with antifungal agents only after physician recommendation.

**Antibacterials**
If conventional treatment fails, unresolved diaper rash can also lead to secondary bacterial infections. *Staphylococcus aureus* and

---

CHAPTER 65 | COMMON SKIN DISORDERS

Patient Encounter 3

A woman presents to a community pharmacy inquiring about a product to purchase for her 4-month-old son who recently developed a rash in his diaper area. She says the rash has worsened from light pink to bright red. After further questioning, it is determined that the rash has lasted about 2 to 3 days, seems to be painful for her son when she cleans him with diaper wipes during changing. She has tried using white petrolatum a few times and is now concerned about the rash becoming infected.

What reported symptoms support the diagnosis of diaper rash?

What additional information would aid in your assessment of this patient?

What are your treatment goals for this patient?

What nonpharmacologic and pharmacologic treatment options are available for this diagnosis?

Given the information presented, develop a treatment regimen for this patient that includes the following:

(a) A statement of the problem
(b) A patient-specific therapeutic plan
(c) Monitoring parameters to assess efficacy and safety

Streptococcus are the most likely pathogens responsible for these infections and require treatment with systemic antibiotics. While topical protectants may be used as an adjunct in treatment, suspected bacterial infections should always be referred to a physician for accurate diagnosis and the selection of an appropriate antibacterial regimen. Figure 65–6 shows a useful algorithm for the effective treatment of diaper dermatitis.

OUTCOME EVALUATION

Most diaper rashes can be effectively treated in less than 1 week. If symptoms do not resolve or begin to worsen, advise caregivers to seek medical attention to determine the presence of secondary fungal or bacterial infections. In addition, provide educational information on proper diaper hygiene techniques in order to prevent the development of future diaper rashes.

Patient Assessment:

- Assess rash symptoms. Determine the level of severity—is there a possibility of a secondary fungal or bacterial infection?
- Identify signs and symptoms that require immediate physician referral.
- Inquire about the patient’s history, including similar rashes in the past.
- Obtain patient allergy status.

Therapy Evaluation:

- Determine what treatment options, if any, have been tried and if they were successful.
- Discuss labs that may be necessary if a secondary infection is suspected (cultures, biopsies).

Care Plan Development:

- Discuss available barrier treatment options with the caregiver and develop a treatment plan.
- Include proper usage instructions and potential side effects in patient counseling.
- Educate the caregiver on the importance of frequent diaper changes and proper hygiene.
- Emphasize importance of treatment compliance and use of preventative measures

Follow-Up Evaluation:

- Provide any further patient education about diaper rash etiology, treatment, and prevention.
- Discuss symptoms to report to a physician (blistering, oozing, bleeding, changes in rash, or no improvement in symptoms within 2 to 3 days).

streptococcus are the most likely pathogens responsible for these infections and require treatment with systemic antibiotics. while topical protectants may be used as an adjunct in treatment, suspected bacterial infections should always be referred to a physician for accurate diagnosis and the selection of an appropriate antibacterial regimen. figure 65–6 shows a useful algorithm for the effective treatment of diaper dermatitis.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify common causes of anemia.
2. Describe common signs and symptoms of anemia.
3. Describe diagnostic evaluation required to determine the etiology of anemia.
4. Recommend a treatment regimen considering the underlying cause and patient-specific variables.
5. Compare and contrast oral and parenteral iron preparations.
6. Explain the optimal use of folic acid and vitamin B₁₂ in patients with macrocytic anemia.
7. Evaluate the proper use of epoetin and darbepoetin in patients with anemia caused by cancer chemotherapy or chronic kidney disease.
8. Develop a plan to monitor the outcomes of pharmacotherapy for the treatment of anemia.

INTRODUCTION

Anemia is a reduction in the concentration of hemoglobin (Hgb) that results in reduced oxygen-carrying capacity of the blood. Some patients with anemia may be asymptomatic initially, but eventually, the lack of oxygen to tissues results in fatigue, lethargy, shortness of breath, headache, edema, and tachycardia. Common causes include blood loss, decreased red blood cell (RBC) production, and increased RBC destruction. Determination of the underlying cause of anemia is essential for successful management.

EPIDEMIOLOGY AND ETIOLOGY

Anemia is a common diagnosis with a prevalence that varies widely based on age, gender, and race/ethnicity (Table 66–1). Patients with specific comorbidities such as cancer and chronic kidney disease (CKD) have significantly higher rates of anemia. The incidence of anemia in cancer patients ranges from 30% to 90%. Contributing factors include the underlying malignancy and myelosuppressive antineoplastic therapy. The prevalence of anemia in patients with CKD ranges from 15% to 20% in patients with CKD stages 1 through 3 and up to 70% in patients with stage 5.

A decrease in erythrocyte production can be multifactorial. Nutritional deficiencies (iron, vitamin B₁₂, and folic acid) are common causes and often easily treatable. Patients with cancer or CKD are at risk for developing anemia caused by dysregulation of iron and erythropoietin (EPO) hemostasis. Patients with chronic immune-related diseases such as rheumatoid arthritis and systemic lupus erythematosus are also at increased risk to develop anemia as a complication of their disease. Anemia related to chronic inflammatory conditions is termed anemia of chronic disease (ACD).

PATHOPHYSIOLOGY

Erythropoiesis

Erythropoiesis begins with a pluripotent stem cell in the bone marrow undergoing differentiation and ends with the appearance of RBCs in peripheral blood. The production of RBCs is stimulated by EPO, a hormone secreted by the kidney in response to detection of decreased oxygen-carrying capacity of blood. EPO stimulates RBC production by stimulating differentiation of RBC precursors in the bone marrow to become reticulocytes (Figure 66–1). Reticulocytes become erythrocytes after 1 to 2 days in the bloodstream.

Decreased-Production Anemias

Nutritional Deficiencies

Deficiencies in folic acid and vitamin B₁₂ may hinder the process of erythrocyte maturation. Folic acid and vitamin B₁₂ are required for the formation of DNA. Significant decreases in the amount of either nutrient inhibits DNA synthesis and consequently RBC production. Poor diet can contribute to folic acid and vitamin B₁₂ deficiencies. Pernicious anemia describes a severe anemia caused by the malabsorption of vitamin B₁₂ due to the absence of intrinsic factor, a glycoprotein produced by gastric parietal cells that binds to vitamin B₁₂ and facilitates its absorption in the ileum. This condition results in B₁₂ deficiency despite adequate dietary B₁₂ intake.

Iron is also essential for RBC production. It is required for formation of Hgb. Lack of iron leads to a decrease in Hgb synthesis and decreased RBC production. Normal homeostasis of iron transport and metabolism is depicted in Figure 66–2.

### Dysregulation of Iron Homeostasis and Impaired Marrow Production

Chronic diseases associated with ACD include infection, autoimmune disease, CKD, and cancer. A major contributing factor for development of ACD is disturbance of iron homeostasis related to activation of the immune system. Hepcidin is an acute-phase protein expressed in response to upregulation of interleukin-6 and exposure to lipopolysaccharide. Increased expression of hepcidin causes decreased iron absorption from the gastrointestinal (GI) tract and inhibition of iron release from macrophages. In addition, immune activation can cause upregulation of cytokines that impair the proliferation and differentiation of erythroid precursors. Decreased production and blunted responsiveness to EPO can also contribute to ACD; this is best documented in patients with CKD. Finally, disruption of erythropoiesis secondary to infiltration of the bone marrow by cancer can lead to anemia.

### Desired Outcomes

The goal of anemia therapy is to increase Hgb to levels that improve red cell oxygen-carrying capacity, alleviate symptoms, and prevent complications from anemia. Normal Hgb values are 14.0 to 17.5 g/dL (140–175 g/L or 8.69–10.9 mmol/L) for males and 12.3 to 15.3 g/dL (123–153 g/L or 7.63–9.50 mmol/L) for females. It is important to note that continuation of therapy should be assessed primarily by resolution of clinical symptoms. Patients who experience a resolution in their symptoms (eg, shortness of breath, tachycardia, fatigue, dizziness,) may not require aggressive therapy to maintain their Hgb values within normal limits. Hypoxia and cardiovascular sequelae due to anemia can be avoided if Hgb levels are greater than 7.0 g/dL (70 g/L or 4.34 mmol/L).

### General Approach to the Anemic Patient

The underlying cause of anemia must be determined and used to guide therapy. A complete blood count (CBC) is the laboratory evaluation that provides objective characteristics of RBCs useful in determining etiology and appropriate treatment.
Clinical Presentation and Diagnosis of Anemia

**Signs and Symptoms**
Generally, the signs and symptoms of anemia are nonspecific and may include the following:
- Fatigue, lethargy, dizziness
- Shortness of breath
- Headache
- Edema
- Tachycardia

Other findings that may be present in some patients include:
- Dry skin, chapped lips
- Nail brittleness
- Hunger for ice, starch, or clay (termed pica)

**Past Medical History**
Inquire about the following conditions:
- History of blood loss, such as hemorrhoids, melena, or menorrhagia (IDA)
- Malnourished or recent weight loss (vitamin B₁₂ or folate deficiency)
- Alcoholism (folate deficiency)
- Cancer or chronic kidney disease (CKD)
- Chronic autoimmune disorders or infections, such as HIV infection or rheumatoid arthritis (anemia of chronic disease)

**Physical Examination**
These findings aid the clinician in determining the severity of the anemia:
- Orthostatic hypotension and tachycardia secondary to volume depletion
- Cutaneous changes such as pallor, jaundice, and nail brittleness

**Laboratory Evaluation**
Table 66–2 describes common tests used to determine the etiology of anemia. A diagnostic and treatment algorithm for anemia is outlined in Figure 66–3.

1. A CBC is a necessary first step in evaluating a patient with anemia. If the Hgb and Hct are less than the normal range, the patient is anemic. Subsequent evaluations of RBC indices and the peripheral smear are often necessary to determine the etiology (and ultimately, the treatment) of the anemia.
2. Evaluating the mean corpuscular volume (MCV) is the next step in an anemia workup. It is classified as microcytic, normocytic, or macrocytic if the MCV is below, within, or above the normal range of 80 to 96 fl/cell, respectively.

**Microcytic Anemia and Iron Evaluation**
Iron studies (see Table 66–2) should be evaluated in the setting of a low MCV. These include:
- Serum iron
- Serum ferritin—the best indirect determinant of body iron stores. It is commonly decreased in patients with IDA
- Total iron-binding capacity (TIBC)—quantifies the iron-binding capacity of transferrin and is increased in IDA
- Transferrin saturation (serum iron/TIBC)—indicates the amount of transferrin that is bound with iron; it is lower in IDA

**Macrocytic Anemia**
- Evaluate folic acid and vitamin B₁₂ levels in the setting of an elevated MCV
- Further investigation by administering radiolabeled B₁₂ (i.e., Schilling test) to determine if lack of intrinsic factor

**Normocytic Anemia**
- Evaluate reticulocytes and CBC
- High reticulocyte counts may indicate RBCs loss via acute blood loss, hemolysis, or splenic sequestration
- Low serum iron with normal to increased ferritin consistent with ACD

**Patient Encounter 1, Part 1**
A 27-year-old African American woman scheduled a prenatal visit after a positive home pregnancy test. Previous pregnancies and deliveries were uncomplicated; she has healthy children ages 1.5 and 3 years. No other significant past medical history. Earlier this week she states feeling dizzy and short of breath after walking up stairs.

**What aspects of this patient’s history suggest she may be anemic?**
**What laboratory assessments are required to make an appropriate diagnosis and therapeutic plan?**
**How would the requested laboratory parameter(s) aid your decision making?**

The mean corpuscular volume and determination of iron, ferritin, folate, and vitamin B₁₂ levels are required to correctly diagnose a patient’s anemia. Figure 66–3 and Table 66–2 illustrate how laboratory test results determine the correct diagnosis.

**Nonpharmacologic Therapy**
The primary nonpharmacologic treatment of anemia is transfusion of RBCs. Safety concerns, cost, and the limited availability of this therapy support efforts to establish the “optimum” threshold for administering RBC transfusions. A Cochrane review concluded it is appropriate to use “restrictive transfusion triggers in patients free of serious cardiac disease.” The authors concluded a reasonable “trigger for transfusion” for patients without significant cardiovascular disease is 7.0 g/dL (70 g/L or 4.34 mmol/L).

The Transfusion Requirements In Critical Care trial reported no significant differences in in-hospital mortality between patients
randomly assigned to maintain Hgb levels of 7.0 to 9.0 g/dL (70–90 g/L or 4.34–5.59 mmol/L) and 10.0 to 12.0 g/dL (100–120 g/L or 6.21–7.45 mmol/L). Typically, only patients with acute symptoms (ie, dyspnea, chest pain) and Hgb concentrations in the range of 7.0 to 9.0 g/dL (70–90 g/L or 4.34–5.59 mmol/L) require blood transfusions.

Anemia can be attributed to diets poor in iron, folic acid, or vitamin B₁₂. However, in the United States, nutrient-poor diets rarely cause anemia. Therefore, ingesting a diet that is rich in iron, folic acid, or vitamin B₁₂ should be encouraged, but is rarely the sole modality of treatment. Food sources of iron, folic acid, and vitamin B₁₂ are listed in Table 66–3.

**Pharmacologic Therapy**

**Iron-Deficiency Anemia**

The initial treatment of IDA is oral iron therapy that provides 150 to 200 mg of elemental iron daily. Many different iron products and salt forms are available. Table 66–4 lists commonly prescribed oral iron products and the amount of elemental iron provided by each.

Iron supplementation resolves anemia by replenishing iron stores to levels necessary for RBC production and maturation. Reticulocytosis should occur in 7 to 10 days, and Hgb values should rise by about 1.0 g/dL (10 g/L or 0.62 mmol/L) per week. Patients should be reassessed if Hgb does not increase by 2.0 g/dL (20 g/L or 1.24 mmol/L) in 3 weeks. The preferred regimen for oral iron is 50 to 65 mg of elemental iron two to three doses daily on an empty stomach. Administration on an empty stomach (1 hour before or 2 hours after a meal) is preferred for maximal absorption. If patients develop intolerable GI side effects (ie, heartburn, nausea, bloating) after taking iron on an empty stomach, they should be advised to take it with meals. After absorption, iron binds to transferrin in the plasma and is transported to the muscles (for myoglobin), liver...

**FIGURE 66–3.** The anemia evaluation process. ACD, anemia of chronic disease; MCV, mean corpuscular volume; Pb, lead; TIBC, total iron-binding capacity. A2, hemoglobin A2 type; F, hemoglobin F type.
for storage), or bone marrow (for red cell production). Common toxicities associated with oral iron include abdominal pain, nausea, heartburn, constipation, and dark stools. Potentially clinically significant drug interactions involving iron products include fluoroquinolones, tetracyclines, eltrombopag, and mycophenolate mofetil. Iron decreases the absorption of these drugs. The absorption of iron is influenced by gastric acidity. Limited data support drugs that decrease gastric acidity (antacids, proton pump inhibitors, and H₂-receptor antagonists) may impair the absorption of iron. If concurrent administration cannot be avoided, to minimize this effect oral iron should be administered at least several hours before or after the affected drug.

Parenteral iron therapy is indicated when patients cannot tolerate oral formulations, are noncompliant, or fail to respond to oral iron because of malabsorption syndromes. Six parenteral iron formulations are available in the United States. Parental iron is extremely low, the absolute rate of life-threatening events is substantially higher for HMW ID. 

Table 66–5 provides details pertinent to the use of these products. The dose of iron dextran is calculated by the following equation: dose (mL) = 0.0442 (desired Hgb – observed Hgb) × body weight + (0.26 × body weight). The body weight that should be used is lean body weight for adults and children weighing more than 15 kg and actual body weight for children weighing 5 to 15 kg. Hemoglobin should be expressed units of g/dL (hemoglobin expressed in g/L × 0.10, or mmol/L × 1.61). The dose in milligrams can be calculated based on a standard concentration of 50 mg of elemental iron per milliliter. Prescribing information recommends administering iron dextran in 100-mg aliquots daily until the total dose is achieved. However, anecdotal evidence reports that the total calculated dose can be administered safely over 4 to 6 hours in 1 day. Because of the risk of anaphylaxis, a test dose of iron dextran (0.5 mL over at least 30 seconds) must be administered to patients before their first dose of iron dextran. Patients should be monitored for signs of anaphylaxis.

**Patient Encounter 1, Part 2**

Laboratory parameters are ordered, and the following is reported:

**CBC**
- WBC: 6.50 \( \times \) 10³/μL (6.50 \( \times \) 10⁹/L)
- Hgb: 8.3 g/dL (83 g/L; 5.15 mmol/L)
- Hct: 24.8% (0.248)
- Plt: 210 \( \times \) 10³/μL (210 \( \times \) 10⁹/L)

**Red Blood Cell Indices**
- MCV: 103.4 μm³ (103.4 fl)
- MCH: 28.4 pg/cell
- MCHC: 35.3 g/dL (353 g/L; 21.9 mmol/L)

**Others**
- RBC count: 3.6 \( \times \) 10³/μL (3.6 \( \times \) 10¹²/L)
- RDW: 22% (0.22)

**Iron Studies**
- Serum iron: 100 mcg/dL (17.9 μmol/L)
- Serum ferritin: 123 ng/L (123 mcg/L; 276 pmol/L)
- TIBC: 300 mcg/dL (53.7 μmol/L)
- Transferrin saturation: 36% (0.36)

**B₁₂ and Folate**
- Serum folate: 2.3 ng/mL (5.2 nmol/L)
- Serum B₁₂: 496 pg/mL (366 pmol/L)

Is this a macrocytic or microcytic anemia?
Specifically, what is the etiology of the anemia?
Recommend the most appropriate drug regimen (drug, dosage form, and schedule).
for at least 1 hour before administering the total dose. Other adverse effects include arthralgias, arrhythmias, hypotension, flushing, and pruritus.20

> **Vitamin B\textsubscript{12} and Folic Acid Anemia**

**KEY CONCEPT** Anemia from vitamin B\textsubscript{12} or folic acid deficiency is treated by replacing the missing nutrient. Both folic acid and vitamin B\textsubscript{12} are essential for erythrocyte production and maturation.

Oral and parenteral vitamin B\textsubscript{12} (cyanocobalamin) replacement therapies are equally effective. Vitamin B\textsubscript{12} is absorbed completely following parenteral administration, whereas oral vitamin B\textsubscript{12} is absorbed poorly via the GI tract. Consequently, cyanocobalamin is commonly administered as an intramuscular or subcutaneous injection of 1000 mcg/day for 1 week, followed by 1000 mcg/week for a month or until the Hgb normalizes. Life-long maintenance therapy (1000 mcg/month) is required for patients with pernicious anemia or surgical resection of the terminal ileum. If the etiology was a dietary deficiency or reversible malabsorption syndrome, treatment can be discontinued after the underlying cause is corrected and vitamin B\textsubscript{12} stores normalized. A common oral dosing regimen is from 1000 to 2000 mcg/day. If parenteral cyanocobalamin is used initially, oral vitamin B\textsubscript{12} can be useful as maintenance therapy. Typically, resolution of neurologic symptoms, disappearance of megaloblastic RBCs, and increased Hgb levels occur within a week of therapy.

Vitamin B\textsubscript{12} is well tolerated. Reported adverse effects include injection-site pain, pruritus, and rash. Clinical significance of decreases in protein-bound cyanocobalamin related to proton pump inhibitor therapy has not been established.23

> The effective dose of folic acid is 1 mg/day by mouth. Absorption of folic acid is rapid and complete. However, patients with malabsorption syndromes may require doses up to 5 mg/day. Resolution of symptoms and reticulocytosis occurs within days of commencing therapy. Typically a patient’s Hgb will start to rise after 2 weeks of therapy and normalize after 2 to 4 months of therapy.

Folic acid is well tolerated. Nonspecific adverse effects include allergic reactions, flushing, and rash. A small study evaluating the effect of folic acid doses of 10 mg/day on phenytoin levels reported decreased phenytoin levels in 3 of 4 subjects. However, the occurrence of this interaction at folic acid doses of 1 mg/day has not been reported.23

> **Anemia of Chronic Disease**

**KEY CONCEPT** Decreased RBC transfusion requirements is an outcome achieved in patients with ACD treated with the erythropoietin stimulating agent (ESAs). However, in 2007, the FDA product labeling for epoetin and darbepoetin were revised to include new data documenting safety concerns. Subsequently, the Centers for Medicare and Medicaid Services (CMS) implemented more restrictive ESA coverage determination guidelines. In 2010, the FDA implemented a risk evaluation and mitigation strategy (REMS) for ESAs administered to treat patients with cancer who are undergoing chemotherapy. Table 66–6 summarizes the FDA-labeled dosing regimens for patients whose anemia is related to cancer chemotherapy, CKD, or zidovudine treatment.

**Anemia Due to Chemotherapy in Patients with Cancer**

Epoetin, a recombinant human EPO, and darbepoetin, a synthetic EPO analog, bind to the EPO receptors on RBC precursor cells in the bone marrow and result in increased RBC production. Darbepoetin differs from epoetin in that it is a glycosylated protein and exhibits a longer half-life, allowing for a longer dosing interval. Clinical practice guidelines consider epoetin and darbepoetin to be therapeutic equivalents.24-26 **KEY CONCEPT** ESAs should only be used to prevent a transfusion and should not be initiated unless the hemoglobin is less than 10.0 g/dL (100 g/L, 6.21 mmol/L) and chemotherapy is planned for a minimum of two additional months. ESA-labeled dosing regimens for treatment of patients receiving chemotherapy are summarized in Table 66–6.

Postmarketing outcome data documented that patients administered ESAs experienced increased thrombotic events and

shorter progression-free and overall survival. ESAs increased on study mortality (combined hazard ratio [cHR] 1.17; 95% confidence interval [CI] 1.06–1.30) and worsened overall survival (cHR 1.06; 95% CI 1.00–1.12). This corresponds to a 17% increased risk of mortality for patients treated with ESAs while on study and a 6% increase overall. Based on these data, the FDA revised ESA product labeling, restricting their administration to patients with chemotherapy-induced anemia without a curative intent. The 2010 update of the American Society of Clinical Oncology/American Society of Hematology clinical practice guideline on the use of ESAs in patients with cancer adopted FDA recommendations for more restrictive use of ESA in patients with cancer.

CMS published more restrictive coverage criteria for ESA treatment of anemia associated with cancer chemotherapy in 2008. Patients should be monitored every 4 weeks. If Hgb has not increased by 1.0 g/dL (10 g/L; 0.62 mmol/L) after 4 weeks and remains less than 10.0 g/dL (100 g/L; 6.21 mmol/L), a one-time dose escalation of 25% is appropriate. If Hgb increases by more than 1.0 g/dL (10 g/L; 0.62 mmol/L), or is more than 10.0 g/dL (100 g/L, 6.21 mmol/L), the ESA should be discontinued. At 8 weeks if Hgb has increased by 1 g/dL (10 g/L; 0.62 mmol/L) but remains less than 10.0 g/dL(100 g/L, 6.21 mmol/L), continued ESA administration is covered. However, if after 8 weeks Hgb fails to increase by 1 g/dL (10 g/L, 0.62 mmol/L), CMS payment of therapy is not covered. CMS covers ESA therapy for up to 8 weeks after completion of chemotherapy for patients achieving response.

“Functional” iron deficiency exists when total iron stores are normal or increased but disruption of iron homeostasis prevents utilization of the stored iron for erythropoiesis.

“Functional” iron deficiency has been described in patients with ACD. Therefore, it is imperative that patients starting ESA therapy have laboratory studies performed to assess iron stores. If results document a patient has suboptimal iron stores, iron replacement therapy is indicated.

**Anemia Due to CKD** Anemia is common in patients with CKD. Early treatment of anemia in patients with CKD on dialysis has been associated with slower disease progression and lower risk of death. It is essential to evaluate and treat anemia in patients before they progress to stage 5 CKD (glomerular filtration rate [GFR] of less than 15 mL/min/1.73 m² [0.14 mL/s/m²]).

Patients with CKD typically develop normocytic, normochromic anemia as a result of EPO deficiency. However, a thorough workup of anemia should be performed to rule out other etiologies. Regardless, ESA therapy is effective in treating CKD anemia. The National Kidney Foundation Clinical Practice Recommendations 2007 update recommend a Hgb target range of 11.0 to 12.0 g/dL (110–120 g/L or 6.83–7.45 mmol/L) in dialysis and nondialysis patients. However, in June 2011, the FDA notified health care providers that the target Hgb range in patients with CKD was lowered to 11.0 g/dL (110 g/L or 6.83 mmol/L) in patients on hemodialysis and to 10.0 g/dL (100 g/dL or 6.21 mmol/L) in CKD patients not on hemodialysis. This revision was adopted to decrease the risk of serious adverse

---

**Patient Encounter 2, Part 1**

A 55-year-old woman presents to her primary care physician complaining of lack of energy that has gotten more noticeable the last month. She reports she has been unable to keep up her marathon training because of this. She is a vegetarian for the past 30 years. She is a dental hygienist and works part time. Her physical exam was notable for pallor. Past medical history is negative.

What aspects of this patient’s history suggest she may be anemic?

What laboratory assessments are required to make an appropriate diagnosis and therapeutic plan?

---

**Patient Encounter 2, Part 2**

Laboratory results:

**CBC**
- WBC: 7.7 × 10³/mm³ (7.7 × 10³/L)
- Hgb: 8.7 g/dL (87 g/L; 5.40 mmol/L)
- Hct: 30.8% (0.308)
- Plt: 210 × 10³/μL (210 × 10³/L)

**Red Blood Cell Indices**
- MCV: 71 μm³ 71 fl
- MCH: 23 pg/cell
- MCHC: 28.3 g/dL (283 g/L; 17.6 mmol/L)

**Iron Studies**
- Serum iron: 27 mcg/dL (4.8 μmol/L)
- Serum ferritin: 6.9 mg/mL (6.9 mcg/mL; 16 pmol/L)
- TIBC: 459 mcg/dL (82.2 μmol/L)
- Transferrin saturation: 11% (0.11)

**B₁₂ and Folate**
- Serum B₁₂: 707 pg/mL (522 pmol/L)
- Serum folate: 10 ng/mL (22.7 nmol/L)

Is this a macrocytic or microcytic anemia?

Specifically, what is the etiology of the anemia?

What would be the preferred drug regimen (drug, dosage form, and schedule)?

---

**Patient Encounter 2, Part 3**

The patient is diagnosed with iron-deficiency anemia and is started on ferrous sulfate 325 mg orally three times daily to be taken on an empty stomach. Follow-up CBC 1 month later reveals Hgb of 10.5 g/dL (105 g/L; 6.52 mmol/L), previously 8.3 g/dL (83 g/L; 5.15 mmol/L). The patient reports improvement in energy level and has resumed running. However, she often develops heartburn after taking the iron tablets.

What hemoglobin level would constitute a therapeutic response in this patient?

What recommendation would you make regarding the heartburn?
Patient Care Process

Patient Assessment:
- Based on physical exam and review of systems, determine if the patient exhibits signs or symptoms of anemia.
- Review CBC, if anemia present, assess RBC indices to determine if microcytic, normocytic, or macrocytic.
- Determine whether transfusion or pharmacotherapy is indicated.
- Assess iron, folic acid, and vitamin B12 studies to determine etiology of anemia.
- When initiating ESAs, assess the patient’s iron status.
- Initiate appropriate therapy.

Therapy Evaluation:
- Monitor symptoms such as fatigue, shortness of breath, lethargy, headache, edema, and tachycardia for resolution.
- Discuss importance of medication adherence.

Care Plan Development:
- Based on physical exam and review of systems, determine if the patient exhibits signs or symptoms of anemia.
- Review CBC, if anemia present, assess RBC indices to determine if microcytic, normocytic, or macrocytic.
- Determine whether transfusion or pharmacotherapy is indicated.
- Assess iron, folic acid, and vitamin B12 studies to determine etiology of anemia.
- When initiating ESAs, assess the patient’s iron status.
- Initiate appropriate therapy.

Follow-Up Evaluation:
- Follow up monthly to assess efficacy and tolerance of therapy until resolution of symptoms and Hgb goal achieved.
- Monitor the CBC monthly.
- Monitor side effects of therapy, such as:
  - Oral iron: nausea, vomiting, abdominal pain, heartburn, constipation, and dark stools
  - Parenteral iron: anaphylaxis (test dose required for iron dextran and observe for 1 hour after), injection-site pain/irritation, arthralgias, myalgias, flushing, malaise, and fever
  - Folic acid: bad taste and nausea, rash, and allergic reactions
  - Vitamin B12: pain and nausea at injection site
  - ESAs: hypertension (monitor blood pressure), thrombosis (eg, deep vein thrombosis/pulmonary embolism, myocardial infarction, cerebrovascular accident, and transient ischemic attack), arthralgias, and headache

Outcomes Evaluation

- Patients should be monitored for Hgb response, symptom resolution, and adverse effects at appropriate intervals, and treatment regimens adjusted accordingly. The goal of anemia therapy is to correct the underlying etiology of the anemia, normalize the Hgb, and alleviate associated symptoms.
- To ensure response for patients with IDA, monitor CBC with special attention to occurrence of reticulocytosis and iron studies.
- A 1.0-g/dL (10 g/L or 0.62 mmol/L) per week increase in Hgb is desirable in patients with IDA. Reevaluate patients with increases less than 2.0 g/dL (20 g/L or 1.24 mmol/L) in 3 weeks.
- For patients with folic acid deficiency, monitor Hgb periodically and reevaluate patients who fail to normalize Hgb levels after 2 months of therapy.

- For patients with vitamin B12 deficiency, monitor for resolution of neurologic symptoms (ie, confusion and paresthesias), if applicable, and Hgb levels weekly until the levels normalize.
- For patients treated with chemotherapy, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and monitor Hgb levels weekly. If Hgb increases exceed 1.0 g/dL (10 g/L or 0.62 mmol/L) or exceed 10.0 g/dL (100 g/L or 6.21 mmol/L), hold therapy until the level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions.
- For patients with CKD on dialysis, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and monitor Hgb levels weekly. If Hgb levels approach or exceed 11.0 g/dL (110 g/L or 6.83 mmol/L), reduce or hold further doses until the level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions.
- For patients with CKD not on dialysis, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and monitor Hgb levels weekly. If Hgb levels exceed 10.0 g/dL (100 g/L or 6.21 mmol/L), reduce or hold further doses until the level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions.

Abbreviations Introduced in This Chapter
- CFU-E: Erythroid colony-forming unit

- Hgb: Hemoglobin
REFERENCES

INTRODUCTION

Components of the Hemostatic System

Following endothelial injury, vessel-wall response involves vasoconstriction, platelet plug formation, coagulation, and fibrinolysis regulation. In normal circumstances, platelets circulate in the blood in an inactive form. After injury, platelets undergo activation, which consists of (a) adhesion to the subendothelium, (b) secretion of granules containing chemical mediators (eg, adenosine diphosphate, thromboxane A2, thrombin, etc), and (c) aggregation. Chemical factors released from the injured tissue and platelets stimulate the coagulation cascade and thrombin formation. In turn, thrombin catalyzes the conversion of fibrinogen to fibrin and its subsequent incorporation into the platelet plug.

The coagulation system consists of intrinsic and extrinsic pathways. Both pathways are composed of a series of enzymatic reactions that ultimately produce thrombin, fibrin, and a stable clot. In parallel with the coagulation, the fibrinolytic system is activated locally. Plasminogen is converted to plasmin, which dissolves the fibrin mesh (Figure 67–1).¹

INHERITED COAGULATION DISORDERS

HEMOPHILIA

Etiology and Epidemiology

Hemophilia A and B are coagulation disorders that result from defects in the genes encoding for plasma coagulation proteins. Hemophilia A (classic hemophilia) is caused by the deficiency of factor VIII, and hemophilia B (Christmas disease) is caused by the deficiency of factor IX. The incidences of hemophilia A and B are estimated at 1 in 5000 and 1 in 30,000 male births, respectively. Both types of hemophilia are evenly distributed across all ethnic and racial groups.¹

Pathophysiology

The pathophysiology of hemophilia is based on the deficiency of factor VIII or IX resulting in inadequate thrombin generation and an impaired intrinsic-pathway coagulation cascade (see Figure 67–1). Factor VIII and IX genes are located on the X chromosome. Hemophilias are recessive X-linked diseases. Generally, affected males carrying either defective allele on their X chromosome do not transmit the gene to their sons. However, their daughters are obligate carriers. More than 1000 mutations in factor VIII and IX genes have been identified to cause clinical hemophilia.²

Consequently, hemophilia is not a result of a single genetic mutation. However, inversion at intron 22 of the factor VIII gene accounts for 40% of severe hemophilia A cases. Owing to the high incidence, this mutation is used for carrier and prenatal testing.³

Complications of Hemophilia

The severity of bleeding associated with hemophilia correlates with the degree of factor VIII or factor IX deficiency as measured against the normal plasma standard. Table 67–1 summarizes the age at onset and laboratory and clinical manifestations of hemophilia A and B.⁴
Currently, there is no cure for hemophilia A or B. The life expectancy of hemophiliacs was only 8 to 11 years in the 1920s and 1930s. With the development of effective treatment strategies, life expectancy is currently about 63 to 75 years, or nearly that of the normal population. The short-term goals of hemophilia treatment are to:
- Decrease the number of bleeding episodes per year or bleeding frequency
- Normalize or improve clotting factor concentrate levels

The long-term goals of hemophilia treatment are to:
- Maintain clinical joint function
- Normalize orthopedic joint score
- Normalize radiologic joint score
- Maintain quality-of-life measurements

### General Approach to Treatment

**Intravenous factor replacement with recombinant or plasma-derived products to treat or prevent bleeding is the primary treatment of hemophilia.** Primary prophylaxis is defined as the regular administration of factor concentrates with the intention of preventing joint bleeds. The rationale for primary prophylaxis is that individuals with factor levels of greater than 0.02 IU/mL (20 IU/L) rarely suffer from spontaneous bleeds and arthropathy. Therefore, to maintain a trough level above this might convert “severe” hemophilia to “moderate” disease, with the abolition of joint bleeds and the associated arthropathy. Although primary prophylaxis is expensive, historical cohorts show progressively better outcomes (joint function and radiologic appearances) with its use. The Medical and Scientific Advisory Council of the National Hemophilia Foundation of the United States recommends primary prophylaxis in patients with...
Hemophilias A and B are clinically indistinguishable.

**Symptoms**
- Ecchymoses
- **Hemarthrosis**—bleeding into joint spaces\(^a\) (especially knee, elbow, and ankle)
- Joint pain, swelling, and erythema
- Cutaneous warmth
- Decreased range of motion
- Muscle hemorrhage
- Swelling
- Pain with motion of affected muscle
- Signs of nerve compression
- Potential life-threatening blood loss, especially with thigh bleeding
- Mouth bleeding with dental extractions or trauma
- Genitourinary bleeding
- Gastrointestinal (GI) bleeding
- Hematuria
- Intracranial hemorrhage (spontaneous or following trauma), with headache, vomiting, change in mental status, and focal neurologic signs
- Excessive bleeding with surgery

**Diagnostic Parameters/Laboratory testing**
- Family history
- Normal prothrombin time (PT)
- Normal platelet count
- Prolonged activated partial thromboplastin time (aPTT)
- Low factor VIII level (hemophilia A)
- Low factor IX level (hemophilia B)

\(^a\)Hallmark of hemophilia; recurrent inadequately managed hemarthrosis leads to deformity and chronic pain (hemophilic arthropathy).

**Nonpharmacologic Therapy**

**Supportive Care** Rest, ice, compression, elevation (RICE) can be used during the bleeding episode, following with casts, splints, and crutches after the bleeding has been controlled.

**Surgery** Surgical arthroscopic synovectomy reduces replacement therapy–resistant disease and repetitive hemarthrosis of a single joint. This procedure removes inflamed joint tissue. Patients may have decreased range of motion after the surgery.

**Orthotics** Joint prostheses do not deal with the deformities directly. Orthotics in hemophilia serve as an important supportive measure before or after surgery.

**Pharmacologic Therapy**

**Hemophilia A**

**DDAVP** Primary therapy is based on disease severity and type of hemorrhage.\(^10\) Most patients with mild to moderate disease and a minor bleeding episode can be treated with 1-desamino-8-D-arginine vasopressin (desmopressin acetate [DDAVP]), a synthetic analogue of the antiidiuretic hormone, vasopressin. DDAVP causes release of von Willebrand factor (vWF) and factor VIII from endothelial storage sites. DDAVP increases plasma factor VIII levels by threefold to fivefold within 30 minutes. The recommended dose is 0.3 mcg/kg IV (in 50 mL of normal saline infused over 15–30 minutes) or subcutaneously (in < 1.5 mL) or 150 to 300 mcg intranasally via concentrated nasal spray, may repeat after 24 hours.\(^10\) Peak effect with intranasal administration

---

**Patient Encounter 1, Part 1: Hemophilia**

A 2-month-old boy without any significant past medical history developed mild bleeding into the joint spaces of the knees and elbows. The baby is irritable and has warm swollen joints. Patient’s parents report family history significant for maternal grandfather with hemophilia.

**What additional information do you need to create a treatment plan for this patient?**

**What are this patient’s risk factors for hemophilia?**

**Patient Encounter 1, Part 2: Hemophilia**

**Meds:** None

**PE:**
- Swollen red joints of elbows and knees bilaterally. Wt 11.1 lb (5.04 kg)

**Labs:**
- Platelet count: 145 × 10\(^3\)/mm\(^3\) (145 × 10\(^9\)/L) (normal 140–440 × 10\(^3\)/mm\(^3\) [140–440 × 10\(^9\)/L])
- aPTT: 90 seconds (normal 25–40 seconds)
- INR: 1 (normal 0.8–1.2)
- Factor VIII: 5% (normal 50%–150%)
- Ristocetin cofactor activity (vWF:RCo): 150 IU/dL or 1500 IU/L (normal 50–200 IU/dL or 500–2000 IU/L)

**Given this additional information, is this patient’s presentation consistent with hemophilia? Which type of hemophilia does this patient have?**

**Identify your treatment goals for this patient.**
occurs 60 to 90 minutes after administration, which is somewhat later than with IV administration. Desmopressin infusion may be administered daily for up to 2 to 3 days. Facial flushing, hypertension or hypotension, GI upset, and headache are common side effects of desmopressin. Water retention and hyponatremia may occur; patients should be instructed to limit water intake while taking desmopressin. Serious side effects include seizures related to hyponatremia and myocardial infarction. Due to higher incidence of hyponatremia-related seizures in patients less than 2 years old, use of desmopressin is not recommended in this population. Tachyphylaxis, an attenuated response with repeated administration, may occur after several doses.\(^\text{11}\)

According to the manufacturer, use of DDAVP is contraindicated in patients with creatinine clearance less than 50 mL/min (0.83 mL/s); however, it has been used off label in patients with impaired renal function.

**Antifibrinolytic Therapy** Aminocaproic acid and tranexamic acid are antifibrinolytic agents that reduce plasminogen activity leading to inhibition of clot lysis and clot stabilization. These agents are usually used as adjuncts in dental procedures or in difficult-to-control epistaxis and menorrhagia episodes and have to be administered with appropriate factor concentrates to form a clot.\(^\text{30}\)

**Factor VIII Replacement** Patients with severe hemophilia may receive primary (before the first major bleed) or secondary (after the first major bleed) prophylaxis. All hemophiliacs with a major bleed require factor VIII replacement.\(^\text{12}\) The therapy may include recombinant (produced via transfection of mammalian cells with the human factor VIII gene) or plasma-derived (concentrate from pooled plasma) factor VIII (Table 67–2). The choice of product and dose are based on the overall clinical scenario because the efficacy of various preparations does not differ. Newer generation plasma-derived coagulation factor concentrates are considerably safer owing to advancements in viral testing and inactivation technology. Although original recombinant factor VIII concentrates were stabilized with human serum albumin, potentially creating a source for viral contamination, newer generation recombinant factor VIII concentrates are stabilized with sucrose, eliminating the concern for viral transmission.\(^\text{30}\)

The severity of hemorrhage and its location are major determinants of percentage correction to target, as well as duration of therapy (Table 67–3). The normal range of factor VIII activity level is 1 IU/mL (1000 IU/L), which corresponds to 100% of the factor found in 1 mL of normal plasma. Minor bleeding may be treated with a goal of 25% to 30% (0.25–0.30 IU/mL [250–300 IU/L]) of normal activity, whereas serious or life-threatening bleeding requires greater than 75% of normal activity. Factor VIII is a large molecule that remains in the intravascular space, and its estimated volume of distribution is approximately 50 mL/kg. Generally, factor VIII levels increase by 2% (0.02 IU/mL

APCC, activated prothrombin complex concentrate; PCC, prothrombin complex concentrate; vWF, von Willebrand factor.
Factor IX Replacement Hemophilia B therapy may include recombinant (produced via transfection of mammalian cells with the human factor IX gene) or plasma-derived (concentrate from pooled plasma) factor IX (see Table 67–2). Guidelines for choosing the factor-concentrate formulation for hemophilia B are similar to the guidelines for hemophilia A. However, older generation factor IX concentrates containing other vitamin K–dependent proteins (eg, factors II, VII, and IX), called prothrombin complex concentrates (PCCs), have been associated with thrombogenic side effects. Consequently, these products are not first-line treatment for hemophilia B. Because it is a small protein, the factor IX molecule passes into both the intravascular and the extravascular spaces. Therefore, the volume of distribution of recombinant factor IX is twice that of factor VIII. Consequently, 1 unit of factor IX administered per kilogram of body weight yields a 1% rise in the plasma factor IX level (0.01 IU/mL [10 IU/L]). To calculate the factor IX replacement dose, the following equation can be used:

Dose of factor IX (units) = weight (kg) × (desired percentage increase) × F

Where (F = 1 for human plasma-derived products; F = 1.1 for RixUBis; F = 1.4 for Benefix in adults and 1.2 in children).

Thus, to increase factor IX levels by 50% (eg, from 0% to 50%) in a 70-kg (154-lb) patient, the required dose of factor IX is 4900 units IV (using Benefix). The half-life of factor IX ranges from 16 to 17 hours; therefore, doses are given every 18 to 24 hours. Factor IX fusion protein can be given every 1 to 2 weeks.17

Gene therapy for the treatment of hemophilia is currently under investigation. A recent clinical trial has shown long-term therapeutic levels of factor IX in six subjects with severe hemophilia B receiving a single infusion of a factor IX transgene vector.18,19

### Treatment of Patients with Factor VIII or IX Inhibitors

Factor VIII and IX inhibitors are antibodies that develop in approximately 30% and 5% of hemophilia A and hemophilia B patients, respectively, in response to replacement therapy. There is no difference between plasma-derived and recombinant products in their potential for inhibitor development. These antibodies bind to and neutralize the activity of infused factor concentrates. Although the inhibitors do not increase hemorrhage frequency, their existence challenges the treatment of bleeding episodes. Titers of inhibitors are measured and reported in Bethesda units (BU), and this measurement is used to guide therapy (Figure 67–2). Management options for acute bleeding in patients with factor inhibitors include the administration of factor VIII concentrates, PCCs, recombinant factor VIIa (rFVIIa), and porcine factor VIII (currently, recombinant porcine factor VIII is in phase II/III clinical trials in the United States). Immune tolerance induction can be attempted to prevent future bleeding episodes.

Factor VIII concentrates can be used in patients with low inhibitor levels to control acute bleeding episodes. The dose of factor VIII is determined based on clinical response (see Figure 67–2).

PCCs contain the vitamin K–dependent factors II, VII, IX, and X. These agents bypass factor VIII at which the antibody is directed (see Figure 67–2). However, PCCs carry the risk of serious thrombotic complications.

Factor VIIa (rFVIIa) is a bypassing agent designed to generate thrombin only at tissue injury sites, where it binds tissue factor. Due to its local action, rFVIIa is associated with fewer systemic thrombotic events than PCC. rFVIIa is used effectively in surgeries and spontaneous bleeds.20

Plasma-derived porcine factor VIII participates in the coagulation cascade in place of human factor VIII. However, due to contamination with parvovirus, it is no longer available. Recombinant porcine factor VIII is currently under review and could serve as a third-line agent (only after factor VIIa and a PCC have failed) owing to the relatively high incidence of cross-reactivity with factor VIII inhibitors.
SECTION 14 | HEMATOLOGIC DISORDERS

1008

**Induction of immune tolerance** is often performed with the goal of eliminating the inhibitor. Immune tolerance induction is accomplished by the administration of repetitive doses of factor VIII or IX with or without immunosuppressive therapy. It is effective in 70% of patients with hemophilia A and 30% of patients with hemophilia B.

**Pain Associated with Hemophilia**

Pain commonly occurs in patients with hemophilia. Acute bleeding episodes and long-term joint destruction are common sources of pain. Acetaminophen and opioid analgesics are recommended to control mild to moderate and severe pain, respectively. Nonsteroidal anti-inflammatory drugs and aspirin should be avoided if possible, because these drugs bind to platelets and increase the risk of bleeding episodes. Cyclooxygenase-2 (COX-2) inhibitors can be used with caution.  

**Outcome Evaluation**

The main goal of hemophilia treatment is to prevent bleeding episodes and their long-term complications. Clinicians should evaluate patients for the following:

- Musculoskeletal status, including joint range of motion and radiologic assessment, as indicated.
- Number and type of bleeding episodes to assess adequacy of prophylactic treatment and home therapy.
- Use of clotting-factor concentrates to check for the development of inhibitors, especially in patients with severe disease and poor treatment responders.
- Vaccination against hepatitis A and B is recommended in all hemophiliacs without evidence of immunity.

**VON WILLEBRAND DISEASE**

**Epidemiology and Etiology**

von Willebrand disease (vWD) is the most common inherited bleeding disorder caused by a deficiency or dysfunction of vWF. It is classified based on the quantitative deficiency of vWF or qualitative abnormalities of vWF. The disease prevalence is estimated at 30 to 100 cases per million. In contrast to hemophilia, the majority of vWD cases are inherited as an autosomal dominant disorder, ensuing equal frequency in males and females.

**Pathophysiology**

vWF is a large multimeric glycoprotein with two main functions in hemostasis: to aid platelet adhesion to injured blood vessel walls and to carry and stabilize factor VIII in plasma. Table 67–4 represents three main vWD phenotypes, their frequency, and genetic transmission.

**Treatment**

**Desired Outcomes**

Unlike hemophilia, the bleeding tendency in vWD is less frequent and generally less severe. Consequently, chronic prophylaxis is usually unwarranted. The goal of two mainstay therapeutic options in vWD is:

- To stop spontaneous bleeding as necessary
- To prevent surgical and postpartum bleeding
Nonpharmacologic Therapy
Local measures, including pressure and ice, may be used to control superficial bleeding.

Pharmacologic Therapy
Systemic therapy is used to prevent bleeding associated with surgery, childbirth, and dental extractions and to treat bleeding that cannot be controlled with local measures. The two systemic approaches involve using desmopressin, which stimulates the release of endogenous vWF, or administering products that contain vWF. The general approach to the treatment of vWD is depicted in Figure 67–3. In 2008, The National Heart, Lung, and Blood Institute issued comprehensive evidence-based guidelines for the diagnosis and management of vWD.24

DDAVP Most patients with type 1 vWD (functionally normal vWF) and a minor bleeding episode can be treated successfully with desmopressin, which induces release of factor VIII and vWF from endothelial cells through interaction with vasopressin V2 receptors. The recommended dose is the same as that used to treat mild factor VIII deficiency (0.3 mcg/kg IV in 50 mL of normal saline infused over 15 to 30 min or 150 to 300 mcg intranasally via concentrated nasal spray, may repeat after 24 hours). This therapy is generally ineffective in type 2A patients, who secrete abnormal vWF. It is recommended in type 2B patients who respond to it. It may increase the risk of postinfusion thrombocytopenia, in which case a concomitant platelet infusion is administered. Type 3 vWD patients who lack releasable stores of vWF do not respond to DDAVP therapy.25

The individual responsiveness to desmopressin is consistent, and a test dose administered at the time of diagnosis or prior to therapy is the best predictor of response. Generally, DDAVP is more effective in vWD than in hemophilia patients, with an average twofold to fivefold increase in vWF and factor VIII levels over baseline. In patients with an adequate response, desmopressin is first-line therapy because it allows for once-daily administration (elevates plasma levels for 8 to 10 hours), does not pose a threat in terms of viral transmission, and costs substantially less than the plasma-derived products.

Antifibrinolytic Therapy
Fibrinolysis inhibitors and oral contraceptives are used successfully in the management of epistaxis and menorrhagia or as adjuvant treatments.26 Fibrinolysis inhibitors include aminocaproic acid (25–60 mg/kg orally or IV (or 4–5 g) every 4 to 6 hours, to a maximum dose of 24 g/day) and tranexamic acid (10 mg/kg IV every 8 hours). Oral tranexamic

Clinical Presentation and Diagnosis of vWD
Clinical manifestations vary depending on the subtype. Patients with mild disease may be asymptomatic into adulthood.

Symptoms
- Bruising
- Mucocutaneous bleeding
- Epistaxis
- Oral cavity bleeding
- Menorrhagia
- GI bleeding
- Joint and deep tissue bleeding
- Postoperative bleeding

Laboratory Testing
- Low or normal von Willebrand factor antigen concentration in plasma (vWF:Ag)
- Low or normal factor VIII coagulation assay (FVIII:C)4
- Low ristocetin cofactor activity (vWF:RCo)5

4Factor VIII coagulation assay measures the ability of vWF to bind and maintain adequate levels of factor VIII.
5Ristocetin cofactor activity (vWF:RCo) assay measures the ability of vWF to interact with intact platelets (normal 50–200 IU/dL [500–2000 IU/L]).

| Table 67–4 Classification of vWD |
|---|---|
| Phenotype | Mechanism of Disease | Percentage of Cases | Genetic Transmission |
| Type 1 vWD | Partial (mild to moderate) quantitative deficiency of vWF and factor VIII | 70–80 | Autosomal dominant |
| Type 2 vWD | Qualitative abnormalities of vWF | 10–30 | Autosomal dominant |
| 2A | Decreased platelet-dependent vWF function owing to lack of larger multimers | 10–20 | Autosomal dominant (or recessive) |
| 2B | Decreased vWF function due to increased affinity to platelet GP 1b and resultant sequestration or loss | 5 | Autosomal dominant |
| 2M | Defective platelet-dependent vWF functions not associated with multimer defects | Uncommon | Autosomal dominant (or recessive) |
| 2N | Defective vWF binding to factor VIII | Uncommon | Autosomal recessive |
| Type 3 vWD | Severe quantitative deficiency of vWF | Rare | Autosomal recessive |

Clinical manifestations vary depending on the subtype. Patients with mild disease may be asymptomatic into adulthood.

Symptoms
- Bruising
- Mucocutaneous bleeding
- Epistaxis
- Oral cavity bleeding
- Menorrhagia
- GI bleeding
- Joint and deep tissue bleeding
- Postoperative bleeding

Laboratory Testing
- Low or normal von Willebrand factor antigen concentration in plasma (vWF:Ag)
- Low or normal factor VIII coagulation assay (FVIII:C)4
- Low ristocetin cofactor activity (vWF:RCo)5

4Factor VIII coagulation assay measures the ability of vWF to bind and maintain adequate levels of factor VIII.
5Ristocetin cofactor activity (vWF:RCo) assay measures the ability of vWF to interact with intact platelets (normal 50–200 IU/dL [500–2000 IU/L]).
Acid recently received FDA approval for the treatment of cyclic heavy menstrual bleeding; its use is currently not approved for vWD patients. The IV form of tranexamic acid given as swish and swallow or spit every 6 to 8 hours has been used as bleeding prophylaxis in dental surgery. Both aminocaproic acid and tranexamic acid are dose adjusted for patients with renal insufficiency.

Replacement Therapy Key Concept: Type 1 patients unresponsive to desmopressin, patients with types 2 and 3 vWD, and major surgery patients require replacement therapy with plasma-derived, intermediate- and high-purity virus-inactivated factor VIII concentrates containing vWF.

Table 67–5 provides typical dosing guidelines and target levels of replacement therapy–concentrates to control various types of hemorrhage. Ultra-high-purity (monoclonal) plasma-derived and recombinant factor VIII concentrates do not contain vWF and should not be used in the treatment of vWD.

aPTT, activated partial thromboplastin time; PT, prothrombin time.

Outcome Evaluation

The main goal of vWF treatment is to prevent bleeding with surgery or dental procedures. Clinicians should evaluate patients every 6 to 12 months for the following:

- Number and type of bleeding episodes to assess the need for prophylactic treatment.
- Ensure adequate levels of vWF and factor VIII prior to minor and major surgical procedures and for the treatment of bleeding.
- Vaccination against hepatitis A and B is recommended in all patients with vWF deficiency with no evidence of immunity.

OTHER CLOTTING FACTOR DEFICIENCIES

Etiology and Epidemiology

Recessively inherited coagulation disorders (RICDs) refer to relatively rare deficiencies in factor II, V, VII, and X to XIII resulting in either decreased clotting factor production or production of a dysfunctional molecule with reduced activity. The clinical severity of bleeding varies and generally is poorly correlated with the factor blood levels. Table 67–6 illustrates these clotting factor deficiencies and some of their characteristics.

Pathophysiology

The RICDs are rare genetic disorders. Mutations in the genes responsible for the respective clotting factors result in impaired functionality or production of the factor.

Treatment

Desired Outcomes

Therapeutic options for RICDs improve hemostasis via replacement of deficient blood coagulation factors while minimizing the development of immune tolerance. Hemostatic levels should be maintained for the following conditions:

- Spontaneous bleeding—until bleeding stops
- Minor surgery—for 2 to 3 days
- Major surgery—until incision site has healed

Nonpharmacologic Therapy

Transfusional Therapies

The primary treatment of RICDs is single-donor fresh-frozen plasma (FFP) that contains all coagulation factors. Disadvantages of FFP treatment include the risk of the patient becoming volume overloaded, especially when repeated infusions are administered to improve and maintain hemostasis; risk of infections; and risk of inhibitor development. PCCs licensed for the treatment of hemophilia B also contain significant levels of vitamin K–dependent factors and may be used off label for treatment of RICD. Table 67–7 lists the recommended RICD treatment schedules in different clinical scenarios.

Pharmacologic Therapy

Less severe hemorrhages may be treated successfully with antifibrinolytic amino acids alone or in combination with factor replacement therapy. Tranexamic acid and aminocaproic acid may be administered IV or orally (for doses, see von Willebrand Disease, Pharmacologic Therapy mentioned earlier).

Numbers indicate lines of therapy. FFP, fresh-frozen plasma; PCC, prothrombin complex concentrates.
platelet production. Several congenital and iatrogenic disorders may result in low platelet count; among them, drug-induced thrombocytopenia, infection-induced thrombocytopenia, disseminated intravascular coagulation, congenital thrombocytopenia, and idiopathic immune thrombocytopenia. Two types of thrombocytopenic disorders and their treatments are discussed below.

IMMUNE THROMBOCYTOPENIC PURPURA

Etiology and Epidemiology
Immune (or idiopathic) thrombocytopenic purpura (ITP) is one of the most common causes of acquired thrombocytopenia. The estimated incidence is 1.9 to 6.4 cases per 100,000 persons in children and 3.3 cases per 100,000 in adults.29 ITP is an autoimmune disorder caused by the binding of antibodies (usually immunoglobulin G [IgG]) to platelet surface antigens, resulting in shortened platelet life span. ITP can occur as an isolated condition or secondary to an underlying disorder. Childhood-onset and adult-onset ITP present very differently. Adult-onset ITP is generally chronic (> 6 months) and affects women two to three times more often than men. By contrast, childhood-onset ITP is acute in onset and usually follows an infectious illness, and both sexes are equally affected. Childhood ITP typically resolves on its own within 4 to 6 weeks without major sequelae. In adults presenting with ITP, testing for human immunodeficiency virus (HIV) and hepatitis C virus (HCV) is recommended, because treating these infections may improve ITP course. ITP occurs in 1 to 2 of every 1000 pregnancies. In pregnant women with pre-existing ITP, both maternal and fetal complications may occur, requiring separate management.

Pathophysiology
In ITP, IgG autoantibodies bind to platelet-antigen complex and are cleared from the blood via binding to mononuclear phagocytes by macrophage Fcγ receptor, leading to thrombocytopenia. Platelet survival time is significantly shorter in patients with ITP (from minutes to 2–3 days compared with normal 7–10 days). Sequestration in spleen, liver, and bone marrow is partially responsible for decreased platelet survival. Megakaryopoiesis may be reduced due to antibody binding to megakaryocyte precursors in the bone marrow.

PLATELET DISORDERS
Platelets, in combination with several other factors such as blood vessel wall and coagulation factors, play key role in hemostasis. Normal platelet count is 150–450 × 10^3/mm^3 (150–450 × 10^9/L). Thrombopoietin, a hormone synthesized in the liver, regulates platelet production. Several congenital and iatrogenic disorders may result in low platelet count; among them, drug-induced thrombocytopenia, infection-induced thrombocytopenia, disseminated intravascular coagulation, congenital thrombocytopenia, and idiopathic immune thrombocytopenia. Two types of thrombocytopenic disorders and their treatments are discussed below.

IMMUNE THROMBOCYTOPENIC PURPURA

Etiology and Epidemiology
Immune (or idiopathic) thrombocytopenic purpura (ITP) is one of the most common causes of acquired thrombocytopenia. The estimated incidence is 1.9 to 6.4 cases per 100,000 persons in children and 3.3 cases per 100,000 in adults.29 ITP is an autoimmune disorder caused by the binding of antibodies (usually immunoglobulin G [IgG]) to platelet surface antigens, resulting in shortened platelet life span. ITP can occur as an isolated condition or secondary to an underlying disorder. Childhood-onset and adult-onset ITP present very differently. Adult-onset ITP is generally chronic (> 6 months) and affects women two to three times more often than men. By contrast, childhood-onset ITP is acute in onset and usually follows an infectious illness, and both sexes are equally affected. Childhood ITP typically resolves on its own within 4 to 6 weeks without major sequelae. In adults presenting with ITP, testing for human immunodeficiency virus (HIV) and hepatitis C virus (HCV) is recommended, because treating these infections may improve ITP course. ITP occurs in 1 to 2 of every 1000 pregnancies. In pregnant women with pre-existing ITP, both maternal and fetal complications may occur, requiring separate management.

Pathophysiology
In ITP, IgG autoantibodies bind to platelet-antigen complex and are cleared from the blood via binding to mononuclear phagocytes by macrophage Fcγ receptor, leading to thrombocytopenia. Platelet survival time is significantly shorter in patients with ITP (from minutes to 2–3 days compared with normal 7–10 days). Sequestration in spleen, liver, and bone marrow is partially responsible for decreased platelet survival. Megakaryopoiesis may be reduced due to antibody binding to megakaryocyte precursors in the bone marrow.

Clinical Presentation and Diagnosis of ITP

General
The typical patient is well with the exception of bleeding.

Symptoms
- Petechiae
- Purpura, wet purpura
- Ecchymoses
- Cutaneous bleeding
- Mucosal site bleeding
- Epistaxis
- Gingival bleeding
- Hematuria

Menorrhagia
Intracranial hemorrhage (rare)

Diagnostic Criteria
- Platelet count less than 100 × 10^3/mm^3 (100 × 10^9/L)
- Otherwise normal complete blood count with differential
- Normal reticulocyte count
- Normal peripheral blood smear (no hemolysis or blast cells)
- History and physical exam ruling out other possible causes of thrombocytopenia30

Other Laboratory Testing
Laboratory testing to rule out other causes of thrombocytopenia, such as HCV, HIV, SLE, Evan syndrome, and others
Patient Encounter 2, Part 1: ITP

A 30-year-old woman with past medical history significant for mild intermittent asthma. Presents with complaints of significant mucosal bleeding from her mouth that was slow to respond to placing ice cubes and swishing cold water. A laboratory analysis reveals platelet count of \(8 \times 10^9/\text{mm}^3\) (8 \(\times\) 10^9/L). Her medications at home include albuterol MDI one to two inhalations every 4 hours as needed; she has no known drug allergies.

What information is suggestive of immune thrombocytopenic purpura (ITP)?
What additional information do you need to create a treatment plan for this patient?

Treatment

**Desired Outcomes**

In children, the main goal of ITP treatment is to maintain the platelet count associated with sufficient hemostasis, while awaiting spontaneous or treatment-induced remission. In adults, the main goal is to maintain platelet count greater than \(30 \times 10^9/\text{mm}^3\) (30 \(\times\) 10^9/L), because below this count, the incidence of bleeding in increased.

**General Approach to Treatment**

The treatment of ITP is determined by the symptom severity. In some cases, no therapy is needed (Table 67–8). The initial treatment of children with ITP is controversial because greater than 75% to 80% of cases resolve spontaneously irrespective of pharmacologic intervention. Therapy should be given to children with severe hemorrhage. Therapy may be considered in children meeting one of the following criteria: platelet counts less than \(10 \times 10^9/\text{mm}^3\) (10 \(\times\) 10^9/L) and mucocutaneous bleeding; platelet counts less than \(30 \times 10^9/\text{mm}^3\) (30 \(\times\) 10^9/L) and moderate systemic or mucosal bleeding; or factors that may increase the risk of bleeding (such as participation in active contact sports increasing risk of head injury). In adults, treatment is indicated when platelet counts are less than \(30 \times 10^9/\text{mm}^3\) (30 \(\times\) 10^9/L).

**Nonpharmacologic Therapy**

- **Splenectomy** In adults, splenectomy is generally considered after 3 to 6 months if the patient continues to require 10 to 20 mg/day of prednisone to maintain the platelet count greater than \(30 \times 10^9/\text{mm}^3\) (30 \(\times\) 10^9/L). Splenectomy may also be considered for urgent treatment of neurologic symptoms or for managing relapse despite an adequate trial of corticosteroids, IV immunoglobulin (IVIg), or anti-Rh(D). Even though individual patient response cannot be predicted, approximately two-thirds of refractory adult patients have a favorable response to splenectomy within several days; however, 30% to 40% will have no response or will experience a relapse sometime after splenectomy.

- In children, splenectomy is usually reserved due to the limited nature of ITP and fear of infectious complications of splenectomy. Splenectomy is recommended in children with ITP duration greater than 1 year with significant bleeding symptoms and unresponsive or intolerant of pharmacological therapies. Between 70% and 80% of children attain complete remission following splenectomy. Laparoscopic splenectomy is preferable to open splenectomy because it speeds the recovery and shortens the duration of hospitalization. The major drawback of splenectomy is bacterial sepsis, occurring at incidence rates of approximately 1%. Immunization with *Haemophilus influenzae* type b, pneumococcal, and meningococcal vaccines is indicated in all patients 2 weeks prior to splenectomy.

- **Platelet Transfusions** Platelet transfusions are indicated if a patient has severe life-threatening bleeding, such as intracranial hemorrhage. In such situations, platelet transfusions are administered along with IV Immunoglobulin and glucocorticoids (see below).

Patient Encounter 2, Part 2: ITP

**PE:**

Wt 75 kg; vital signs within normal limits. Petechial rash present on lower extremities; bleeding mucous surfaces noted within oral cavity.

**Labs:**

- Platelet count: \(8 \times 10^9/\text{mm}^3\) (8 \(\times\) 10^9/L) (normal 140–440 \(\times\) 10^9/mm³ [140–440 \(\times\) 10^9/L])
- aPTT: 35 seconds (normal 25–40 seconds)
- PT: 11 seconds (normal 10–12 seconds)
- Hemoglobin 13 g/dL (130 g/L or 8.07 mmol/L) (normal 13.8–17.2 g/dL or 138–172 g/L or 8.57–10.68 mmol/L)
- HCV antibody negative
- HIV negative

Given this additional information, is this patient’s presentation consistent with ITP?

Identify your treatment goals for this patient.
Pharmacologic Therapy

The general approach to management of ITP in adults is summarized in Table 67–8.

Glucocorticoids Glucocorticoids may decrease splenic sequestration of antibody-coated platelets, diminish antibody generation by the spleen and the bone marrow, and increase platelet output by the bone marrow. In adults, the response rate to oral prednisone (1 mg/kg/day) is 50% to 75%, with patients usually responding within the first 1 to 2 weeks. The duration of therapy depends on the platelet count response; guidelines advocate longer course of prednisone therapy (21 days), followed by a taper. High-dose dexamethasone (40 mg orally or intravenously daily) administered for 4 to 8 days in 14- to 28-day cycles has also been used successfully. In children, oral or parenteral corticosteroids (prednisone, dexamethasone, methylprednisolone) can be used; various dosage regimens have been studied with no specific drug or dosage regimen showing superiority.31

IV Immunoglobulin (IVIg) IVIg impairs the clearance of platelets coated with IgG by activating inhibitory receptor FcRyIIb. Roughly 80% of adults will respond to IVIg, but remission usually is not sustained. In adults, use of IVIg (1 g/kg/day given as a single dose, repeated if necessary) is reserved for situations in which rapid increase in platelet count is necessary, such as life-threatening bleeding and very low platelet count, or for patients who have contraindications to glucocorticoids. If treatment is indicated in children, a single dose of IVIg (0.8–1 g/kg) is usually effective. IVIg use is complicated by many serious adverse effects and high cost.

Anti-Rh(D) Anti-Rh(D) can be used only in Rh(D)-positive patients who have not had splenectomy. It is as efficacious as IVIg and is generally less expensive. The indications for use of anti-Rh(D) are identical to those for IVIg. Anti-Rh(D) is a desirable form of treatment in chronic ITP when the goal is to circumvent long-term exposure to corticosteroids. At doses of 50 to 75 mcg/kg/day, anti-Rh(D) may increase the platelet count in about 70% to 80% of children with ITP. Dosage adjustment is recommended based on hemoglobin levels. Response to anti-Rh(D) lasts about 3 to 5 weeks, and substantial numbers of patients treated repetitively with anti-Rh(D) can postpone or avoid splenectomy. Rare fatal intravascular hemolysis has been reported with use of anti-Rh(D); special monitoring for this side effect is recommended.

Immunosuppressants Immunosuppressant therapy is generally utilized for patients who are refractory to or intolerant of all other ITP treatments. Rituximab, an anti-CD20 antibody, at a dose of 375 mg/m² once weekly for four doses, can induce long-term response in 21% to 27% of patients.32 Progressive multifocal leukoencephalopathy has been rarely reported with rituximab use. Rituximab can be considered as a second- or third-line therapy in patients who have experienced treatment failure with corticosteroids, IVIg, or splenectomy. Azathioprine and cyclophosphamide produce response rates of 20% to 40% in adult patients who are treated for 2 to 6 months. Other medications used in ITP include vincristine, vinblastine, cyclosporine, danazol, and mycophenolate mofetil; due to major toxicities and lack of adequate evidence-based recommendations, their use is reserved for refractory ITP.

Thrombopoietic Growth Factors Additional treatment options for ITP include a thrombopoiesis-stimulating protein and a small-molecule thrombopoietin (TPO) receptor agonist. These agents stimulate the bone marrow to make enough platelets to overcome the body’s premature destruction of platelets. Romiplostim and eltrombopag are two TPO mimetics that have been approved by the FDA for the treatment of thrombocytopenia in patients with chronic ITP who have had an insufficient response to corticosteroids, immunoglobulins, or splenectomy. Currently, these agents are not FDA approved for use in children; several clinical trials are underway to establish role of these agents in managing childhood ITP.

Romiplostim is a TPO peptide mimetic that binds to and activates the human TPO receptor. As a once weekly subcutaneous injection, romiplostim stimulates megakaryopoiesis, resulting in enhanced platelet production. Initial dose of romiplostim is based on the actual body weight, adjusted weekly by increments of 1 mcg/kg subcutaneously until a maximum of 10 mcg/kg and the patient achieves a platelet count greater than or equal to 50 × 10⁹/mm³ (50 × 10⁹/L) as necessary to reduce the risk for bleeding. Eltrombopag is a once-daily oral nonpeptide thrombopoietin receptor agonist with a low immunogenic potential that stimulates megakaryocyte proliferation and differentiation.

For most patients, the initial dose of eltrombopag is 50 mg once daily. The daily dose is subsequently adjusted to a maximum dose of 75 mg daily in order to achieve and maintain a platelet count greater than or equal to 50 × 10⁹/mm³ (50 × 10⁹/L) in order to reduce the risk for bleeding. Both agents need to be discontinued if platelet counts do not increase after 4 weeks at a maximum dose.

Romiplostim and eltrombopag are effective in increasing platelet counts in patients with ITP and can be used in combination with therapies that inhibit platelet destruction. Although usually well tolerated, a number of rare but serious risks have been reported, including changes in the bone marrow, worsened thrombocytopenia and the risk of bleeding after cessation of the medication, thrombotic/thromboembolic complications (including portal vein thrombosis with eltrombopag), and worsening of blood cancers. Eltrombopag carries a “black box warning” regarding hepatic decompensation in patients with hepatitis C treated with interferon and ribavirin. It is also associated with development of cataracts and has drug–drug interactions with antacids and several minerals (calcium, iron, aluminum, magnesium, selenium, zinc).

Use of TPO-mimetic agents is reserved for refractory ITP due to cost considerations, lack of durability of response after discontinuation, and limited knowledge of long-term side effects.

Outcome Evaluation

- Monitor platelet counts as indicated clinically.
- In adults, the goal of therapy is to maintain platelet count greater than or equal to 30 × 10⁹/mm³ (30 × 10⁹/L).
- Monitor for signs and symptoms of bleeding.

Patient Encounter 2, Part 3: ITP: Creating a Care Plan

Based on the information presented, create a care plan for this patient. Please include whether pharmacologic therapy is indicated, and if so, please list first-line and alternative therapies.
Patient Care Process ITP

**Patient Assessment:**
- Conduct physical examination evaluating sites of bleeding. Obtain a complete medical and medication history.
- Evaluate CBC, peripheral blood smear, order tests to rule out other diseases commonly associated with thrombocytopenia.

**Therapy Evaluation and Care Plan Development:**
- If patient meets clinical criteria for diagnosis of ITP and is a candidate for treatment, evaluation of platelet count, occupational risks of bleeding, and actual bleeding severity dictates initial treatment approach.
- First-line treatment for patients meeting criteria for pharmacotherapy is corticosteroids for up to 21 days. Anti-D or IVIg can be considered if corticosteroids are contraindicated or rapid rise in platelet count is necessary. Alternatives to first-line agents include immunosuppressants and TPO mimetics, which are reserved for patients failing to respond after adequate trial of first-line agents. Surgical splenectomy is reserved for refractory ITP.

**Follow-Up Evaluation:**
- In adults, monitor regularly to ensure platelet counts stay above $30 \times 10^{12}/\text{mm}^3$ ($30 \times 10^9/\text{L}$).
- Patients should be instructed to contact their primary health care provider at new signs of bleeding.

---

**Clinical Presentation and Diagnosis of TTP**

**Typical Pentad of Symptoms (Rare That All Five Are Present)**

1. Thrombocytopenia
   - Thrombocytopenic purpura
   - Bleeding
2. Fever
3. Microangiopathic hemolytic anemia
4. Neurologic symptoms
   - Headache, confusion, difficulty speaking, transient paralysis, numbness
5. Renal abnormalities
   - Proteinuria, hematuria, mild renal insufficiency

**Laboratory Testing**
- Decreased hemoglobin, hematocrit, and platelets
- Peripheral blood smear showing schistocytes
- Decreased serum haptoglobin
- Elevated lactate dehydrogenase (LDH)
- Elevated indirect bilirubin level
- Elevated reticulocyte count
- Normal PT and aPTT
- Elevated urine protein, red blood cells, and/or serum creatinine

---

**THROMBOTIC THROMBOCYTOPENIC PURPURA**

**Etiology and Epidemiology**

Thrombotic thrombocytopenic purpura (TTP) is a severe systemic disorder characterized by thrombi formation within the circulation that results in the platelet consumption and subsequent thrombocytopenia. Acute idiopathic TTP is more common in women and African Americans and most frequently occurs in people between 30 and 40 years of age. The estimated annual incidence of TTP is 4.5 cases per million. Common conditions associated with TTP are summarized in Table 67–9.

**Pathophysiology**

Endothelial cells normally synthesize vWF in the form of a high-molecular-weight multimer composed of smaller identical monomers. Each monomer is able to bind platelets, and the number of monomers on the vWF multimer is directly proportional to its platelet-binding capacity. Consequently, particularly adherent ultra-large molecules of the vWF (ULvWF) are broken down to smaller size by vWF-cleaving proteases such as ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 repeats) to avoid undesired clot formation. TTP results from genetic or acquired deficiency in the vWF-cleaving protease ADAMTS13 activity. This, in turn, elevates circulating levels of ULvWF, leading to inappropriate platelet agglutination. Thrombocytopenia develops because the rate of aggregated platelet consumption is faster than megakaryocyte bone marrow production. Microangiopathic hemolytic anemia generally follows as a consequence of red blood cell damage by platelet clumps occluding the microcirculation. Occlusive ischemia of the brain or GI tract is common, and renal dysfunction may occur.

---

*TTP diagnosis can be based on the presence of thrombocytopenia and microangiopathic hemolytic anemia in the absence of other possible causes.

In patients suspected to have TTP, the differential diagnosis includes disseminated intravascular coagulation (DIC) and hemolytic uremic syndrome (HUS). Both TTP and HUS can present with thrombotic microangiopathic anemia; however, HUS is usually linked to a diarrheal illness and acute renal failure. Some sources advocate for TTP-HUS spectrum as a single disease since clinical presentation is essentially identical.
Table 67–9
Conditions Associated with TTP
- Infections
- Bacterial, fungal, viral, atypical
- Transplantation
- Solid organ or bone marrow
- Malignancy
- Pregnancy
- Collagen vascular diseases
- Medications
- Antineoplastic agents, ticlopidine, clopidogrel, antibiotics, immunosuppressants, others

Patient Encounter 3, Part 2: TTP
PE/ROS:
Wt 55 kg, T 100.8°F (38.2°C), patient appears lethargic and has difficulty concentrating

Labs:
- Platelet count: 9 × 10^3/mm^3 (9 × 10^9/L) (normal 140–440 × 10^9/L)
- aPTT: 35 seconds (normal 25–40 seconds)
- PT: 11 seconds (normal 10–12 seconds)
- Haptoglobin 10 mg/dL (100 mg/L) (normal 30–200 mg/dL or 300–2000 mg/L)
- LDH 1900 U/L (31.7 μkat/L) (normal 100–250 U/L, or 1.67–4.17 μkat/L)
- Hemoglobin 9 g/dL (90 g/L; 5.59 mmol/L) (normal 12.1–15.1 g/dL or 121–151 g/L or 7.51–9.37 mmol/L)
- Blood peripheral smear: numerous schistocytes (10–15 per high power field)
- Serum creatinine 1.8 mg/dL (159 μmol/L) (increased from 0.8 mg/dL [71 μmol/L] on record from last year’s physical exam) (normal 0.6–1.2 mg/dL [53–106 μmol/L])

Given this additional information, is this patient’s presentation consistent with TTP?
What is the likely etiology of this patient’s TTP?
Identify your treatment goals for this patient.

Treatment

Desired Outcomes
The main goal of TTP treatment is to prevent end-organ damage.

Nonpharmacologic Therapy

The present standard of treatment for TTP is urgent plasma exchange (PEX). If PEX is unavailable, treatment with plasma infusion and glucocorticoids is indicated until PEX is available.

Plasma Exchange
The procedure involves removal of the patient’s plasma and its substitution with donor plasma. In this manner, circulating antibody inhibitor of ADAMTS13 is removed and enzyme is replenished. PEX involves placement of two IV lines (cannulae) into two separate veins. Blood removed through one cannula is centrifuged to separate the blood cells from the plasma. The blood cells are mixed subsequently with donor plasma and returned to the patient via the second cannula. The goal is to exchange 1 to 1.5 plasma volumes (40–60 mL/kg). The procedure generally is repeated daily until neurologic symptoms resolve and normal lactate dehydrogenase (LDH) and platelet counts are maintained for several days. After complete remission is achieved, PEX frequency can be reduced to every other day for an additional few days, with subsequent PEX discontinuation and close patient follow-up. When PEX is started immediately upon diagnosis, remission and survival rates at 6 months are approximately 80%. Although generally considered safe, complications from catheter insertion or catheter infection may occur and include hemorrhage, pneumothorax, sepsis, and thrombosis. Allergic reactions to plasma can cause severe hypotension and hypoxia.

Splenectomy
Splenectomy is reserved for patients with frequently relapsing disease who are refractory to PEX or immunosuppressive therapy.

Pharmacologic Therapy

Glucocorticoids
Glucocorticoids can be used for their immunosuppressive effect in combination with PEX; however, they are not as efficacious as monotherapy in TTP. The most commonly used agents are methylprednisolone 250 mg/day IV for or prednisone 1 mg/kg/day orally for the duration of PEX therapy and 1 to 2 weeks after normalized platelet counts are maintained.

Immunosuppressants
TTP that fails to respond adequately to PEX can be treated with immunosuppressive agents. Cytotoxic immunosuppressive therapies with the most potential benefit in refractory TTP include cyclosporine and rituximab. Other agents that had been used include vincristine, cyclophosphamide, azathioprine, and IV Ig.

Patient Encounter 3, Part 1: TTP
A 35-year-old African American woman presented to her primary care physician complaining of headache, weakness, fever, chills, nausea, vomiting, and vaginal bleeding. She was recently diagnosed with genital herpes and prescribed valacyclovir 1 g twice daily for 10 days, which she’s been taking for 9 days now. Otherwise, she suffers from seasonal allergies for which she takes loratadine 10 mg by mouth daily. She is allergic to ibuprofen (rash).

What information is suggestive of TTP?
What additional information do you need to create a treatment plan for this patient?

Patient Encounter 3, Part 3: TTP
Creating a Care Plan
Based on the information presented, create a care plan for this patient’s TTP.
CHAPTER 67 | COAGULATION AND PLATELET DISORDERS

**Patient Care Process TTP**

**Patient Assessment:**
- Obtain a complete medical and medication history.
- Evaluate CBC, vital signs, neurologic symptoms, chemistry 7 panel, and urinalysis for presence of thrombocytopenia, fever, anemia, and renal abnormalities. Evaluate neurologic symptoms.

**Therapy Evaluation and Care Plan Development:**
- If patient meets clinical criteria for diagnosis of TTP, start daily PEX. If ADAMTS13 deficiency is suspected, start glucocorticoids.

**Follow-up Evaluation:**
- When platelet counts stay above 150 × 10^9/L (150 × 10^9/mm^3) for 2 days, PEX may be discontinued; glucocorticoids may be continued for an additional 1 to 2 weeks.
- Follow patients indefinitely with periodic CBC/LDH measurements to screen for possible relapse of TTP.

**Outcome Evaluation**
Monitor platelet counts, hemoglobin, and LDH.

**Abbreviations Introduced in This Chapter**

- ADAMTS13: A disintegrin and metalloprotease with thrombospondin type 1 repeats (vWF-cleaving metalloprotease)
- BU: Bethesda units
- DDAVP: 1-Desamino-8-D-arginine vasopressin (desmopressin acetate)
- DIC: Disseminated intravascular coagulation
- FFP: Fresh-frozen plasma
- HCV: Hepatitis C virus
- ICH: Intracranial hemorrhage
- ITP: Immune thrombocytopenic purpura
- IVlg: IV immunoglobulin
- PCC: Prothrombin complex concentrate
- PEX: Plasma exchange
- rFVIIa: Recombinant factor VIIa
- RICD: Recessively inherited coagulation disorder
- TTP: Thrombotic thrombocytopenic purpura
- ULvWF: Ultra-large molecules of vWF
- vWD: von Willebrand disease
- vWF: von Willebrand factor

**REFERENCES**

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of sickle cell disease (SCD) and their relationship to patient signs and symptoms.
2. Identify the typical characteristics of SCD as well as symptoms that indicate complicated disease.
3. Identify the desired therapeutic outcomes for patients with SCD.
4. Recommend appropriate pharmacotherapy and nonpharmacotherapy interventions for patients with SCD.
5. Recognize when chronic maintenance therapy is indicated for a patient with SCD.
6. Describe the components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for SCD.
7. Educate patients about the disease state, appropriate therapy, and drug therapy required for effective treatment and prevention of complications.

INTRODUCTION

“Sickle cell syndrome” refers to a collection of autosomal recessive genetic disorders that are characterized by the presence of at least one sickle hemoglobin gene (HbS).1,2

Sickle cell disease (SCD) is a chronic illness that is associated with frequent crisis episodes. Acute complications are unpredictable and potentially fatal. Common symptoms include excruciating musculoskeletal pain, life-threatening pneumonia-like illness, cerebrovascular accidents, and splenic and renal dysfunction.2 As the disease progresses, patients may develop organ damage from the combination of hemolysis and infarction. Because of the complexity and severity of SCD, it is imperative that patients have access to comprehensive care with providers who have a good understanding of the countless clinical presentations and the management options of this disorder.

EPIDEMIOLOGY AND ETIOLOGY

Sickle cell trait (SCT) is the heterozygous form (HbAS) of SCD in which a person inherits one normal adult hemoglobin (HbA) gene and one sickle hemoglobin (HbS) gene. These individuals are carriers of the SCT and are usually asymptomatic.2 Symptomatic disease is seen in homozygous and compound heterozygous genotypes of SCD. Sickle cell anemia (SCA) is the homozygous (HbSS) state of SCD.2 It is the most common and severe form of SCD. SCD affects both males and females equally because it is not a sex-linked disease.

SCD is the HbSS state of SCD in which individuals inherit the mutant hemoglobin gene (HbS) from both parents. The progeny of two carriers will have a 25% probability of having SCD and a 50% risk of being a carrier. β-Thalassemia can be found in conjunction with HbS. Patients with HbSS and HbSβ°-thalassemia do not have normal β-globulin production and usually have a more severe course than those with HbSC and HbSβ+-thalassemia.
Impaired circulation, destruction of RBCs, and vascular stasis are three known problems that are primarily responsible for the clinical manifestations of SCD (Figure 68–1).

### PATHOPHYSIOLOGY

**KEY CONCEPT** *SCD involves multiple organ systems, and its clinical manifestations vary greatly between and among genotypes.*

**Sickle Hemoglobin Polymerization**

The primary event in the molecular pathogenesis of SCD involves polymerization of deoxygenated HbS. HbS carries oxygen normally, and when oxygenated, the solubility of HbS and HbA are the same. Once the oxygen is unloaded to the tissues, HbS solubility decreases. This promotes hydrophobic interactions between the hemoglobin molecules and polymerization, which leads to the distortion of the RBC into the characteristic crescent or sickle shape.

**Viscosity of Erythrocytes and Sickle Cell Adhesion**

When HbS becomes reoxygenated, the polymers within the RBCs disappear, and the cells eventually return to normal shape. Vasocclusion is caused by a combination of factors. Repeated assaults on RBCs from sickling and unsickling can lead to cell membrane damage, loss of membrane flexibility, and rearrangement of surface phospholipids. The life span of sickled RBCs is markedly shorter (10–20 days) than that of normal RBCs (100–120 days). As intracellular membrane viscosity of HbS-containing RBCs increases, blood viscosity increases, which further contributes to vasooclusion. There is also increasing evidence that suggest sickle cells adhere to vascular endothelium. The combined effects of decreased RBC deformability, slow transit through microcirculation, and adhesion to vascular endothelium contribute to obstruction of small and sometimes large blood vessels. The resulting local tissue hypoxia can accentuate the pathologic process of SCD.

**Protective Hemoglobin Types**

Fetal hemoglobin (HbF) binds oxygen more tightly than HbA, and it has a decreased propensity to sickling. HbA2 also possesses this characteristic but to a lesser extent. RBCs that contain HbF sickle less readily than cells without. HbF is composed of two α chains and two β chains; therefore, it is not affected by point mutations on β chains. Irreversibly sickled cells (ISCs) are found to have low HbF concentrations. In some patients, higher HbF may ameliorate the disease.

**Other Pathophysiologic Effects**

Other factors may be responsible for the pathogenesis of some of the clinical features of SCD. Sickle cells can obstruct blood flow to the spleen leading to functional asplenia. Impaired splenic function can increase the propensity to infection by encapsulated organisms, particularly *Streptococcus pneumoniae*. Additionally,
Identified by neonatal screening before 2 months of age

Chronic hemolytic anemia is common

Health Maintenance

Maintain or increase the hemoglobin level to the patient’s baseline

Low HgF and increased reticulocytes, platelets, and white blood cells (WBCs)

Presence of sickled cells on blood smear

Neonatal screening: hemoglobin electrophoresis, isoelectric focusing, or DNA analysis

Signs

• Chronic hemolytic anemia is common
• Enlargement of spleen and heart
• Scleral icterus

Laboratory Tests

• Hgb 7.0 to 10.0 g/dL (70–100 g/L or 4.34–6.21 mmol/L)
• Low HgF and increased reticulocytes, platelets, and white blood cells (WBCs)
• Presence of sickled cells on blood smear
• Neonatal screening: hemoglobin electrophoresis, isoelectric focusing, or DNA analysis

Painful vasoocclusive crises are the hallmark of SCD

Dactylitis (hand–foot syndrome) before age 1 year

Priapism in males

Scleral icterus

Hgb 7.0 to 10.0 g/dL (70–100 g/L or 4.34–6.21 mmol/L)

Neonatal screening: hemoglobin electrophoresis, isoelectric focusing, or DNA analysis

Prevent infectious complications

May develop infarction of the spleen, liver, bone marrow, kidney, brain, and lungs

Prevent or effectively manage pain

Gallstones

Weakness, fatigue

Painful vasoocclusive crises are the hallmark of SCD

Decrease the HbS concentration

Laboratory Tests

General Approach to Treatment

Patients should be educated to recognize the signs and symptoms of complications that would require urgent evaluation. Patients and parents of children with SCD should be educated to seek immediate medical care when a fever develops or signs of infection occur. With acute illnesses, prompt evaluation is important, as deterioration may occur rapidly. Fluid status should be monitored to avoid dehydration or overhydration, both of which may worsen complications of SCD. Patients in acute distress should maintain oxygen saturation at 92% (0.92) or at their baseline. Any supplemental oxygen requirements should be evaluated.4

Nonpharmacologic Therapy

Patients should avoid smoking and excessive alcohol intake. Patients with SCD should maintain adequate hydration in order to help decrease blood viscosity and should be educated to avoid extreme temperature changes and to dress properly in hot and cold weather. Physical exertion that leads to complications should be avoided.4 Regular exams, including ophthalmic, dental, renal, pulmonary, and cardiac function, are required to monitor for organ damage. A treatment overview is shown in Table 68–1.

Pharmacologic Therapy

Health Maintenance

Immunizations

Children with SCD should receive the required immunizations as recommended by the American Academy of Pediatrics and the Advisory Committee on Immunization Practices.7 Additionally, influenza vaccine should be administered yearly to SCD patients 6 months of age and older, including adult patients. All adult patients with SCD should also receive the vaccine for meningococcal disease as well as a one-time dose of Haemophilus influenzae type b vaccine. The quadrivalent meningococcal vaccine should be administered in two doses at least 2 months apart.6

Because patients with SCD have impaired splenic function, they are less adequately protected against encapsulated organisms such as S. pneumoniae, H. influenzae, and Salmonella. KEY CONCEPT

The use of pneumococcal vaccine in SCD patients has dramatically decreased the rates of morbidity and mortality; however, there are still groups of SCD children who continue to have high rates of invasive pneumococcal infections.9–11 Infection is the leading cause of death in children with SCD younger than 3 years of age.11,12 Two pneumococcal vaccines are available. The 13-valent conjugate vaccine (PCV 13: Prevnar) is routinely administered to infants and children and provides good protection against the 13 most common isolates seen in this age range. Administer the first dose of PCV 13 between 6 weeks and 6 months of age, followed by two additional doses at 2-month intervals and a fourth dose at 12 to 15 months of age. The 23-valent polysaccharide vaccine (PPSV 23: Pneumovax 23) is indicated for children older than 2 years and adults. Because PPSV 23 is a polysaccharide vaccine, children younger than 2 years do not respond well. PPV 23 contains the 23 most common isolates of S. pneumoniae seen in older children and adults. Because of the different serotypes seen in the two vaccines, it is recommended that SCD children receive both vaccines, with a dose of PPSV 23 administered after the child turns 2 years of age. The dose of PPSV 23 should be separated from the last dose of PCV 13 by at least 2 months. An additional dose of PPSV 23 should be given to children 3 to 5 years of age to ensure antibody response. This second dose should be administered 5 years after the first PPSV 23 dose. All adults with
| Table 68–1 |
| Management of SCD |

### Options and Comments

**Health maintenance**
- **Infection prophylaxis**
  - Pneumococcal vaccines (PCV 13 and PPV 23)
  - Penicillin prophylaxis for children younger than 5 years of age
  - Annual influenza vaccine

**Induction of fetal hemoglobin**
- Hydroxyurea is the primary agent
- Other agents are butyrates (arginine butyrate and sodium phenylbutyrate), decitabine, clotrimazole, and erythropoietin
- Combination HbF inducers have been proposed

**Chronic transfusion therapy**
- Primary indication: stroke prevention in pediatric patients
- May also reduce pain crisis and acute chest syndrome
- Goal: maintain HbS less than 30% (0.30)

### Future prospects
- **Transplantation**
  - May potentially cure the disease
  - Most experience is with HLA-matched donors; umbilical cord blood transplantation is being evaluated

### Crises and complications
- **Fever and infection**
  - Broad-spectrum antibiotic: cefotaxime or ceftriaxone (clindamycin for cephalosporin allergy); vancomycin for staphylococcal and resistant pneumococcal organisms
  - Fluids
  - Acetaminophen or ibuprofen for fever
  - Exchange transfusion

- **Stroke**
  - Fluids
  - Acetaminophen or ibuprofen for fever
  - Exchange transfusion

- **Acute chest syndrome**
  - Broad-spectrum antibiotics (include Mycoplasma coverage)
  - Bronchodilator if wheezing or history of reactive airway disease
  - Fluids
  - Pain management
  - Transfusion

- **Pain crisis**
  - Hydration
  - Analgesics

---

SCD should be vaccinated with both PCV 13 as well as PPSV 23. Adults and children who have not previously received PCV13 or PPSV 23 should receive one dose of PCV 13 followed by a single dose of PPSV 23 at a minimum of 8 weeks later. If an adult or child with SCD has already received at least one dose of PPSV 23, they should additionally receive on dose of PCV 13 at least 1 year after the dose of PPSV 23. When both vaccines are indicated in an unvaccinated patient with SCD, PCV 13 should be administered first, followed by a dose of PPSV 23 at least 8 weeks later. A one-time revaccination with PPSV 23 should occur 5 years after the first dose of PPSV 23. Because some children fall behind on their childhood vaccinations, a catch-up schedule is presented in Table 68–2.

**Penicillin**

Children with SCD should receive prophylactic penicillin until at least the age of 5 years, even if they have been appropriately immunized with PCV 13 against pneumococcal infections. Penicillin V potassium is typically initiated at age 2 months, with a dose of 125 mg orally twice daily until age 3 years, then 250 mg orally twice daily until 5 years of age. The intramuscular use of benzathine penicillin 600,000 units every 4 weeks from age 6 months to 6 years is also an option for nonadherent patients. Penicillin-allergic patients may receive erythromycin 10 mg/kg twice daily. Penicillin prophylaxis usually is not continued in children older than 6 years, but may be considered in patients with a history of invasive pneumococcal infection or surgical splenectomy.

**Folic Acid**

Folic acid supplementation with 1 mg daily is generally recommended in adult SCD patients, women considering pregnancy, and any SCD patient with chronic hemolysis. Because of accelerated erythropoiesis, these patients have an increased need for folic acid. There are conflicting studies in the SCD population, especially among infants and children, but if the child has chronic hemolysis, supplementation is recommended.

**Fetal Hemoglobin Inducers**

Fetal hemoglobin (HbF) induction in patients with SCD, especially those with frequent crises, has been shown to decrease RBC sickling and RBC adhesion. A direct relationship between HbF concentrations and the severity of disease has been demonstrated in studies.

**Hydroxyurea**

Hydroxyurea is a ribonucleotide reductase inhibitor that prevents DNA synthesis and traditionally has been used as the primary agent for fetal hemoglobin induction.

### Patient Encounter 1

A 6-year-old girl with SCD is currently taking penicillin V potassium 250 mg orally twice daily, folic acid 0.4 mg orally daily, and acetaminophen/codeine 120/12 mg per 5 mL orally every 6 hours as needed for pain. She fully completed all her routine childhood vaccinations and is up to date. She has not been hospitalized since age 2 when she had an aplastic crisis.

**What are the general prophylaxis recommendations for children with SCD?**

**What interventions do you want to make today to her medication/immunization regimens?**

**Design an infection prevention plan for this patient.**
Hydroxyurea is teratogenic in high doses in pregnant women and should be avoided in lactating mothers.

---

Hydroxyurea should be considered in SCD with frequent vasoocclusive crises, severe symptomatic anemia, repeated history of ACS, or other history of severe vasoocclusive crisis (VOC) complications. The prevention of organ damage or reversal of previous damage has not been shown to occur with chronic use of hydroxyurea. The goals of therapy with hydroxyurea are to decrease the acute complications of SCD, improve quality of life, and reduce the number and severity of pain crises.

Hydroxyurea is available in 200-, 300-, 400-, and 500-mg capsules. Extemporaneous liquid preparations can be prepared for children who cannot swallow capsules. Doses should start at 10 to 15 mg/kg daily in a single oral dose, which can be increased after 8 to 12 weeks if blood counts are stable and there are no side effects. Individualize the dosage based on the patient’s response and the toxicity seen. With close monitoring, doses can be increased 5 mg/kg/day up to 35 mg/kg daily. In patients with renal failure, dosing of hydroxyurea will need to be adjusted according to the creatinine clearance, as shown in Table 68–3.

Closely monitor patients for efficacy and toxicity while they are receiving hydroxyurea. Monitor mean corpuscular volume (MCV), since it typically increases as the level of HbF increases. If the MCV does not increase with hydroxyurea use, the marrow may be unable to respond, the dose may not be adequate, or the patient may be nonadherent. However, lack of increase in MCV or in HbF is not an indication to discontinue therapy; the clinical response to therapy may take 3 to 6 months. A 6-month trial on the maximum tolerated dose is required prior to consideration of discontinuation due to treatment failure, whether secondary to lack of adherence or failure to respond to therapy. HbF levels can also be monitored to assess response with a goal of increasing HbF to 15% to 20% (0.15–0.20). Assess blood counts every 2 weeks during dose titration and then every 4 to 6 weeks once the dose is stabilized. Temporary discontinuation of therapy is

Data from Refs. 21–26.

warranted if hemoglobin level is less than 4.5 g/dL (45 g/L or 2.79 mmol/L), absolute neutrophil count is less than $2 \times 10^9$/mm$^3$ ($2 \times 10^9/L$), platelets are less than $80 \times 10^9$/mm$^3$ ($80 \times 10^9/L$), or the reticulocytes are less than $80 \times 10^9$/mm$^3$ ($80 \times 10^9/L$). Monitor for increases in serum creatinine and transaminases. Once the patient’s blood counts have returned to baseline, hydroxyurea may be restarted with a dose that is 2.5 to 5 mg/kg less than the dose associated with the patient’s toxicity. Doses may then be increased by 2.5 to 5 mg/kg daily after 12 weeks with no toxicity.

Administer prophylactic folic acid supplementation to SCD patients receiving hydroxyurea, because folate deficiency may be masked by the use of hydroxyurea.

**5-Aza-2’-Deoxycytidine (Decitabine)** For patients who do not respond to hydroxyurea, or cannot tolerate the side effects of hydroxyurea, 5-azacytidine and 5-aza-2’-deoxycytidine (decitabine) may be useful. Both induce HbF by inhibiting methylation of DNA, preventing the switch from γ- to β-globin production. Decitabine appears to be safer and more potent than 5-azacytidine.

### Patient Encounter 2, Part 1

A 16-year-old African American girl with SCD is admitted to the hospital for progressive neck, shoulder, and back pain that began 2 days ago. The patient denies injury.

**PMH:** Sickle cell anemia (HbSS); admitted for vasoocclusive crises five times over the past year, acute chest syndrome at age 9, 12, and 14; multiple blood transfusions

**PSH:** Cholecystectomy, splenectomy

**FH:** Father with SC trait. Mother with SCD

**Allergies:** NKDA

**SH:** Occasional alcohol and marijuana use. Is not sexually active

**Home Meds:** Hydrocodone/acetaminophen 7.5/500 mg, one tablet every 6 hours as needed for pain; folic acid 1 mg daily by mouth

**PE:**

**VS:** T 39.0° C (102.2° F), BP 113/66, P 78, RR 22, O$_2$ Sat 99% (0.99) on 2 L nasal cannula, Ht 163 cm (5’4”), Wt 62.7 kg (138 lb)

**Gen:** Awake, alert x 3, in no acute distress, but obviously in pain

**HEENT:** Normocephalic, atraumatic. PERRLA. No lymphadenopathy

**Chest:** Normal to inspection and palpation. No rhonchi, rales, or wheezes

**CV:** RRR, no m/g/r

**Abd:** Soft, NT/ND

**Ext:** No clubbing, cyanosis, or edema. Shoulder pain with palpation

**Neuro:** Cranial nerves II through XII are grossly intact. Nonfocal

**Labs:** Hgb 7.3 g/dL (73 g/L or 4.53 mmol/L), Hct 23.1% (0.231 fraction), WBC 19 × 10$^9$/μL (19 × 10$^9$/L), BMP WNL

Chest x-ray was within normal limits.

What is your assessment of this patient’s condition?

List treatment goals for this patient.

Devise a detailed therapeutic plan for this patient’s hospital management.

Is the patient a candidate for hydroxyurea? Why or why not?
• **Acute Complications**

**Transfusions for Acute Complications** Red cell transfusion is indicated in patients with acute exacerbations of baseline anemia; in cases of severe vasoocclusive episodes, including ACS, stroke, and acute multiorgan failure; and in preparation for procedures that will require the use of general anesthesia or ionic contrast products. Transfusions also may be useful in patients with complicated obstetric problems, refractory leg ulcers, refractory and prolonged pain crises, or severe priapism. Hyperviscosity may occur if the hemoglobin level is increased to greater than 10.0 to 11.0 g/dL (100–110 g/L or 6.21–6.83 mmol/L). Volume overload leading to congestive heart failure is more likely to occur if the anemia is corrected too rapidly in patients with severe anemia and should be avoided.4

**Infection and Fever** Any fever greater than 38.5°C (101.3°F) in a SCD patient should be immediately evaluated, and the patient should have a blood culture drawn and be started on antibiotics that provide empirical coverage for encapsulated organisms.4

Patients who should be hospitalized include the following:

- Infants younger than 1 year of age
- Patients with a previous sepsis or bacteremia episode
- Patients with temperatures in excess of 40°C (104°F)
- Patients with WBC counts greater than 30 $\times$ 10⁹/mm³ (30 $\times$ 10⁹/L) or less than 0.5 $\times$ 10⁹/mm³ (0.5 $\times$ 10⁹/L) and/or platelets less than 100 $\times$ 10⁹/mm³ (100 $\times$ 10⁹/L) with evidence of other acute complications
- Acutely ill-appearing individuals

Broad IV antibiotic coverage for the encapsulated organisms can include ceftriaxone or cefotaxime. For patients with true cephalosporin allergy, clindamycin may be used. If staphylococcal infection is suspected due to previous history or the patient appears acutely ill, vancomycin should be initiated. Macrolide antibiotics, such as erythromycin or azithromycin, may be

A severe anemia after transfusion also may occur due to a rapid decrease in hemoglobin and hematocrit, along with a suppression of erythropoiesis. Further transfusions may worsen the clinical picture due to autoimmune antibodies. Recovery may occur only after ceasing all transfusions and is evidenced by a gradual increase in hemoglobin with reticulocytosis, which indicates the patient is now making their own RBCs.4

**Allogeneic Hematopoietic Stem Cell Transplant** Allogeneic hematopoietic stem-cell transplantation (HSCT) is the only potential cure for SCD. The best candidates are children with SCD who are younger than 16 years of age with severe complications, who have an identical human leukocyte antigen (HLA)-matched donor, usually a sibling. The transplant-related mortality rate is between 5% and 10%, and graft rejection is approximately 10%. Other risks include secondary malignancies, development of seizures or intracranial bleeding, and infection in the immediate posttransplant period.4,30,31

Experience with HSCT in adult patients with SCD is still somewhat limited. The use of less intense preparative regimens has made HSCT more available for the older patient with SCD. The best results have been seen in the use of progenitor cells (from bone marrow, cord blood, or peripheral blood stem cells) from matched sibling or related donors. The largest published trial to date in adults undergoing nonmyeloablative transplant involved 30 patients with an 87% rate of disease free survival.5,31

In a small study in adults refractory to hydroxyurea, decitabine 0.2 mg/kg subcutaneously one to three times weekly was associated with an increase in HbF in all patients. Additionally, RBC adhesion was reduced. Neutropenia was the only significant toxicity reported.27

**Chronic Transfusion Therapy** Chronic transfusion therapy is warranted to prevent serious complications from SCD, including stroke prevention and recurrence. Especially in children, chronic transfusions have been shown to decrease stroke recurrence from approximately 50% to 10% over 3 years. Without chronic transfusions, approximately 70% of ischemic stroke patients will have another stroke. Chronic transfusion therapy may also be used to prevent vasoocclusive pain and ACS, as well as prevent progression of organ damage.4

The goal of chronic transfusion therapy is to maintain the HbS level at less than 30% (0.30) of total hemoglobin concentration. Transfusions are usually administered every 3 to 4 weeks depending on the HbS concentration. For secondary stroke prevention, current studies have indicated that lifelong transfusion may be required, with increased incidence of recurrence once transfusions are stopped.4

The benefits of transfusion should be weighed with the risks. Risks associated with transfusions include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and transfusion reactions. Although the risk of contracting AIDS has decreased dramatically, hepatitis C remains a concern. All SCD patients should be vaccinated for hepatitis A and B and should be serially monitored for hepatitis C and other infections. Parvovirus occurs in 1 of every 40,000 units of RBCs and can be associated with acute anemia and multiple sickle cell complications.4 Iron overload is a risk for patients maintained on chronic transfusions for more than 1 year. Counsel patients to avoid excessive dietary iron, and monitor serum ferritin regularly. Chelation therapy with deferoxamine or deferasirox should be considered when the serum ferritin level is greater than 1500 to 2000 ng/mL (1500–2000 mcg/L; 3400–4500 pmol/L). Deferoxamine should be initiated at 20 to 40 mg/kg daily (to a maximum of 1–2 g/day) over 8 to 12 hours subcutaneously and has been associated with growth failure.4 Monitor children receiving deferoxamine for adequate growth and development on a regular basis. Deferasirox should be initiated at 20 mg/kg daily and is available in a tablet that should be dispersed in water, orange juice, or apple juice and taken orally 30 minutes before food.28,29 Monitor all chelation patients for auditory and ocular changes on a yearly basis. Exchange transfusions may also be helpful in cases of iron overload.

Sickle cell hemolytic transfusion reaction syndrome is a unique problem in SCD patients. Due to alloimmunization, an acute or delayed transfusion reaction may occur 5 to 20 days posttransfusion. Patients may develop symptoms suggestive of a pain crisis or worsening symptoms if they are already in crisis.

**Patient Encounter 2, Part 2**

Four months later, the patient is seen on follow-up in the outpatient clinic for management of her SCD. She reports that she has a boyfriend and that they are sexually active.

**What are the concerns for using hydroxyurea in this patient?**

**Are there any implications now that she is sexually active?**
Blood gases

Patients may complain of cough, fever, dyspnea, chest pain. Risk factors include young age, low HbF level, high Hgb. CBC with reticulocyte count. Recurrences are up to 80% and can lead to chronic lung disease. Temperature greater than 38.5°C (101.3°F). New infiltrate on chest x-ray. Patients may complain of painful and unwanted erection. Mean age of initial episode is 12 years of age. Prolonged episodes should be considered medical emergencies. Occurs in 15% to 43% of patients and is responsible for 25% of deaths. Risk factors include young age, low HbF level, high Hgb and WBCs, winter seasons, reactive airway disease. Recurrences are up to 80% and can lead to chronic lung disease.

Acute neurologic events, such as stroke, will require hospitalization and close monitoring. Patients should have physical and neurologic examinations every 2 hours. Acute treatment may include exchange transfusion or simple transfusion to maintain hemoglobin at approximately 10.0 g/dL (100 g/L or 6.21 mmol/L) and HbS concentration at less than 30% (0.30). Patients with a history of seizure may need anticonvulsants, and interventions for increased intracranial pressure should be initiated if necessary. Children with history of stroke should be initiated on chronic transfusion therapy. Early detection of ischemic stroke can be done with the use of transcranial Doppler ultrasonography. In the Stroke Prevention Trial in Sickle Cell Anemia (STOP) study, screening with this method followed by chronic transfusion therapy significantly reduced the incidence of stroke. Screening is recommended in all patients older than 2 years.

Acute Chest Syndrome. ACS will require hospitalization for appropriate management of symptoms and to avoid complications. Patients should be encouraged to use incentive spirometry at least every 2 hours. Incentive spirometry helps the patient take long, slow breaths to increase lung expansion. Appropriate management of pain is important, but analgesic-induced hypventilation should be avoided. Patients should maintain appropriate fluid balance because overhydration can lead to pulmonary edema and respiratory distress. Infection with gram-negative, gram-positive, or atypical bacteria is common in ACS, and early use of broad-spectrum antibiotics, including a macrolide, quinolone, or cephalosporin is recommended. Fat emboli, from infarction of the long bones, may lead to ACS. Oxygen therapy should be utilized in any patient presenting with respiratory distress or hypoxia. Oxygen saturations, measured by pulse oximeter, should be maintained at 92% (0.92) or above. Exchanges transfusions are often indicated when there is a rapid progression of ACS symptoms, such as increased needs for supplemental oxygen, increased respiratory distress, or progression of pulmonary infiltrates, and patients who present with wheezing may require inhaled bronchodilators.

The use of corticosteroids is controversial. Although they may decrease the inflammation and endothelial cell adhesion seen with ACS, their use has also been associated with higher readmission rates for other complications.

Priapism. By age 18, approximately 90% of SCD males will have had at least one episode of priapism. Stuttering priapism, where erection episodes last anywhere from a few minutes to less than 2 hours, resolves spontaneously. Erections lasting more than 2 hours should be evaluated promptly. Goals of therapy are to provide pain relief, reduce anxiety, provide detumescence, and preserve testicular function and fertility. Initial treatment should include aggressive hydration and analgesia. Transfusion may or may not be helpful, but should be considered in anemic patients. Avoid the use of ice packs due to the risk of tissue damage.

Both vasoconstrictors and vasodilators have been used in the treatment of priapism. Vasoconstrictors are thought to work by forcing blood out of the cavernosum and into the venous return.
Clinical Presentation and Diagnosis of Acute Aplastic Crisis in SCD

**General**
- Transient suppression of RBC production in response to bacterial or viral infection
- Most commonly due to infection with parvovirus B19

**Symptoms**
- Patients may complain of headache, fatigue, dyspnea, pallor, or fever
- Patients may also complain of upper respiratory or GI infection symptoms

**Signs**
- Temperature greater than 38.5°C (101.3°F) may occur
- Hypoxia
- Tachycardia
- Acute decrease in Hgb with decreased reticulocyte count

**Laboratory Tests**
- CBC with reticulocyte count
- Chest x-ray
- Parvovirus titers
- Cultures (blood, urine, and throat)

Aspiration of the penile blood followed by intracavernous irrigation with epinephrine (1:1,000,000 solution) has been effective with minimal complications. In severe cases, surgical intervention to place penile shunts has been used, but there is a high failure rate, and the risk of complications, from skin sloughing to fistulas, limits its use.

Pseudoephedrine dosed at 30 to 60 mg daily taken at bedtime has been used to prevent or decrease the number of episodes of priapism. Terbutaline 5 mg has been used orally to prevent priapism, with mixed results. Leuprolide, a gonadotropin-releasing hormone, also has been used for this indication. Hydroxyurea may be helpful in some patients. The use of antiandrogens is under investigation.

**Treatment of Acute Complications**

**Aplastic Crisis** Most patients in aplastic crisis will recover spontaneously and therefore treatment is supportive. If anemia is severe or symptomatic, transfusion may be indicated. Infection with human parvovirus B19 is the most common cause of aplastic crisis. Isolate infected patients because parvovirus is highly contagious. Pregnant individuals should avoid contact with infected patients because midtrimester infection with parvovirus may cause hydrops fetalis and still birth.

**Sequestration Crisis** RBC sequestration in the spleen in young children may lead to a rapid drop in hematocrit, resulting in hypovolemia, shock, and death. Treatment is RBC transfusion to correct the hypovolemia, as well as broad-spectrum antibiotics, because infections may precipitate the crisis.

Clinical Presentation and Diagnosis of Sequestration Crisis in SCD

**General**
- Acute exacerbation of anemia due to sequestration of large blood volume by the spleen
- More common in patients with functioning spleens
- Onset often associated with viral or bacterial infections
- Recurrence is common and can be fatal

**Symptoms**
- Sudden onset of fatigue, dyspnea, and distended abdomen
- Patients may present with vomiting and abdominal pain

**Signs**
- Rapid decrease in Hgb and Hct with elevated reticulocyte count
- Splenomegaly
- May exhibit hypotension and shock

**Evaluation**
- Vital signs
- Spleen size changes
- Oxygen saturations
- CBC with reticulocyte count
- Cultures (blood, urine, throat)

Hydroxyurea may be helpful in some patients.

Clinical Presentation and Diagnosis of Vasoocclusive Crisis in SCD

**General**
- Most often involves the bones, liver, spleen, brain, lungs, and penis
- Precipitating factors include infection, extreme weather conditions, dehydration, and stresses
- Recurrent acute crises result in bone, joint, and organ damage and chronic pain

**Symptoms**
- Patients may complain of deep throbbing pain, local tenderness

**Signs**
- Erythema and swelling of painful area
- Dactylitis in young infants
- Temperature greater than 38.5°C (101.3°F)
- Leukocytosis

**Laboratory tests**
- CBC with reticulocyte count
- Urinalysis
- Abdominal studies (if symptoms exist)
- Cultures (blood and urine)
- Liver function tests and bilirubin
- Chest x-ray
Recurrent episodes are common and can be managed with chronic transfusion and splenectomy. Observation is used commonly in adults because their episodes are milder. Splenectomy is usually delayed until after 2 years of age to lessen the risk of postsplenectomy septicemia. Patients with chronic hypersplenism should be considered for splenectomy.40

**Vasoocclusive Pain Crisis** The mainstay of treatment for vasoocclusive crisis includes hydration and analgesia (Table 68–4). Pain may involve the extremities, back, chest, and abdomen.

*Key Concept* Patients with mild pain crisis may be treated as outpatients with rest, warm compresses to the affected (painful) area, increased fluid intake, and oral analgesia. Patients with moderate to severe crises should be hospitalized. Infection should be ruled out because it may trigger a pain crisis, and any patient presenting with fever or critical illness should be started on empirical broad-spectrum antibiotics. Patients who are anemic should be transfused to their baseline. IV or oral fluids at 1.5 times maintenance is recommended. Close monitoring of the patient’s fluid status is important to avoid overhydration, which can lead to ACS, volume overload, or heart failure.4

Aggressive pain management is required in patients presenting in pain crisis. Assess pain on a regular basis (every 2 to 4 hours), and individualize management to the patient. The use of pain scales may help with quantifying the pain rating. Obtain a good medication history of what has worked well for the patient in the past. Use acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID) for treatment of mild to moderate pain. Patients with bone or joint pain who require IV medications may be helped by the use of ketorolac, an injectable NSAID. Because of the concern for side effects, including GI bleeding, ketorolac should be used only for a maximum of 5 consecutive days. Monitor for the total amount of acetaminophen given daily, because many products contain acetaminophen. Maximum daily dose of acetaminophen for adults is 4 g/day, and for children, five doses over a 24-hour period.41 Add an opioid if pain persists or if pain is moderate to severe in nature. Combining an opioid with an NSAID can enhance the analgesic effects without increasing adverse effects.42–45

Severe pain should be treated with an opioid such as morphine, hydromorphone, methadone, or fentanyl. Moderate pain can be effectively treated in most cases with a weak opioid such as

---

**Table 68–4**

**Management of Acute Pain of SCD**

**Principles**
Treat underlying precipitating factors.

- Avoid delays in analgesia administration.
- Use pain scale to assess severity.
- Choice of initial analgesic should be based on previous pain crisis pattern, history of response, current status, and other medical conditions.
- Schedule pain medication; avoid as-needed dosing.
- Provide rescue dose for breakthrough pain.
- Continuous infusion: 0.004 mg/kg/hour; titrate to effect.
- Morphine: 0.01–0.03 mg/kg/hour basal; demand 0.01–0.03 mg/kg every 6–10 minutes; 4 hours lockout 0.04–0.06 mg/kg.
- Consider nonpharmacologic intervention.
- Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a fast-release product is also needed for breakthrough pain.

**Analgesic Regimens**

**Mild to moderate pain:**

**Acetaminophen with codeine:**
- Dose based on codeine—children: 1 mg/kg per dose every 6 hours; adults: 30–60 mg/dose.

**Hydrocodone + acetaminophen:**
- Dose based on hydrocodone—children: 0.2 mg/kg per dose every 6 hours; adults: 5–10 mg/dose.

**Anti-inflammatory agents:**
- Use with caution in patients with renal failure (dehydration) and bleeding.
- Ibuprofen (oral): children: 10 mg/kg every 6–8 hours; adults: 200–400 mg/dose.
- Naproxen: 5 mg/kg every 12 hours; adults: 250–500 mg/dose.
- Ibuprofen + hydrocodone: Each tablet contains 200 mg ibuprofen and 7.5 mg hydrocodone per tablet; only for older children who can swallow tablets.

**Moderate to severe pain:**

**Morphine—children:** 0.1–0.15 mg/kg per dose every 3–4 hours; adults: 5–10 mg/dose.
- Continuous infusion: 0.04–0.05 mg/kg/hour; titrate to effect.

**Hydromorphone—children:** 0.015 mg/kg per dose every 3–4 hours; adults: 1.5–2 mg/dose.
- Continuous infusion: 0.004 mg/kg/hour; titrate to effect.

**IV anti-inflammatory agents:**
- Ketorolac: 0.5 mg/kg up to 30 mg/dose every 6 hours.

**Patient-controlled analgesics:**
- Morphine: 0.01–0.03 mg/kg/hour basal; demand 0.01–0.03 mg/kg every 6–10 minutes; 4 hours lockout 0.04–0.06 mg/kg.
- Hydromorphone: 0.003–0.005 mg/kg/hour basal; demand 0.003–0.005 mg/kg every 6–10 minutes; 4 hours lock out 0.4–0.6 mg/kg.

**Severe pain:**

Add an opioid if pain persists or if pain is moderate to severe in nature.
codeine or hydrocodone, usually in combination with acetaminophen. Meperidine should be avoided because of its relatively short analgesic effect and its toxic metabolite, normeperidine. Normeperidine may accumulate with repeated dosing and can lead to CNS side effects including seizures.

IV opioids are recommended for use in treatment of severe pain because of their rapid onset of action and ease in titration. Intramuscular injection should be avoided. Analgesia should be individualized and titrated to effect, either by scheduled doses or continuous infusion. The use of continuous infusion will avoid the fluctuations in blood levels between doses that are seen with bolus dosing. As-needed dosing of analgesia is only appropriate for breakthrough pain or uncontrolled pain. Patient-controlled analgesia (PCA) is commonly used and allows the patient to have control over his or her analgesic breakthrough dosing. As the pain crisis resolves, the pain medications can be tapered. Physical therapy and relaxation therapy can be helpful adjuvants to analgesia.42-45

Tolerance to opioids is seen when patients have had continuous long-term use of the medications and can be managed during acute crises by using a different potent opioid or using a larger dose of the same medication. Adverse effects associated with the use of opioids include respiratory depression, itching, nausea and vomiting, constipation, and drowsiness. Patients on continuous infusions of opioids should be on continuous pulse oximeter to assess oxygen saturations. Monitor the patient for oxygen saturations less than 92% (0.92). Oxygen should be administered as needed to keep the saturations above 92% (0.92). Itching can be managed with an antihistamine such as diphenhydramine. Nausea and vomiting can be treated and managed with the administration of antiemetics such as promethazine or the 5HT3 antagonists, but the use of promethazine is contraindicated in children younger than 2 years of age. Assess stool frequency in all patients on a continuous opioid, and start stool softeners or laxatives as needed. Excessive sedation is difficult to control, and the concurrent use of an opioid with diphenhydramine or other sedative medications can exacerbate the drowsiness, leading to hypoxemia. A continuous very low dose of naloxone, an opioid antagonist, has been used successfully when the adverse effects such as itching are unbearable.46

### OUTCOME EVALUATION

SCD treatment and prevention are considered successful when complications are minimized. The major outcome parameters are a decrease in morbidity and mortality, measured by the number of hospitalizations, and the extent of end-organ damage seen over time. Today, with longer survival for SCD, chronic manifestations of the disease contribute to the morbidity later in life (Table 68–5). Thirty years ago, complications from SCD contributed to high mortality. It was estimated that approximately 50% of patients with SCD did not survive to reach adulthood.4 Since that time, data suggest improvement in mortality rates for patients with SCD. The survival age for individuals with HbSS has increased to at least the fifth decade of life. Recent reports suggest 85% survival by 18 years of age.4 SCD is a chronic disease and cannot be cured, except in some patients with transplant.

Starting with birth, SCD patients should have regularly scheduled health assessments and interventions when necessary. Obtain a urine analysis, complete blood count, liver function tests, ferritin or serum iron level and total iron-binding capacity, blood urea nitrogen (BUN), and creatinine on at least a yearly basis and more often for children younger than 5 years of age to monitor for complications. All SCD patients should have regular screening of their hearing and vision.

All patients and parents of children with SCD should have a plan for what to do in the event of symptoms of infection or pain. Obtain a medication history when patients are admitted to the hospital. Assess adherence with prophylactic penicillin and childhood immunization schedules in all pediatric SCD patients.

### Chronic Complications of SCD

Since that time, data suggest improvement in mortality rates for patients with SCD. The survival age for individuals with HbSS has increased to at least the fifth decade of life. Recent reports suggest 85% survival by 18 years of age.4 SCD is a chronic disease and cannot be cured, except in some patients with transplant.

Starting with birth, SCD patients should have regularly scheduled health assessments and interventions when necessary. Obtain a urine analysis, complete blood count, liver function tests, ferritin or serum iron level and total iron-binding capacity, blood urea nitrogen (BUN), and creatinine on at least a yearly basis and more often for children younger than 5 years of age to monitor for complications. All SCD patients should have regular screening of their hearing and vision.

All patients and parents of children with SCD should have a plan for what to do in the event of symptoms of infection or pain. Obtain a medication history when patients are admitted to the hospital. Assess adherence with prophylactic penicillin and childhood immunization schedules in all pediatric SCD patients.
Patient Care Process

**Patient Assessment:**
- Based on physical exam and review of systems, determine whether the patient is experiencing any signs or symptoms of an acute or chronic SCD complication (see Tables 68–1 and 68–5).
- Review the patient’s medical history. Does the patient have a history of previous complications from SCD that would necessitate chronic medication therapy? When was the patient last hospitalized for SCD complications?
- Conduct a medication history including prescriptions, OTC medications, and dietary supplements. Does the patient take any analgesics as needed for pain? Does the patient have any medication allergies? Is the patient experiencing any side effects from their current medication therapy? Is the patient adherent with their chronic medication therapy?
- Review available laboratory tests.
- Is the patient up to date on their immunizations? Have they received their annual influenza vaccine?

**Therapy Evaluation:**
- Which analgesics have been helpful to the patient in the past? Is the patient taking appropriate doses of their pain medication to achieve the desired analgesic effect? If not, why?
- If the patient is having an acute complication of SCD, arrange for referral and/or admission to the hospital.
- If the patient is receiving hydroxyurea, review appropriate laboratory tests. Assess efficacy, safety, and patient adherence.
- If the patient is receiving chelation therapy, review appropriate laboratory tests. Assess efficacy, safety, and patient adherence.
- Determine if the patient has prescription coverage or whether recommended agents are included on the institution’s formulary.

**Care Plan Development:**
- Select lifestyle modifications that are likely to be effective and safe for the patient.
- Determine whether drug doses are optimal.
- Arrange for vaccination if the patient is not up to date with recommendations.
- Address any patient concerns about SCD and its management.
- Discuss the importance of medication adherence and lifestyle modifications to reduce complications of SCD.

**Follow-Up Evaluation:**
- Follow-up at monthly intervals or more frequently to assess effectiveness and safety of therapy, to avoid complications from SCD and improve quality of life for the patient.
- Review medication history and physical exam findings, laboratory tests and results of other diagnostic tests.
- Assess for adverse effects from medications that the patient is taking.
- Stress the importance of adherence with the therapeutic regimen, including lifestyle modifications. Adjust therapeutic regimens as needed based on patient response and adverse effects.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Recognize that antimicrobial resistance is an inevitable consequence of antimicrobial therapy.
2. Describe how antimicrobials differ from other drug classes in terms of their effects on individual patients as well as on society as a whole.
3. Identify two guiding principles to consider when treating patients with antimicrobials, and apply these principles in patient care.
4. Differentiate between microbial colonization and infection based on patient history, physical examination, and laboratory and culture results.
5. Evaluate and apply at least six major drug-specific considerations when selecting antimicrobial therapy.
6. Evaluate and apply at least seven major patient-specific considerations when selecting antimicrobial therapy.
7. Select empirical antimicrobial therapy based on spectrum-of-activity considerations that provide a measured response proportional to the severity of illness. Provide a rationale for why a measured response in antimicrobial selection is appropriate.
8. Identify and apply five major principles of patient education and monitoring response to antimicrobial therapy.
9. Identify two common causes of patients failing to improve while on antimicrobials, and recognize other less common but potential reasons for antimicrobial failure.

INTRODUCTION

Since 1980, infectious disease–related mortality in the United States has increased, in part owing to increases in antimicrobial resistance. The discovery of virtually every new class of antimicrobials has occurred in response to the development of bacterial resistance and loss of clinical effectiveness of existing antimicrobials. An inevitable consequence of exposing microbes to antimicrobials is that some organisms will develop resistance to the antimicrobial. Today, there are many antimicrobial classes and antimicrobials available for clinical use. However, in many cases, differences in mechanisms of action between antimicrobials are minor, and the microbiologic properties of the agents are similar. Antimicrobials are different from other classes of pharmaceuticals because they exert their action on bacteria infecting the host as opposed to acting directly on the host. Because antimicrobial use in one patient affects not only that patient but also other patients if they become infected with resistant bacteria, correct selection, use, and monitoring of clinical response are paramount.

There are two guiding principles to consider when treating patients with antimicrobials: (a) make the correct diagnosis and (b) do no harm! Patients with infections frequently present with signs and symptoms that are nonspecific and may be confused with other noninfectious disease. Not only is it important to determine whether a disease process is of infectious origin, but it is also important to determine the specific causative pathogen of the infection. Antimicrobials vary in their spectrum of activity, the ability to inhibit or kill different species of bacteria. Antimicrobials that kill many different species of bacteria are called broad-spectrum antimicrobials, whereas antimicrobials that kill only a few species of bacteria are called narrow-spectrum antimicrobials. One might argue that treating everybody with broad spectrum antimicrobials will increase the likelihood that a patient will get better even without knowing the bacteria causing infection. However, counter to this argument is the principle of “Do no harm!” Broad antimicrobial coverage does increase the likelihood of empirically killing a causative pathogen; unfortunately, the development of secondary infections can be caused by selection of antimicrobial-resistant nontargeted pathogens. In addition, adverse events are thought to complicate up to 10% of all antimicrobial therapy, and for select agents, the adverse-event rates are similar to high-risk medications such as warfarin, digoxin, or insulin. Therefore, the overall goal of antimicrobial therapy should be to cure the patient’s infection; limit harm by minimizing patient risk for adverse effects, including secondary infections; and limit societal risk from antimicrobial-resistant bacteria.

EPIDEMIOLOGY AND ETIOLOGY

Infectious disease–related illnesses, particularly respiratory tract infections, are among the most common reasons patients seek...
Antimicrobial prescribing has been associated with inappropriate use of antimicrobial agents. During the late 1990s/early 2000s, many organizations initiated campaigns to promote appropriate antimicrobial use. Recent trends in prescribing suggest a modest reduction in antimicrobial use for these infections, suggesting an increased recognition of the negative consequences of antimicrobial use. Up to one-half of all patients receive at least one antimicrobial during hospitalization. In 2011, the number of health care–associated infections in acute care hospitals in the United States was estimated at 721,800, with approximately 75,000 deaths. In 2014, the CDC reported that there were reductions in central line–associated bloodstream infections (44% reduction between 2008 and 2012) and surgical site infections (20% reduction between 2008 and 2012) as well as a slight reduction in hospital-onset MRSA bloodstream infection (4% reduction from 2011 to 2012). Nosocomial infections tend to be associated with antimicrobial-resistant strains of bacteria. However, there has been a shift in the etiology of some community-acquired infections. Increasingly, infections caused by antimicrobial-resistant pathogens, traditionally nosocomial in origin, are being identified in ambulatory care settings. Reasons for this change include an aging populace, improvement in the management of chronic comorbid conditions including immunosuppressive conditions, and increases in outpatient management of more debilitated patients. The majority of infections caused by antimicrobial-resistant pathogens in the ambulatory care setting occur in patients who have had recent exposure to the health care system. The converging bacterial etiologies and increasing resistance in all health care environments emphasize the need to “make the diagnosis.”

**PATHOPHYSIOLOGY**

**Normal Flora and Endogenous Infection**

Many areas of the human body are colonized with bacteria—this is known as normal flora. Infections often arise from one’s own normal flora (called an endogenous infection). Endogenous infection may occur when there are alterations in the normal flora (eg, recent antimicrobial use may allow for overgrowth of other normal flora) or disruption of host defenses (eg, a break or entry in the skin). Knowing what organisms reside where can help guide empirical antimicrobial therapy (Figure 69–1). In addition, it is beneficial to know what anatomic sites are normally sterile. These include the cerebrospinal fluid, blood, and urine.

**Determining Colonization versus Infection**

Infection refers to the presence of bacteria that are causing disease (eg, the organisms are found in normally sterile anatomic sites or in nonsterile sites with signs/symptoms of infection). Colonization refers to the presence of bacteria that are not causing disease. Only bacteria that cause disease should be targeted with antimicrobial therapy, and non–disease-producing colonizing flora should be left intact. It is important to differentiate infection from colonization because antimicrobial therapy targeting colonization is inappropriate and may lead to the development of resistant bacteria.

---

**FIGURE 69–1.** Normal flora and concentrations of bacteria (organisms per milliliter).
Exogenously Acquired Bacterial Infections

Infections acquired from an external source are referred to as *exogenous infections*. These infections may occur as a result of human-to-human transmission, contact with exogenous bacterial populations in the environment, and animal contact. Resistant pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* spp (VRE) may colonize hospitalized patients or patients who access the health care system frequently. It is important to know which patients have acquired these organisms because patients generally become colonized prior to developing infection, and colonized patients should be placed in isolation to minimize transmission.

Contrasting Bacterial Virulence and Resistance

*Virulence* refers to the pathogenicity or disease severity produced by an organism. Bacteria may produce toxins or possess characteristics that contribute to their pathogenicity. Some virulence factors allow the organism to avoid the immune response of the host and cause significant disease. Virulence and resistance are different microbial characteristics. For example, *Streptococcus pyogenes*, a common cause of skin infections, produces toxins that can cause severe disease, yet it is very susceptible to penicillin. *Enterococcus faecium* is a highly resistant organism but is frequently a colonizing flora that causes disease primarily in the immunocompromised.

CLINICAL PRESENTATION AND DIAGNOSIS

Physical Examination

Findings on physical examination, along with the clinical presentation, can help identify the anatomic location of the infection. Once the anatomic site is identified, the most probable pathogens associated with disease can be determined based on likely endogenous or exogenous flora.

Fever often accompanies infection and is defined as a rise in body temperature above the normal 37°C (98.6°F). Oral and axillary temperatures may underestimate core temperature by at least 0.6°C (1°F), whereas rectal temperatures best approximate core temperatures. Fever is a host response to bacterial toxins. However, bacterial infections are not the sole cause of fever. Fever also may be caused by other infections (eg, fungal or viral), medications (eg, penicillins, cephalosporins, salicylates, and phenytoin), trauma, or other medical conditions (eg, autoimmune disease, malignancy, pulmonary embolism, and hyperthyroidism). Some patients with infections may present with hypothermia (eg, patients with overwhelming infection). Elderly patients may be afebrile, as may those with localized infections (eg, urinary tract infection). For others, fever may be the only indication of infection. Neutropenic patients may not have the ability to mount normal immune responses to infection (eg, infiltrate on chest x-ray, pyuria on urinalysis, or erythema or induration around catheter site), and the only finding may be fever.

Imaging Studies

Imaging studies also may help to identify anatomic localization of the infection. These studies usually are performed in conjunction with other tests to establish or rule out the presence of an infection. Radiographs are performed commonly to establish the diagnosis of pneumonia, as well as to determine the severity of disease. Computed tomography (CT) scans are a type of x-ray that produces a three-dimensional image of the combination of soft tissue, bone, and blood vessels. In contrast, magnetic resonance imaging (MRI) uses electromagnetic radio waves to

### Clinical Presentation

- Review of symptoms consistent with an infectious etiology.
- Signs and symptoms may be nonspecific (eg, fever) or specific.
- Specific signs and symptoms are beyond the scope of this chapter (see disease state–specific chapters for these findings).

### Patient History

- History of present illness
- Comorbidities
- Current medications
- Allergies
- Previous antibiotic exposure (may provide clues regarding colonization or infection with new specific pathogens or pathogens that may be resistant to certain antimicrobials)
- Previous hospitalization or health care utilization (also a key determinant in selecting therapy because the patient may be at risk for specific pathogens and/or resistant pathogens)
- Travel history
- Social history
- Pet/animal exposure
- Occupational exposure
- Environmental exposure

### Physical Findings

- Findings consistent with an infectious etiology
- Vital signs
- Body system abnormalities (eg, rales, altered mental status, localized inflammation, erythema, warmth, edema, pain, and pus)

### Diagnostic Imaging

- Radiographs (x-rays)
- CT scans
- MRI
- Labeled leukocyte scans

### Nonmicrobiologic Laboratory Studies

- White blood cell count (WBC) with differential
- Erythrocyte sedimentation rate (ESR)
- C-reactive protein
- Procalcitonin

### Microbiologic Studies

- Gram stain
- Culture and susceptibility testing
produce two- or three-dimensional images of soft tissue and blood vessels with less detail of bony structures.

Nonmicrobiologic Laboratory Studies

Nonmicrobiologic laboratory tests include the white blood cell count (WBC) and differential, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and procalcitonin levels. In most cases, the WBC count is elevated in response to infection, but it may be decreased owing to overwhelming or long-standing infection. The differential is the percentage of each type of WBC (Table 69–1). In response to physiologic stress, neutrophils leave the bloodstream and enter the tissue to “fight” against the offending pathogens (ie, leukocytosis). It is important to recognize that leukocytosis is nonspecific for infection and may temporarily occur in response to noninfectious conditions such as acute myocardial infarction. During an infection, immature neutrophils (eg, bands) are released at an increased rate to help fight infection, leading to what is known as a “bandemia” or “left shift”. Therefore, a WBC count differential is key to determining whether an infection is present. Some patients may present with a normal total WBC with a left shift (eg, the elderly). ESR and CRP are nonspecific markers of inflammation that increase as a result of the acute-phase reactant response, which is a response to inflammatory stimuli such as infection or tissue injury. These tests may be used as markers of infectious disease response because they are elevated when the disease is acutely active and usually fall in response to successful treatment. Clinicians may use these tests to monitor a patient’s response to therapy in osteomyelitis and infective endocarditis. These tests should not be used to diagnose infection because they may be elevated in noninfectious inflammatory conditions. In contrast, procalcitonin, a prohormone of calcitonin, is rapidly produced in response to bacterial infection. Procalcitonin serum levels in conjunction with clinical findings are increasingly being utilized to assess both the need to initiate antibiotic therapy as well as determine when antibiotic therapy may be safely discontinued.

Microbiologic Studies

Microbiologic studies that allow for direct examination of a specimen (eg, sputum, blood, or urine) may aid in a presumptive diagnosis and give an indication of the characteristics of the infecting organism. Generally, microbial cultures are obtained with a Gram stain of the cultured material.

**Patient Encounter 1**

**HPI:** A 72 year old woman with a history of hypertension, diabetes, hyperlipidemia, chronic back pain, osteoarthritis, and a history of frequent urinary tract infections who began feeling poorly 48 hours prior to presenting to the emergency room. She reports extreme fatigue, chills, fever (100.6°F [38.1°C]), nausea, and headache. Her daughter, who is accompanying the patient to the emergency room, notes increasing confusion over the same time period. She has recently been treated for recurrent urinary tract infections 2 and 5 weeks ago with Bactrim DS and levofloxacin.

**PMH:** Hypertension, diabetes, hyperlipidemia, chronic back pain, osteoarthritis, and frequent urinary tract infections (5–10 per year) with the most recent being treated 2 and 5 weeks ago with Bactrim DS and levofloxacin, respectively.

**FH:** Father died of colon cancer at age 72. Mother died of congestive heart failure at age 83.

**SH:** Lives at home. Has 2 daughters and 1 son.

**Allergies:** NKDA

**Meds:** Lisinopril 10 mg daily; hydrochlorothiazide 25 mg daily; metoprolol XL 50 mg daily; atorvastatin 20 mg daily; metformin 1000 mg twice daily; glipizide 5 mg twice daily; pregabalin 150 mg daily; oxycodone 5 mg three times; aspirin 81 mg daily; alendronate 70 mg weekly; calcium carbonate 500 mg twice daily; multivitamin 1 daily; cranberry supplement 300 mg daily

**What information in the history supports an infectious etiology?**

**Is this patient at risk for resistant pathogens? Why?**
A Gram stain of collected specimens can give rapid information that can be applied immediately to patient care. A Gram stain is performed to identify whether bacteria are present and to determine morphologic characteristics of bacteria (eg, gram-positive or gram-negative and shape—cocci, bacilli). Certain specimens do not stain well or at all and must be identified by alternative staining techniques (Mycoplasma spp., Legionella spp., Mycobacterium spp.). Figure 69–2 identifies bacterial pathogens classified by Gram stain and morphologic characteristics. The presence of WBCs on a Gram stain indicates inflammation and suggests that the identified bacteria are pathogenic. The Gram stain may be useful in evaluating a sputum specimen’s adequacy (eg, the presence of epithelial cells on sputum Gram stain suggests that the specimen is either poorly collected or contaminated). A poor specimen can give misleading information regarding the underlying pathogen and may result in inappropriate antimicrobial use.

Culture and susceptibility testing provides additional information to the clinician to select appropriate therapy. Specimens are placed in or on culture media that provide proper growth medium for different bacteria. The results of these tests can help determine the sensitivity of the bacteria to various antibiotics, guiding the selection of the most effective treatment.

**Figure 69–2.** Important bacterial pathogens classified according to Gram stain and morphologic characteristics. (From Rybak MJ, Aeschlimann JR. Laboratory tests to direct antimicrobial pharmacotherapy. In: In DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York: McGraw-Hill; 2014.)
conditions. Once the bacteria grow on culture media, they can be identified through biochemical tests. When a pathogen is identified, susceptibility tests can be performed to various antimicrobial agents. The minimum inhibitory concentration (MIC) is a standard susceptibility test. The MIC is the lowest concentration of antimicrobial that inhibits visible bacterial growth after approximately 24 hours (Figure 69–3). Breakpoint and MIC values determine whether the organism is susceptible (S), intermediate (I), or resistant (R) to an antimicrobial. The breakpoint is the concentration of the antimicrobial that can be achieved in the serum after a standard dose of that antimicrobial. If the MIC is below the breakpoint, the organism is considered to be susceptible to that agent. If the MIC is above the breakpoint, the organism is said to be resistant. Reported culture and susceptibility results may not provide MIC values but generally report the S, I, and R results.

**KEY CONCEPT** In general, bacterial cultures should be obtained prior to initiating antimicrobial therapy in patients with a systemic inflammatory response, risk factors for antimicrobial resistance, or infections where diagnosis or antimicrobial susceptibility is uncertain. The decision to collect a specimen for culture depends on the sensitivity and specificity of the physical and diagnostic findings, and whether or not the pathogens are readily predictable. Culture and susceptibility testing usually is not warranted in a young, otherwise healthy woman who presents with signs and symptoms consistent with a urinary tract infection (UTI) because the primary pathogen, *Escherichia coli*, is readily predictable. Cultures and susceptibility testing are routine for sterile-site specimens (eg, blood and spinal fluid), as well as for material presumed to be infected (eg, material obtained from joints and abscesses). Cultures need to be interpreted with caution. Poor specimen collection technique and processing speed can result in misleading information and inappropriate use of antimicrobials.

**TREATMENT**

**General Approach to Treatment, Including Nonantimicrobial Treatment**

While selection of antimicrobial therapy may be a major consideration in treating infectious diseases, it may not be the only therapeutic intervention. Other important therapies may include adequate hydration, ventilatory support, and supportive medications. In addition, antimicrobials are unlikely to be effective if the source that leads to the infection is not controlled. Source control refers to this process and may involve removal of prosthetic materials such as catheters and infected tissue or drainage of an abscess. Source control considerations should be a fundamental component of any infectious diseases treatment. It is also important to recognize that there may be many different antimicrobial regimens that may cure the patient. While the following therapy sections provide factors to consider when selecting antimicrobial regimens, excellent and more in-depth

---

**Figure 69–3.** Macrotube minimal inhibitory concentration (MIC) determination. The growth control (C), 0.5 mg/L, and 1 mg/L tubes are visibly turgid, indicating bacterial growth. The MIC is read as the first clear test tube (2 mg/L). (From Rybak MJ, Aeschlimann JR. Laboratory tests to direct antimicrobial pharmacotherapy. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York: McGraw-Hill; 2014.)

**Patient Encounter 2: Review of Symptoms, Physical Examination, and Laboratory Examination Data**

**ROS:** Elderly woman who is confused and unable to answer questions.

**PE:**
- VS: BP 89/55 P 92, RR 20, T 38.7°C (101.7°F), O₂ sat 94% (0.94) on room air, Ht 5'3" (160 cm), Wt 68 kg
- HEENT: Dry mucous membranes
- Chest: Clear to auscultation without wheezes, rales or rhonchi
- CV: Tachycardic with irregularly irregular rhythm
- Musculoskeletal: CVA tenderness

**Labs:**
- WBC 16.5 × 10^3/mm^3 (16.5 × 10^9/L), segs 82% (0.82), bands 11% (0.11), lymphs 7% (0.07)
- SCr 1.8 mg/dL (159 μmol/L)
- Glucose 242 mg/dL (13.4 mmol/L)
- Procalcitonin 0.5 μg/L
- Urinalysis:
  - Specific gravity 1.015
  - pH 6.0
  - 1+ protein
  - 2+ blood
  - 2+ leukocytes
  - Positive nitrates
  - Many bacteria
  - 0–2 RBCs/hpf
  - 25–50 WBCs/hpf

**Blood Cultures: Pending**

Antimicrobial Considerations in Selecting Therapy

• **KEY CONCEPT** Drug-specific considerations in antimicrobial selection include spectrum of activity, effects on nontargeted microbial flora, appropriate dose, pharmacokinetic and pharmacodynamic properties, adverse-effect and drug-interaction profile, and cost (Table 69–2).

➤ **Spectrum of Activity and Effects on Nontargeted Flora**

Most initial antimicrobial therapy is empirical because cultures have not had sufficient time for identification of a pathogen. Empirical therapy should be based on patient- and antimicrobial-specific factors such as the anatomic location of the infection, the likely pathogens associated with the presentation, the potential for adverse effects in a given patient, and the antimicrobial spectrum of activity. Prompt initiation of appropriate therapy is paramount in hospitalized patients who are critically ill. Patients who receive appropriate initial antimicrobial therapy survive at twice the rate of patients who receive inadequate therapy.11 Empirical selection of antimicrobial spectrum of activity should be related to the severity of the illness. Generally, acutely ill patients require broader-spectrum antimicrobial coverage, whereas less ill patients may be managed initially with narrow-spectrum therapy. While a detailed description of antimicrobial pathogen-specific spectrum of activity is beyond the scope of this chapter, this information can be obtained readily from a number of sources.12,13

Collateral damage is defined as the development of resistance occurring in a patient’s nontargeted flora that can cause secondary infections. *Clostridium difficile* infection (CDI) is an example of a disease that occurs secondary to collateral damage. Antibiotics can increase the risk of CDI by suppressing normal intestinal flora, resulting in overgrowth of the nonsusceptible *C. difficile* bacteria. In addition, CDI is associated with the prior use of broad-spectrum antibiotics; particularly fluoroquinolones.14 If several different antimicrobials possess activity against a targeted pathogen, the antimicrobial that is least likely to be associated with collateral damage may be preferred.

➤ **Single versus Combination Therapy**

A common debate involves the need for coverage with two antimicrobials for serious infections. Proponents state that double coverage may be synergistic, prevent the emergence of resistance, and improve outcome. However, there are few clinical examples in the literature to support these assertions. Examples where double coverage is considered superior are limited to infections associated with large bacterial loads and in species that are known to readily develop resistance such as active tuberculosis or enterococcal endocarditis.15,16 A study of patients with *Pseudomonas aeruginosa* infections, an intrinsically resistant organism, demonstrated that empirical double coverage with two antipseudomonal antimicrobials improved survival.17 Combination therapy increased the likelihood of appropriate empirical coverage; however, once organism susceptibilities were known, there was no difference in outcome between double coverage and monotherapy. Double antimicrobial coverage with two agents of similar spectra of activity may be beneficial for selected infections associated with high bacterial loads or for initial empirical coverage of critically ill patients in whom antimicrobial-resistant organisms are suspected. Monotherapy usually is satisfactory once antimicrobial susceptibilities are established.

➤ **Antimicrobial Dose**

Clinicians should be aware that antimicrobial dosage regimens may be different depending on the infectious process. For example, ciprofloxacin, a fluoroquinolone, has various dosage regimens based on site of infection. The dosing for uncomplicated UTIs is 250 mg twice daily for 3 days. For complicated UTIs, the dose is 500 mg twice daily for 7 to 14 days. Severe complicated pneumonia requires a dosage regimen of 750 mg twice daily for 7 to 14 days. Clinicians are encouraged to use dosing regimens designed for treatment of the diagnosed infection because they have demonstrated proven efficacy and are most likely to minimize harm.

➤ **Pharmacokinetic Properties**

Pharmacokinetic properties of an antimicrobial may be important in antimicrobial regimens. Pharmacokinetics refers to a mathematical method of describing a patient’s drug exposure in vivo in terms of absorption, distribution, metabolism, and elimination. Bioavailability refers to the amount of antimicrobial that is absorbed orally relative to an equivalent IV dose administered. Drug-related factors that may affect oral bioavailability include the formulation of the antimicrobial, dosage form, and stability of the drug in the gastrointestinal (GI) tract. Patients with systemic signs of infection such as hypotension should receive intravenous antimicrobials to ensure drug delivery as absorption is affected by GI blood flow. In cases where patients have a functioning GI tract and are not hypotensive, antimicrobials with almost complete bioavailability (greater than 80%) such as the fluoroquinolones, fluconazole, and linezolid may be given orally. With antimicrobials with modest bioavailability (eg, many β-lactams), the decision to choose an oral product will depend more on the severity of the illness and the anatomic location of the infection. In sequestered infections, where higher systemic concentrations of antimicrobial may be necessary to reach the infected source (eg, meningitis) or for antimicrobials with poor bioavailability, IV formulations should be used.

Some antimicrobials may be bound to proteins in serum. Only unbound drug is biologically active and distributes freely between tissues. Protein binding is clinically relevant in highly protein-bound antimicrobials (greater than 50%) as the agents may not be able to penetrate sequestered compartments, such as cerebral spinal fluid, resulting in insufficient concentrations to inhibit bacteria. In addition, some drugs may not achieve
sufficient concentrations in specific compartments based on distribution characteristics. For example, *Legionella pneumophila*, an organism that causes severe pneumonia, is known to survive and reside inside pulmonary macrophages. Treatment with an antibiotic that inhibits bacterial cell wall synthesis, such as a cephalosporin, will be ineffective because it only distributes into extracellular host tissues. However, macrolide or fluoroquinolone antimicrobials, which concentrate in human pulmonary macrophages, are highly effective against this organism.

Many antimicrobials undergo some degree of metabolism once ingested. Metabolism may occur via hepatic, renal, or nonorgan-specific enzymatic processes. The route of elimination of the metabolic pathway may be exploited for infections associated with tissues related to the metabolic pathways. For example, many fluoroquinolone antimicrobials are partially metabolized and undergo renal elimination. Urinary concentrations of active drug are many times those achieved in the systemic circulation, making several of these agents good choices for complicated urinary tract infections.

### Pharmacodynamic Properties

Pharmacodynamics describes the relationship between drug exposure and pharmacologic effect of antibacterial activity or human toxicity. Antimicrobials are categorized based on their concentration-related effects on bacteria. Concentration-dependent pharmacodynamic activity occurs where higher drug concentrations are associated with greater rates and extents of bacterial killing. Concentration-dependent antimicrobial activity is maximized when peak antimicrobial concentrations are high. In contrast, concentration-independent (or time-dependent) activity refers to a minimal increase in the rate or extent of bacterial killing with an increase in antimicrobial dose. Concentration-independent antimicrobial activity is maximized when these antimicrobials are dosed to maintain blood and/or tissue concentrations above the MIC in a time-dependent manner. Fluoroquinolones, aminoglycosides, and metronidazole are examples of antimicrobials that exhibit concentration-dependent activity, whereas β-lactam and glycopeptide antimicrobials exhibit concentration-independent activity. Pharmacodynamic properties have been optimized to develop new dosing strategies for older antimicrobials. Examples include single-daily-dose aminoglycoside or β-lactam therapy administered by continuous or extended infusion. The product labeling for many new antimicrobials takes pharmacodynamic properties into account.

Antimicrobials also can be classified as possessing bactericidal or bacteriostatic activity in vitro. Bactericidal antibiotics generally kill at least 99.9% of a bacterial population, whereas bacteriostatic antibiotics possess antimicrobial activity but reduce bacterial load by less than 3 logs (99.9%). Clinically, bactericidal antibiotics may be necessary to achieve success in infections such as endocarditis or meningitis. A full discussion of the application of antimicrobial pharmacodynamics is beyond the scope of this chapter, but excellent sources of information are available.

### Adverse-Effect and Drug-Interaction Properties

A major concern when selecting antimicrobial regimens should be the propensity for the regimen to cause adverse effects and the potential for drug interactions. In general, if several different antimicrobial options are available, antimicrobials with a low propensity to cause adverse events should be selected, particularly for patients with risk factors for a particular complication.

Risk factors for adverse events may include the coadministration of other drugs that are associated with a similar type of adverse event. For example, coadministration of the known nephrotoxin gentamicin with vancomycin increases the risk for nephrotoxicity compared with administration of either drug alone. Other drug interactions may predispose the patient to dose-related toxicity through inhibition of drug metabolism. For example, erythromycin has the potential to prolong cardiac QT intervals in a dose-dependent manner, potentially increasing the risk for sudden cardiac death.

### Antimicrobial Cost

A final consideration in selecting antimicrobial therapy relates to cost. The least expensive antimicrobial is not necessarily the most cost-effective antimicrobial. Antimicrobial costs constitute a relatively small portion of the overall cost of care. Careful consideration of antimicrobial microbiologic, pharmacologic, and patient-related factors such as compliance and a variety of clinical outcomes is necessary to establish the cost versus benefit of an antimicrobial in a given patient. If there is no difference or a small difference in these factors, the least costly antimicrobial may be the best choice.

### Patient Considerations in Antimicrobial Selection

#### Key Concept
Key patient-specific considerations in antimicrobial selection include recent previous antimicrobial exposures, identification of the anatomic location of infection through physical examination and diagnostic imaging, history of drug allergies, pregnancy or breast-feeding status, organ dysfunction that may affect drug clearance, immunosuppression, compliance, and the severity of illness (see Table 69–2).

#### Host Factors

Host factors can help to ensure selection of the most appropriate antimicrobial agent. Age is an important factor in antimicrobial selection. Populations with diminished renal function include neonates and the elderly. Hepatic function in the neonate is not fully developed, and drugs that are metabolized or eliminated by this route may produce adverse effects. For example, sulfonamides andceftriaxone may compete with bilirubin for binding sites and may result in hyperbilirubinemia and kernicterus. Gastrointestinal acidity also depends on age; the elderly and children younger than 3 years tend to be achlorhydric. Drugs that need an acidic environment (eg, ketoconazole) are not well absorbed, and those whose absorption is enhanced in an alkaline environment will have increased concentrations (eg, penicillin G).

Disruption of host defenses due to IV or indwelling Foley catheters, burns, trauma, surgery, and increased gastric pH may place patients at higher risk for infection. Breaks in skin integrity provide a route for infection because the natural barrier of the skin is disrupted. Increased gastric pH can allow for bacterial overgrowth and has been associated with an increased risk of pneumonia.

Recognizing the presumed site of infection and most common pathogens associated with the infectious source should guide antimicrobial choice, dose, and route of administration. For example, community-acquired pneumonia is caused most commonly by *Streptococcus pneumoniae*, *E. coli* is the primary cause of uncomplicated UTIs, and staphylococci and streptococci are implicated most frequently in skin and skin-structure infections (eg, cellulitis).
Failure to adjust the antimicrobial dose or interval may result in adverse events. In particular, penicillin-related allergy is common and can be problematic because there is an approximately 4% cross-reactivity with cephalosporins as well as carbapenems. A patient’s medical history should be reviewed to determine the offending β-lactam and nature of the allergic reaction. In some cases, patients with mild or nonimmunologic reactions to penicillins may receive a β-lactam antimicrobial with low cross-reactive potential (such as cephalosporins). However, patients with a history of findings consistent with IgE-mediated reactions such as anaphylaxis, urticaria, or bronchospasm should not be administered any type of β-lactam antimicrobial, including cephalosporins, unless there are no other alternatives, and even then they should be administered with caution. Administration of potentially cross-reactive agents in this situation should occur under close observation in a health care setting prepared to treat serious reactions, and some patients may need to undergo desensitization. If the specific medical history relating to a reported allergy cannot be obtained, the patient should be assumed to have had an IgE-mediated reaction and should be managed in a similar manner. Monobactams (ie, aztreonam) may be administered to patients with IgE-mediated allergic reactions to penicillin.

Renal and/or hepatic function should be considered prior to initiation of antimicrobial therapy. Most antimicrobials undergo renal elimination and dosing adjustments are frequently necessary and recommendations for adjustment are available in the literature. In contrast, dosing adjustments for antimicrobials that undergo nonrenal elimination are less well documented. Failure to adjust the antimicrobial dose or interval may result in drug accumulation and adverse effects.

Concomitant administration of other medications may influence the selection of the antimicrobial, dose, and monitoring. Medications that commonly interact with antibiotics include, but are not limited to, warfarin, rifampin, phenytoin, digoxin, theophylline, multivalent cations (eg, calcium, magnesium, and zinc), and sulfamate. Drug interactions between antimicrobials and other medications may occur via the cytochrome P-450 system, protein-binding displacement, and alteration of vitamin K–producing bacteria. Interactions may result in increased concentrations of one or both agents, increasing the risk of adverse effects or additive toxicity. A key consideration in selecting antimicrobial regimens starts with obtaining a good patient medical and drug history, recognizing drug-specific adverse-event characteristics, and anticipating potential problems proactively. If it is necessary to use an antimicrobial with a relatively high frequency of adverse effects, informing patients of the risks and benefits of therapy, as well as what to do if an adverse effect occurs, may improve patient compliance and safety.

Antimicrobial agents must be used with caution in pregnant and nursing women. Some agents pose potential threats to the fetus or infant (eg, quinolones, tetracyclines, and sulfonamides). For some agents, avoidance during a specific trimester of pregnancy is warranted (eg, the first trimester with trimethoprim/sulfamethoxazole). Pharmacokinetic variables also are altered during pregnancy. Both the clearance and volume of distribution are increased during pregnancy. As a result, increased dosages and/or more frequent administration of certain drugs may be required to achieve adequate concentrations. This information can be obtained from a number of sources.

Adherence is essential to ensure efficacy. Patients may stop taking their antibiotics once the symptoms subside and save them for a “future” infection. If the patient does not complete the course of therapy, the infection may not be eradicated, and resistance may emerge. Self-medication of saved antibiotics may be harmful, leading to overtreatment, which may further contribute to antibiotic resistance. Poor adherence may be due to adverse effects, tolerability, cost, and lack of patient education.

**OUTCOME EVALUATION**

Figure 69–4 provides an overview of patient- and antimicrobial agent–specific factors to consider when selecting an antimicrobial regimen. It further delineates monitoring of therapy and actions to take depending on the response to therapy. Duration of therapy depends on patient response and type of infection being treated.

After selection and initiation of an antimicrobial regimen, there are additional patient care and monitoring considerations that should be addressed to improve the likelihood of a successful outcome. **Patient education, de-escalation of antimicrobial therapy based on culture results, monitoring for clinical response and adverse effects, and appropriate duration of therapy are important.**

**Modifying Empirical Therapy Based on Cultures and Clinical Response**

If a successful clinical response occurs and culture results are available, therapy should be de-escalated. Antibiotic de-escalation generally refers to the discontinuation of antibiotics that are providing a spectrum of activity greater than necessary to treat the infection, discontinuation of duplicative spectrum antibiotics, or switching to a narrower spectrum antibiotic once a patient is clinically stable. De-escalation of empirical therapy...
Obtain patient history including clinical presentation and examination
- Hx of present illness
- Comorbidities
- Current medications
- Allergies
- Previous antibiotic exposure
- Previous hospitalization or healthcare utilization
- Travel history
- Social history
- Pet/animal exposure
- Occupational exposure
- Environmental exposure

Obtain appropriate diagnostic imaging and labs including cultures
- Review of symptoms consistent with infection?
- Physical examination consistent with infection?
- Imaging consistent with infectious etiology?
- WBC, ESR, CRP elevated?
- Appropriate Gram stain culture suggests infection?

Pathogen known before starting antimicrobials? Y/N

Is the patient severely ill? Y/N

Consider broad-spectrum empirical therapy.

Considerations for selecting antimicrobial regimens

Drug specific
- Spectrum of activity and effects on nontargeted flora
- Dosing
- Pharmacokinetic properties
- Pharmacodynamic properties
- Adverse effect potential
- Drug interaction potential
- Cost

Patient specific
- Anatomical location of infection
- Antimicrobial history
- Drug allergy history
- Renal and hepatic function
- Concomitant medications
- Pregnancy or lactation
- Compliance potential

Start empirical antimicrobial therapy: provide patient education as needed. Consider adjunctive therapy.

Start definitive therapy: provide patient education as needed. Consider adjunctive therapies.

Monitoring of therapy
Clinical presentation/Physical findings

Efficacy
- Vital signs
- Clinical findings
- Physical exam findings

Toxicity
- Adverse effects

Imaging
Repeat diagnostic testing as needed

Laboratory Data
- WBC—other inflammatory markers (eg, ESR, CRP)
- Follow-up on culture and susceptibility reports

Patient improving on therapy? Y/N

Yes

Patient cured; stop antimicrobials

No

Patient improving on therapy? Y/N

Yes

De-escalate therapy based on culture results including discontinuation of unnecessary antimicrobials

IV to oral conversion

No

Consider alternative noninfectious diagnosis.
- Reevaluate for sources of untreated infection.
- Perform source control: remove catheters, drain abscesses, debride.
- Consider other drug- and patient-specific factors: appropriate dosing, patient compliance, and drug interactions.

Change antimicrobial therapy based upon findings.
may also include discontinuing antibiotics based on clinical criteria and negative culture results, such as the absence of antibiotic-resistant pathogens.27 The purpose of de-escalation therapy is to minimize the likelihood of secondary infections owing to antimicrobial-resistant organisms. In cases in which a specific organism is recovered that has a known preferred antimicrobial treatment of choice, therapy might be changed to that specific agent. For example, antistaphylococcal penicillins are considered to be the agents of choice for methicillin-resistant *S. aureus* owing to their bactericidal activity and narrow-spectrum activity and may be preferable to other antibiotic regimens. In other cases, empirical coverage might be discontinued if a specific suspected pathogen is excluded by culture or an alternative, noninfectious diagnosis is established. In addition, IV antimicrobials frequently are more expensive than oral therapy. Therefore, it is usually desirable to convert therapy to oral antimicrobials with a comparable antimicrobial spectrum or specific pathogen sensitivity as soon as the patient improves clinically.28

**Failure of Antimicrobial Therapy**

While many infections respond readily to antimicrobials, some infections do not. A common question when a patient fails to improve relates to whether the antimicrobial therapy has failed. Changing antimicrobials generally is one of the easiest interventions relative to other options. However, it is important to remember that antimicrobial therapy comprises only a portion of the overall disease treatment, and there may be many factors that contribute to a lack of improvement. **KEY CONCEPT** In general, inadequate diagnosis resulting in poor initial antimicrobial or other nonantibiotic drug selection, poor source control, or the development of a new infection with a resistant organism are relatively common causes of antimicrobial failure. An infection-related diagnosis may be difficult to establish and generally has two components: (a) differentiating infection from noninfectious disease and (b) providing adequate empirical spectrum of activity if the cause is infectious. Failure of improvement in a patient’s condition should warrant broadening the differential diagnosis to include noninfectious causes, as well as considering other potential infectious sources and/or pathogenic organisms. Another common cause of failure is poor source control. A diagnostic search for unknown sources of infection and removal of indwelling devices in the infected environment or surgical drainage of abscesses should be undertaken if the patient’s condition is not improving. Less common causes of therapeutic failure include the development of secondary infections. In this case, the patient generally improves, but then develops a new infection caused by an antimicrobial-resistant pathogen and relapses. The emergence of resistance to a targeted pathogen while on antimicrobial therapy can be associated with clinical failure but usually is limited to tuberculosis, pseudomonads, or other gram-negative enterics. Drug- and patient-specific factors such as appropriate dosing, patient compliance, and drug interactions can be associated with therapeutic failure and also should be considered. A common assumption is that the correct diagnosis was made, but the patient was not treated long enough with antimicrobials. There are certain types of infections (eg, endocarditis or osteomyelitis) where the standard of care is to treat for prolonged periods of time (ie, weeks or months). However, the optimal duration of therapy for many infectious diseases is somewhat subjective. Studies of several infectious processes have suggested that shorter durations of therapy can result in similar clinical outcomes as longer durations of therapy, frequently with fewer complications or secondary infections.29-31 In this period of extensive antimicrobial resistance, clinicians should keep abreast of changing recommendations emphasizing shorter durations of therapy.

### Patient Encounter 4: Patient Care and Monitoring

**Update:** The patient was admitted to the hospital with a presumptive diagnosis of pyelonephritis, sepsis, and acute kidney injury. She received IV hydration with normal saline, 4 L oxygen, and empirical antibiotic therapy with piperacillin/tazobactam.

After 48 hours of therapy, the following parameters are obtained:

**PE:**

- VS: BP 130/70, P 70, RR 22, T 37.2°C (98.9°F), *O₂* sat 94% (0.94) on room air

**Labs:**

- WBC 9.2 × 10⁶/mm³ (9.2 × 10⁹/L)
- WBC differential 85% (0.85) segs, 10% (0.10) lymphs, 5% (0.05) monos
- SCr 1.1 mg/dL (97 μmol/L)
- Glucose 126 mg/dL (7.0 mmol/L)
- Blood cultures × 2: *Escherichia coli* (confirmed as an extended spectrum beta lactamase [ESBL] enzyme producer)
- Urine culture: *Escherichia coli* (confirmed as an extended spectrum beta lactamase [ESBL] enzyme producer)

**Susceptibility Report:**

- Cefazolin resistant (MIC greater than 16 mg/L)
- Cefepime resistant (MIC greater than 16 mg/L)
- Ceftriaxone resistant (MIC greater than 32 mg/L)
- Piperacillin/tazo susceptible (MIC less than equal to 16 mg/L)
- Meropenem susceptible (MIC less than equal to 1 mg/L)
- Gentamicin susceptible (MIC less than equal to 4 mg/L)
- Tobramycin resistant (MIC greater than 8 mg/L)
- Nitrofurantoin susceptible (MIC less than equal to 32 mg/L)
- Ciprofloxacin resistant (MIC greater than 4 mg/L)
- Levofloxacin resistant (MIC greater than 4 mg/L)
- Trimethoprim/sulfamethoxazole resistant (MIC greater than 2/38)

**What information suggests improvement in the patient’s condition?**

**Do any of the antimicrobial doses need to be adjusted for changes in organ function?**

**Should antimicrobial therapy be modified based on the culture results?**

**Can the antimicrobial therapy be converted from IV to oral therapy?**
**Patient Assessment:**
- Based on patient presentation, physical examination, and review of systems, determine whether the patient is experiencing signs or symptoms that are consistent with an infection.
- Review the medical history. Does the patient have risk factors for infection? Does the patient have risk factors for resistant pathogens?
- Conduct a medication history. Has the patient received recent antimicrobial therapy?
- Review available laboratory tests. Do laboratory findings suggest infection?

**Therapy Evaluation:**
- Determine whether antimicrobial therapy is indicated.
- Do no harm.
- Determine whether the patient has prescription coverage or whether recommended agents are included on institution’s formulary.

**Care Plan Development:**
- Select appropriate antimicrobial therapy based on presumed site of infection, likely pathogens, supporting laboratory data, previous antimicrobial therapy (if applicable), patient’s renal/hepatic function, and other pertinent patient factors (eg, age, concomitant disease states, concomitant medications, pregnant/lactating).
- For further guidance on appropriate antimicrobial therapy selection, refer to The Infectious Diseases Society of America practice guidelines (www.idsociety.org).
- Determine whether antimicrobial therapy doses are optimal.
- Address patient concerns about antimicrobial therapy and management of the infection.
- Discuss importance of medication adherence.

**Follow-Up Evaluation:**
- Follow up daily (if in-patient or at appropriate intervals if outpatient) to assess efficacy and toxicity of therapy until resolution of infection.
- Review medical history, clinical and physical examination findings, laboratory tests (including culture and susceptibility data), and results of other diagnostic tests to evaluate response to therapy.
- Follow up on culture and susceptibility reports with subsequent de-escalation of therapy, if possible.
- Reculture of specimens is not performed routinely except in few cases (eg, endocarditis) or where a secondary infection is suspected because data may be misleading and lead to the addition of broader or more powerful antimicrobials.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Discuss the pathophysiology of CNS infections and the impact on antimicrobial treatment regimens (including antimicrobial dosing and CNS penetration).
2. Describe the signs, symptoms, and clinical presentation of CNS infections.
3. List the most common pathogens causing CNS infections and identify risk factors for infection with each pathogen.
4. State the goals of therapy for CNS infections.
5. Design appropriate empirical antimicrobial regimens for patients suspected of having CNS infections caused by each of the following pathogens (taking age, vaccine history, and other patient-specific information into account), and analyze the impact of antimicrobial resistance on both empirical and definitive therapy:
   - Neisseria meningitidis meningitis
   - Haemophilus influenzae meningitis
   - Listeria monocytogenes meningitis
   - Group B Streptococcus meningitis
   - Gram-negative bacillary meningitis, postneurosurgical infection
   - CNS shunt infection
   - Herpes simplex encephalitis
6. Modify empirical antimicrobial regimens based on laboratory data and other diagnostic criteria.
7. Discuss the management of close contacts of patients diagnosed with CNS infections.
8. Identify candidates for vaccines and other prophylactic therapies to prevent CNS infections.
9. Describe the role of adjunctive agents (eg, dexamethasone) in the management of CNS infections.
10. Formulate a monitoring plan to assess efficacy and adverse effects of therapy for CNS infections.

INTRODUCTION

The term CNS infections describes a variety of infections involving the brain and spinal cord and associated tissues, fluids, and membranes, including meningitis, encephalitis, brain abscess, cerebrospinal fluid shunt infections, and postoperative infections. CNS infections, such as meningitis, are considered neurologic emergencies that require prompt recognition, diagnosis, and management to prevent death and residual neurologic deficits. Improperly treated, CNS infections are associated with high rates of morbidity and mortality. Despite advances in care, the overall mortality of bacterial meningitis in the United States remains at approximately 15%, and at least 10% to 30% of survivors are afflicted with neurologic impairment, including hearing loss, hemiparesis, and learning disabilities. Antimicrobial therapy and preventive vaccines have revolutionized management and improved outcomes of bacterial meningitis and other CNS infections dramatically.

EPIDEMOLOGY AND ETIOLOGY

CNS infections are uncommon, with an incidence 1.38 cases per 100,000 in 2006 and 2007. However, the severity of these infections demands prompt medical intervention and treatment. CNS infections can be caused by bacteria, fungi, mycobacteria, viruses, parasites, and spirochetes.

Bacterial meningitis is the most common cause of CNS infections. While vaccination has reduced the incidence of disease by many common pathogens as of 2010, Streptococcus pneumoniae (pneumococcus) was the most common pathogen for bacterial meningitis (0.306 cases per 100,000), followed by Neisseria meningitidis (meningococcus, 0.123 cases per 100,000). Haemophilus influenza was a top causative pathogen; however, its incidence has declined to 0.058 cases per 100,000. Staphylococcal species and gram-negative bacteria account for 0.114 and 0.127 cases per 100,000 persons, respectively in the United States. Group B Streptococcus and Listeria monocytogenes remain important causes, but current data on their incidence are lacking. Vaccines directed against bacteria causing meningitis and related infections (eg, pneumonia and ear infections) have reduced the risk of infections due to S. pneumoniae, N. meningitidis, and H. influenzae type b (Hib) dramatically. Prior to the availability of Hib conjugate vaccines, Hib meningitis or other invasive disease was documented in one in 200 children by the age of 5 years and due to widespread use, its incidence has decreased such that it is no longer a leading pathogen. Historically, a 7-valent conjugate pneumococcal vaccine (PCV7) was administered,
but despite use of the PCV7, S. pneumoniae remained the most common pathogen for pediatric bacterial meningitis. In 2010, a 13-valent conjugate pneumococcal vaccine was licensed for use in the United States; however, its impact on the epidemiology of disease in the United States is still unknown. In France the 13-valent vaccine reduced the incidence of pneumococcal meningitis by 27.4%.5

Encephalitis may result from viral, bacterial, parasitic, or other noninfectious causes. Herpes simplex virus (HSV) is the most common cause of encephalitis in the United States, accounting for 10% of all cases.10 The annual incidence of viral encephalitis is 3.5 to 7.4 infections per 100,000 persons.6 Other pathogens including common bacterial meningitis causes, Rickettsia species, enteroviruses, arboviruses, varicella-zoster virus, rotavirus, coronavirus, influenza viruses A and B, West Nile virus, and Epstein-Barr virus may be associated with a meningoencephalopathic presentation.7 Approximately 20,000 hospitalizations each year are secondary to encephalitis, accounting for $650 million in health care costs.6 Over the past 10 to 20 years, mortality secondary to encephalitis has remained constant, correlating well with the increased number of people living with human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS).

Neurosurgical procedures may place patients at risk for meningitis due to bacteria acquired at the time of surgery or in the postoperative period, including Staphylococcus aureus, coagulase-negative staphylococci, and gram-negative bacilli. In addition to bacteria, other pathogens may cause meningitis in at-risk patients. Immunocompromised patients, such as solid-organ transplant patients and patients living with HIV, are at risk for fungal meningitis with Cryptococcus neoformans and encephalitis secondary to Toxoplasma gondii and JC virus. Tuberculosis can spread from pulmonary sites to cause clinical disease in the CNS. Life-threatening viral encephalitis and meningitis can occur in otherwise healthy, young individuals, as well as in patients immunocompromised by age or other factors.

Risk factors for CNS infections can be classified as follows:

- **Environmental**: Recent exposures (eg, close contact with meningitis or respiratory tract infection, contaminated foods), active or passive exposure to cigarette smoke, close living conditions
- **Recent infection in the patient**: Respiratory infection, otitis media, sinusitis, mastoiditis
- **Immunosuppression**: Anatomic or functional asplenia, sickle cell disease, alcoholism, cirrhosis, immunoglobulin or complement deficiency, cancer, HIV/AIDS, uncontrolled diabetes mellitus, debilitated state of health
- **Surgery, trauma**: Neurosurgery, head trauma, CSF shunt, cochlear implant
- **Noninfectious causes of meningitis include malignancy, medications (eg, sulfonamides, nonsteroidal anti-inflammatory drugs [NSAIDs], IV immunoglobulin), autoimmune disease (eg, lupus), and trauma.6,7**
- **The most common pathogens causing bacterial meningitis, by age group and other risk factors, are found in Table 70–1.**

### Patient Encounter 1, Part 1

NB is a 57-year-old woman resident of an elderly singles living facility. She maintains her activities of daily living on her own. NB participates in group activities with co-residents on a weekly basis, with the most recent being a knitting party a week ago. She now presents to the emergency department with a 2-day history of headache, fever, and photophobia. Physical findings and laboratory values include temperature of 38.3°C (101°F) and WBC of $13.4 \times 10^9$/mm³ ($13.4 \times 10^9$/L), with 70% (0.70) polymorphonuclear cells. Examination reveals nuchal rigidity; remainder is benign for additional findings. NB also reports occasional nausea. She has a significant history for osteoporosis for which she takes alendronate and calcium with vitamin D. She receives the influenza vaccine yearly.

**What signs and symptoms consistent with meningitis are present in NB?**

**What causative pathogens should be suspected in NB?**

**What empiric antimicrobials should be started?**

---

### PATHOPHYSIOLOGY

Meningitis is an inflammation of the membranes of the brain and spinal cord (meninges) and the CSF in contact with these membranes, whereas encephalitis is an inflammation of the brain tissue. CSF produced in the brain ventricles flows through the subarachnoid space and downward through the spinal cord, insulating and protecting delicate CNS tissue.

To initiate a CNS infection, pathogens must gain entry into the CNS by **contiguous** spread, **hematogenous** seeding, direct inoculation, or reactivation of latent infection. Contiguous spread occurs when infections in adjacent structures (e.g., sinus cavities or the middle ear) invade directly through the blood–brain barrier. Hematogenous seeding occurs when a remote infection causes bacteremia that seeds the CSF, such as pneumococcal pneumonia. Reactivation of latent infection results from dormant viral, fungal, or mycobacterial pathogens in the spine, brain, or nerve tracts. Direct inoculation of bacteria into the CNS is the result of trauma, congenital malformations, or complications of neurosurgery.

Once through the blood–brain barrier, pathogens replicate due to limited host defenses in the CNS. **Figure 70–1** depicts the pathophysiologic changes associated with meningitis. Neurologic tissue damage is the result of the host’s immune reaction to bacterial cellular components, which trigger **cytokine** production, particularly tumor necrosis factor alpha (TNF-α) and interleukin 1 (IL-1), and other inflammatory mediators. **Bacteriolysis** resulting from antibiotic therapy further contributes to the inflammatory process. Cytokines increase permeability of the blood–brain barrier, allowing influx of neutrophils and other host defense cells that contribute to the development of cerebral edema and increased intracranial pressure characteristic of meningitis. The increase in intracranial pressure is responsible for the hallmark clinical signs and symptoms of meningitis: headache, neck stiffness, altered mental status, photophobia, and seizures. Untreated, these pathophysiologic changes may result in cerebral ischemia and death.
The CNS response to infection is cellular and chemical changes in the CSF. **KEY CONCEPT** Ideally, LP to obtain CSF for direct examination and laboratory analysis, as well as blood cultures and other relevant cultures, should be obtained before initiation of antimicrobial therapy. However, initiation of antimicrobial therapy should not be delayed if a pretreatment LP cannot be performed.

Normal CSF has a characteristic composition in terms of protein and glucose content, as well as cell count. **Table 70–2** lists CSF findings normally observed and in the setting of meningitis.

### CLINICAL PRESENTATION AND DIAGNOSIS

A high index of suspicion should be maintained for patients at risk for CNS infections. Prompt recognition and diagnosis are essential so that antimicrobial therapy can be initiated as quickly as possible. A medical history (including risk factors for infection and history of possible recent exposures) and physical examination yield important information to help guide the diagnosis and treatment of meningitis. Common signs and symptoms include fever, headache, nuchal rigidity (stiff neck), and photophobia. Infants present with nonspecific signs and symptoms, including excessive irritability or crying, vomiting or diarrhea, tachypnea, altered sleep pattern, and poor eating. Depending on involved pathogens and disease severity, patients may also present with altered mental status, stupor, and seizures.

### TREATMENT

#### Goals of Therapy

Prior to antibiotic therapy and vaccination bacterial meningitis was almost universally fatal, with survivors suffering from debilitating residual neurologic deficits, such as permanent hearing loss. Although significant improvements have been made, the fatality rate of meningitis remains above 15% in adults, likely due to its occurrence in debilitated patient populations.

The treatment goals for CNS infections are to prevent death and residual neurologic deficits, eradicate or control causative micro-organisms, ameliorate clinical signs and symptoms, and implement vaccination and suppressive measures to prevent future infections. Surgical debridement should be employed, if appropriate (as in postneurosurgical infections and brain abscess). Supportive care, consisting of hydration, electrolyte replacement, antipyretics, antiemetics, analgesics, antiepileptic drugs, and wound care (for surgical wounds), is an important adjunct to antimicrobial therapy, particularly early in the treatment course.

#### Treatment Principles

**KEY CONCEPT** Prompt initiation of IV high-dose bactericidal antimicrobial therapy directed at the most likely pathogen(s) is essential due to the high morbidity and mortality associated with CNS infections. Although there are no prospective studies that relate timing of antibiotic administration to clinical outcome in bacterial meningitis, a longer duration of symptoms and more advanced disease before treatment initiation increase the risk of a poor outcome. Initiation of antibiotic therapy as soon as possible after bacterial meningitis is suspected or proven (even before hospitalization) reduces mortality and neurologic sequelae.

High-dose parenteral bactericidal antibiotic therapy is required to achieve CSF antibiotic concentrations adequate to rapidly sterilize the CSF and reduce the risk of complications. Data from animal studies and patients demonstrate better outcomes when bactericidal antibiotic therapy (vs bacteriostatic therapy) is used to sterilize the CSF. However, successful treatment of meningitis has been reported with bacteriostatic agents. The presence of infection in the CSF reduces the activity of some classes of antibiotics. For example, the decreased pH of CSF associated with meningitis significantly reduces the activity of aminoglycoside antibiotics.

Antimicrobial pharmacokinetics and pharmacodynamics must be considered when designing treatment regimens for CNS infections. Ability of antibiotics to reach and achieve effective concentrations at the infection site is the key to treatment success. In experimental models of meningitis, maximum bactericidal activity is achieved when CSF concentrations exceed the minimum bactericidal concentration (MBC) of the infecting pathogen by 10- to 30-fold. In general, low-molecular-weight lipophilic antibiotics that are unionized at physiologic pH and not highly

CSF, cerebrospinal fluid; PMNs, polymorphonuclear neutrophils.

Data from Refs. 5, 11, 20, and 33.
Clinical Presentation and Diagnosis of CNS Infections

**General**
- Evaluate patient risk factors and recent exposures
- Evaluate other possible causes: space-occupying lesion (which may or may not be malignant), drug-induced CNS pathology autoimmune disease, and trauma

**Signs and Symptoms**
- 95% of patients with bacterial meningitis have two of the following: headache, fever, neck stiffness, and altered mental status
- Headache (87%)
- Nuchal rigidity (stiff neck) (83%)
- Fever (77%)
- Nausea (74%)
- Altered mental status (ie, confusion, lethargy, and obtundation) (69%)
- Focal neurologic defects (including positive Brudzinski sign and Kernig sign) (33%)
- Seizures
- Malaise, restlessness
- Photophobia
- Skin lesions (diffuse petechial rash observed in 50% of patients with meningococcal meningitis)

**Laboratory Tests**
- CSF examination via lumbar puncture (LP, spinal tap); contraindicated in patients with cardiorespiratory compromise, increased intracranial pressure and papilledema, focal neurologic signs, seizures, bleeding disorders, abnormal level of consciousness, and possible brain herniation (a CT scan should be performed before LP if there is a question of a CNS mass to avoid potential for brain herniation) (see Table 70–2 for specific CSF findings)
- Elevated opening pressure (may be decreased in neonates, infants, and children)
- Cloudy CSF
- Decreased glucose
- Elevated protein
- Elevated WBC (differential provides clues to offending pathogen)
- Gram stain (adequate for diagnosis in 60%–90% of patients with bacterial meningitis)
- Culture and sensitivity (positive in 70%–85% without prior antibiotic therapy, positive in less than 20% who have had prior therapy)
- If CSF Gram stain and/or culture is negative, rapid diagnostic tests (such as latex agglutination) may be useful; these tests are positive even if bacteria are dead
- Polymerase chain reaction (PCR; DNA amplification of the most common bacterial meningitis pathogens) may be useful to help exclude bacterial meningitis
- Elevated CSF lactate and C-reactive protein
- Blood cultures (at least two cultures, one “set”; positive in 66%)
- Scraping of skin lesions (eg, rash) for direct microscopic examination and culture
- Other cultures should be obtained as clinically indicated (eg, sputum)
- WBC with differential
- Fungal meningitis: CSF culture, CSF and serum cryptococcal antigen titers, microscopic examination of CSF specimens
- Tuberculous meningitis: CSF culture, PCR evaluation (preferred), and acid-fast stain

**Patient Encounter 1, Part 2**

The 67-year-old patient with signs and symptoms of meningitis underwent lumbar puncture. Initial results from CSF studies are WBC $1.8 \times 10^3$/mm$^3$ ($1.8 \times 10^9$/L) with 82% (0.82) PMNs and 41% (0.41) monocytes, protein 176 mg/dL (1,760 mg/L), glucose 18 mg/dL (1.0 mmol/L). Gram stain shows gram-negative diplococci. Vital signs remain stable in the ED. First doses of antimicrobial therapy are initiated in the ED, and NB is admitted to a medicine ward for continued treatment and confirmation of final diagnosis. Culture results confirm *Neisseria meningitidis* infection. Antimicrobials are streamlined and continued for the full duration.

**What clues in the CSF results are suggestive of bacterial meningitis?**
**Would adjunctive steroids offer additional benefit in this patient?**
**How can her antibiotic regimen be streamlined at this time?**

**Patient Encounter 1, Part 3**

NB has clinically improved on hospital day 3 and would like to be discharged home to continue therapy, but would prefer oral therapy if available. As her friends at the home learn of her illness, they are concerned about the possibility of getting sick and begin to follow up with the on-call physician at the group home. They wonder about medications and vaccinations to prevent the disease.

**How long should therapy be continued in NB?**
**What oral options are viable options for continuation as an outpatient in this case?**
**Who should receive antimicrobial prophylaxis for Neisseria?**
protein bound penetrate best into CSF and other body tissues and fluids.\textsuperscript{13,14} In addition to drug characteristics, integrity of the blood–brain barrier determines antibiotic penetration into CSF. The CSF penetration of most, but not all, antibiotics is enhanced by the presence of infection and inflammation. Sulfonamides, trimethoprim, chloramphenicol, rifampin, and most antitubercular drugs achieve therapeutic CSF levels even without meningeal inflammation.\textsuperscript{7} Most β-lactams and related antibiotics (ie, carbapenems and monobactams), vancomycin, quinolones, acyclovir, linezolid, daptomycin, and colistin achieve therapeutic CSF levels in the presence of meningeal inflammation.\textsuperscript{7} Aminoglycosides, first-generation cephaporsins, second-generation cephaporsins (except cefuroxime), clindamycin, and amphotericin do not achieve therapeutic CSF levels, even with inflammation, but clindamycin does achieve therapeutic brain tissue levels.\textsuperscript{7}

An adequate duration of therapy is required to treat meningitis successfully (Table 70–3).\textsuperscript{15} Parenteral (IV) therapy is administered for the full course of therapy for CNS infections to ensure adequate CSF penetration throughout the course of treatment. Antibiotic treatment (and dexamethasone, if used as a treatment adjunct) reduces the inflammation associated with meningitis, which, in turn, reduces the penetration of some antibiotics into the CSF, and parenteral therapy must be used throughout the entire treatment course to ensure adequate concentrations. Carefully selected patients who have close medical monitoring and follow-up may be able to receive a portion of their parenteral meningitis treatment on an outpatient basis.\textsuperscript{11,18} A management algorithm for adults with suspected bacterial meningitis, as recommended by the Infectious Diseases Society of America (IDSA), is summarized in Figure 70–2.

### Empirical Antimicrobial Therapy

After diagnosis, prompt and aggressive antimicrobial therapy with an appropriate empirical treatment is of the utmost importance in patients with suspected CNS infections. In most patients, a diagnostic LP will be performed before beginning antibiotics, but this never should delay initiation of antimicrobials. Antibiotic pretreatment may alter the CSF profile and complicate interpretation.\textsuperscript{13} Empirical therapy should be directed at the most likely pathogen(s) for a specific patient, taking into account age, risk factors for infection (including underlying disease and immune dysfunction, vaccine history, and recent exposures), CSF Gram stain results, CSF antibiotic penetration, and local antimicrobial resistance patterns. Results of the CSF Gram stain may be used to help narrow empirical therapy for bacterial meningitis. In the absence of a positive Gram stain, empirical therapy should be continued for at least 48 to 72 hours, when meningitis may, in most cases, be ruled out by CSF findings inconsistent with bacterial meningitis, negative CSF culture, and negative polymerase chain reaction (PCR) evaluations. A repeat LP may be useful in the absence of other findings. Table 70–1 outlines recommendations for empirical antibiotic therapy for bacterial meningitis by most likely pathogen(s) and patient risk factors.

### Impact of Antimicrobial Resistance on Treatment Regimens for Meningitis

Development of resistance to β-lactam antibiotics, including penicillins and cephalosporins, has significantly impacted the management of bacterial meningitis with one-fifth of CSF isolates resistant to penicillin and 3.5% of isolates resistant to cephalosporins.\textsuperscript{19} The Clinical and Laboratory Standards Institute (CLSI) has set a lower ceftriaxone susceptibility breakpoint for pneumococcal CSF isolates (1 mg/L) than for isolates from non-CNS sites (2 mg/L). Empirical treatment regimens now include the combination of a third-generation cephalosporin plus vancomycin. Recognition of relative and high-level resistance to \textit{N. meningitidis} in the laboratory, as well as in clinical treatment failures, has led to greater use of third-generation cephalosporins for empirical therapy of meningococcal meningitis.\textsuperscript{11,18} Treatment of suspected or proven β-lactamase-mediated HIB meningitis also requires a third-generation cephalosporin. Increasing rates of methicillin-resistant \textit{S. aureus} (about one-third of staphylococcal CSF isolates) and coagulase-negative staphylococci require the use of vancomycin for empirical therapy when these pathogens are suspected.\textsuperscript{11,18}

The emergence and continued rise of multidrug-resistant strains of gram-negative organisms such as \textit{Pseudomonas aeruginosa}, \textit{Acinetobacter} species, AmpC, and extended-spectrum β-lactamase (ESBL) producing strains of \textit{Enterobacteriaceae} have become a recognized threat nationally, and broad-spectrum therapy taking into account local resistance patterns should be used.

#### Pathogen-Directed Antimicrobial Therapy

**Empirical antimicrobial therapy should be modified on the basis of laboratory data and clinical response.** If cultures, CSF Gram stain, or antigen/antibody testing indicate a specific pathogen, therapy should be adjusted quickly as needed to ensure adequate coverage for the offending pathogen(s). Table 70–3 outlines recommended definitive pathogen-directed treatment regimens, recommended treatment duration, and key adverse effects that should be monitored during antibiotic therapy for meningitis. Table 70–4 provides pediatric doses of selected agents used in bacterial meningitis treatment.

- **Neisseria Meningitidis Meningitis**

\textit{N. meningitidis} CNS infections most commonly occur in children and young adults. From 11% to 19% of survivors of meningococcal meningitis experience long-term sequelae, including hearing loss, limb loss, and neurologic deficits.\textsuperscript{20} Nearly all meningococcal disease is caused by five serogroups: A, B, C, Y, and W-135. In the United States, serotypes B, C, and Y each are responsible for approximately 30% of cases.\textsuperscript{3,4}

Meningococcal meningitis is observed most commonly in individuals living in close quarters (eg, college students, military personnel). Infants younger than 1 year are at highest risk, possibly because pneumococcal vaccination reduces bactericidal antibodies.\textsuperscript{21} However, nearly 60% of cases occur in patients over 11 years of age.\textsuperscript{22,23} \textit{N. meningitidis} colonizes the nasopharynx and usually is transmitted via inhaled respiratory droplets from patients or asymptomatic carriers. A subclinical bacteremia typically ensues, seeding the meninges. Meningococcal disease is often (approximately 50%) associated with a diffuse petechial rash, and patients may experience behavioral changes. Patients may develop fulminant meningococcal sepsis, characterized by shock, disseminated intravascular coagulation, and multiorgan failure.\textsuperscript{24} Meningococcal sepsis has a poor prognosis and carries a mortality rate of up to 80%, whereas the mortality rate with meningococcal meningitis alone is 13%.\textsuperscript{23,24} Patients with suspected meningococcal infection should be kept on respiratory isolation for the first 24 hours of treatment.\textsuperscript{20}

Increasing penicillin resistance requires that third-generation cephalosporins now be used for empirical treatment until in vitro susceptibilities are known.\textsuperscript{11,15} Patients with a history of type I penicillin allergy or cephalosporin allergy may be treated with vancomycin. Treatment should be continued for 7 days, after which no further treatment is necessary.

*Hepatic*: No dose adjustment |

LFTs, liver function tests; MIC, minimum inhibitory concentration; SJS, Stevens-Johnson Syndrome.

*Empiric therapy with a third-generation cephalosporin should be used until in vitro susceptibility data are known.

Prevention of meningococcal disease by vaccination is a key to reducing the incidence of meningococcal meningitis. Routine vaccination should be administered between ages 11 and 21 years (preferably as soon as possible), with quadrivalent vaccine that provides protection against serogroups A, C, Y, and W. Additionally, children less than 2 years may also need quadrivalent vaccine, depending on risk factors. The quadrivalent conjugate meningococcal vaccine protects against four of the five serotypes causing invasive disease (A, C, Y, and W-135). Meningococcal vaccines do not protect against serotype B, which causes more than 50% of the cases of meningococcal meningitis in children younger than 2 years.

LFTs, liver function tests; MIC, minimum inhibitory concentration.

Meningococcal vaccines can be used in outbreak situations, with protective antibodies measurable within 7 to 10 days. **KEY CONCEPT** Close contacts of patients with meningococcal infections should be evaluated for antimicrobial prophylaxis. Close contacts include members of the same household, individuals who share sleeping quarters, daycare contacts, and individuals exposed to oral secretions of meningitis patients. After consultation with the local health department, close contacts should receive prophylactic antibiotics to eradicate nasopharyngeal carriage of the organism. Household contacts of patients with meningococcal meningitis have a 400- to 800-fold increased risk of developing meningitis. Prophylactic antibiotics should be started as soon as possible, preferably within 24 hours of exposure and within 14 days. Recommended regimens, all of which are 90% to 95% effective, for adults include rifampin 600 mg orally every 12 hours for 2 days, ciprofloxacin 500 mg orally for one dose, or ceftriaxone 250 mg intramuscularly for one dose. Regimens for children include rifampin 5 mg/kg orally every 12 hours for 2 days (less than 1 month of age), rifampin 10 mg/kg orally every 12 hours for 2 days (greater than 1 month of age), or ceftriaxone 125 mg intramuscularly for one dose (less than 12 years of age). It is not known whether close contacts who have been vaccinated will benefit from prophylaxis. Patients with meningococcal meningitis who are treated with antibiotics other than third-generation cephalosporins also should be considered for prophylaxis to eradicate the nasopharyngeal carrier state.

**Streptococcus Pneumoniae Meningitis**

*S. pneumoniae* is the most common cause of meningitis in adults and in children younger than 2 years of age. Pneumococcus is associated with the highest mortality observed with bacterial meningitis in adults (14%–18%), and coma and seizures are more common in pneumococcal meningitis. Patients at high risk for pneumococcal meningitis include the elderly, alcoholics, splenectomized patients, patients with sickle cell disease, and patients with cochlear implants. At least 50% of pneumococcal meningitis cases are due to a primary infection of the ears, sinuses, or lungs. Due to increases in pneumococcal resistance to high-dose penicillin, the preferred empirical treatment now includes a third-generation cephalosporin in combination with vancomycin.

All CSF isolates should be tested for penicillin and cephalosporin resistance by methods endorsed by the CLSI. Once in vitro sensitivity results are known, therapy may be tailored (see Table 70–3). Patients with a history of type I penicillin or cephalosporin allergy may be treated with vancomycin. Treatment should be continued for 10 to 14 days, after which no further maintenance therapy is required. Antimicrobial prophylaxis is not indicated for close contacts.

Administration of vaccines to high-risk individuals is a key strategy to reduce the risk of invasive pneumococcal disease. However, 2013 reports note only 82% of children aged 35 months completed the full series of the pneumococcal conjugate vaccine. The 23-valent pneumococcal vaccine targets serotypes that account for more than 90% of invasive disease in high-risk patients. However, the 23-valent vaccine does not produce a reliable immunologic response in children younger than 2 years, nor does it reduce pneumococcal carriage. The 7-valent pneumococcal protein-polysaccharide conjugate vaccine used between 2000 and 2010 targeted the seven most common serotypes in children and provided protection (94% reduction) against invasive pneumococcal disease (such as sepsis and meningitis) in children younger than 5 years. Widespread administration of the 7-valent conjugate vaccine to children has also contributed to a 28% reduction in invasive pneumococcal disease in adults. PCV13, a 13-valent vaccine introduced in 2010, confers protection against serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F. It is intended for use in children younger than 18 years in the same schedule as the 7-valent conjugate vaccine. PCV13 is specifically recommended for immunocompromised children aged 6 to 18 years. Immunization schedules provided by CDC are updated at least annually and should be consulted for additional details.

**Haemophilus Influenzae Meningitis**

Prior to the introduction of the Hib conjugate vaccine, *H. influenzae* type b was the most common cause of bacterial meningitis in the United States. Routine inoculation of pediatric patients against Hib has significantly reduced the incidence of Hib meningitis between 1998 and 2007. The Hib vaccine is also recommended for patients undergoing splenectomy. Hib meningitis disease is often associated with a parameningeal focus such as a sinus or middle ear infection. Due to β-lactamase–mediated resistance, the empirical treatment of choice is third-generation cephalosporins (e.g., ceftriaxone and cefotaxime). Treatment should be continued for 7 days, after which no further maintenance therapy is required. Close contacts of patients with *H. influenzae* type B meningitis should be evaluated for antimicrobial prophylaxis. The risk of Hib meningitis in close contacts may be up to 200- to 1000-fold higher than in the general population. Invasive Hib disease, including meningitis, should be reported to the local health department and the CDC. Prophylaxis to eliminate nasal and oropharyngeal carriage of Hib in exposed individuals should be initiated after consultation with local health officials. Rifampin (600 mg/day for adults; 20 mg/kg/day for children, maximum of 600 mg/day) is administered for 4 days. Rifampin prophylaxis is not necessary for individuals who have received the full Hib vaccine series. Exposed, unvaccinated children between 12 and 48 months of age should receive one dose of vaccine, and unvaccinated children 2 to 11 months of age should receive three doses of vaccine, as well as rifampin prophylaxis. According to the CDC, up to 18% of children at 35 months have not completed the Hib vaccine series.
Listeria monocytogenes Meningitis

*L. monocytogenes* is an intracellular gram-positive bacillus that contaminates foods, such as soft cheese, unpasteurized milk, raw meats and fish, processed meats, and raw vegetables. Bacteria from contaminated foods colonize the GI tract, pass into the bloodstream, and overcome natural cellular immune responses to cause infection. *L. monocytogenes* meningitis, usually observed in patients at extremes of age and in immunocompromised patients with depressed cellular immunity (including patients with leukemia, solid-organ transplants, and HIV/AIDS) has an overall mortality rate of up to 30%.29,30

Only a limited number of antibiotics show bactericidal activity against *Listeria*. The combination of high-dose ampicillin or penicillin G and an aminoglycoside is synergistic and bactericidal against *Listeria*. A total treatment course of at least 3 weeks is required. Because of concerns about the risk of nephrotoxicity with an extended treatment course of aminoglycosides, patients are treated with combination therapy for 10 days and may finish out the remainder of their treatment with ampicillin or penicillin alone.29 In penicillin-allergic patients, trimethoprim-sulfamethoxazole is the agent of choice due to documented in vitro bactericidal activity against *Listeria*, as well as good CNS penetration. Vancomycin and cephalosporins are not effective treatments for *Listeria* meningitis. Prophylaxis is not needed for close contacts, nor is suppressive therapy indicated. Patients with severe depression of cell-mediated immunity should be advised to avoid foods that may be contaminated with *Listeria*.

**Group B Streptococcus Meningitis**

Infection with group B *Streptococcus* (eg, *S. agalactiae*) is the most common cause of neonatal sepsis and meningitis. Around 15% to 35% of pregnant women are a carrier of group B *Streptococcus* in the vagina or rectum. Group B streptococci can be acquired during childbirth after exposure to infected secretions from the mother’s birth canal or rectum. Neonates born to women who are carriers are at very high risk (1 of every 100–200 babies) of developing invasive group B streptococcal disease.31 Neonatal meningitis is associated with significant morbidity and mortality. Synergistic treatment with penicillin or ampicillin, plus gentamicin, for 14 to 21 days is recommended for group B streptococcal meningitis.31

To reduce the risk of clinical group B streptococcal disease in neonates, pregnant women should be screened at 35 to 37 weeks’ gestation to determine whether they are carriers of group B streptococci.31 Intrapartum antibiotics (eg, penicillin or ampicillin) are recommended for pregnant women with the following characteristics: group B streptococcal carrier state detected at screening, history of group B streptococcal bacteriuria at any time during pregnancy, and history of delivery of infant with invasive group B streptococcal disease.31

**Gram-Negative Bacillary Meningitis**

Meningitis caused by enteric gram-negative bacilli is an important cause of morbidity and mortality in populations at risk, including those with diabetes, malignancy, cirrhosis, immunosuppression, advanced age, parameningeal infection, and/or a defect allowing communication from skin to CNS (eg, neurosurgery, congenital defects, cranial trauma).7

The optimal treatment for gram-negative bacillary meningitis is not well defined. The introduction of extended-spectrum cephalosporins has improved patient outcomes significantly. Although the third-generation cephalosporins ceftriaxone and cefotaxime provide good coverage for most Enterobacteriaceae, these antibiotics are not active against *P. aeruginosa*. Ceftazidime, cefepime, and carbapenems are effective in pseudomonal meningitis.15,17 Addition of an aminoglycoside may improve treatment results; however, CNS penetration of aminoglycosides is extremely poor, even in the setting of inflamed meninges. Intrathecal or intraventricular administration of aminoglycosides may be useful, but intraventricular antibiotics have been associated with increased mortality in neonates.25,32 Intrathecal therapy is accomplished by administering the antibiotic into the CSF via LP, whereas intraventricular therapy is usually administered into a reservoir implanted in the ventricles of the brain.

Initial therapy of suspected or documented pseudomonal meningitis should include an antipseudomonal β-lactam (eg, ceftazidime, meropenem) plus an aminoglycoside (eg tobramycin, amikacin). Although the carbapenem imipenem-cilastatin has similar activity to these β-lactams, its use is not recommended in meningitis because of the risk of seizures. Aminoglycosides may be useful, but intraventricular antibiotics have been associated with increased mortality in neonates.25,32 Intrathecal therapy is accomplished by administering the antibiotic into the CSF via LP, whereas intraventricular therapy is usually administered into a reservoir implanted in the ventricles of the brain.

**Postoperative Infections in the Neurosurgical Patient and Shunt Infections**

Patients who undergo neurosurgical procedures or have invasive or implanted foreign devices (eg, CSF shunts, intraspinal pumps or catheters, epidural catheters) are at risk for CNS infections. Key pathogens in postneurosurgical infections include coagulase-negative staphylococci, *S. aureus*, streptococci, propionibacteria, and gram-negative bacilli, including *P. aeruginosa*. Clinical signs and symptoms may be similar to those of other CNS infections, and there also may be evidence of malfunction of implanted hardware or visible signs of a postoperative wound infection.
Empirical therapy for postoperative infections in neurosurgical patients (including patients with CSF shunts) should include vancomycin in combination with either cefepime, ceftazidime, or meropenem. Linezolid reaches adequate CSF concentrations and resolves cases of meningitis refractory to vancomycin. However, data with linezolid are limited. The addition of rifampin may be considered for treatment of shunt infections. Removal of infected devices is desirable; aggressive antibiotic therapy (including high-dose IV antibiotic therapy plus intraventricular vancomycin and/or tobramycin) may be effective for patients in whom hardware removal is not possible. If methicillin-resistant *S. aureus* is identified as the causative organism, daptomycin may be considered an alternative therapy.

The use of prophylactic antibiotics against meningitis postcraniotomy remains controversial. One meta-analysis suggests that prophylaxis reduces rates of postoperative meningitis by nearly one-half. Breakthrough meningitis that does occur may be a result of drug-resistant pathogens. Brain abscesses are localized collections of pus within the cranium. These infections are difficult to treat due to the presence of walled-off infections in the brain tissue reducing antibiotic penetration. In addition to appropriate antimicrobial therapy (a discussion of which is beyond the scope of this chapter), surgical debridement is often required as an adjunctive measure. Surgical debridement may also be required in the management of neurosurgical postoperative infections.

**Viral Encephalitis and Meningitis**

Viral encephalitis and meningitis may mimic bacterial meningitis on clinical presentation but often can be differentiated by CSF findings (see Table 70–2). The most common viral pathogens are enteroviruses, which cause approximately 85% of cases of viral CNS infections. Other viruses that may cause CNS infections include arboviruses, HSV, cytomegalovirus, varicella-zoster virus, rotavirus, coronavirus, influenza viruses A and B, West Nile virus, and Epstein-Barr virus. Viral CNS infections are acquired through hematogenous or neuronal spread. Most cases of enteroviral meningitis or encephalitis are self-limiting with supportive treatment. However, arbovirus, West Nile virus, and Eastern equine virus infections are associated with a less favorable prognosis.

In contrast to other viral encephalitides, HSV type 1 and 2 encephalitis are treatable. Although rare (one case per 250,000 population per year in the United States), HSV encephalitis is a serious, life-threatening infection. More than 90% of HSV encephalitis in adults is due to HSV type 1, whereas HSV type 2 predominates in neonatal HSV encephalitis (greater than 70%). HSV encephalitis is the result of reactivation of a latent infection (two-thirds of cases) or a severe case of primary infection (one-third). Without effective treatment, the mortality rate may be as high as 85%, and survivors often have significant residual neurologic deficits. In accordance with 2008 IDSA guidelines, high-dose IV acyclovir is the drug of choice, given for 2 to 3 weeks at a dose of 10 mg/kg IV every 8 hours in adults, based on ideal body weight, and for 3 weeks at a dose of 20 mg/kg IV every 8 hours in neonates. Patients receiving acyclovir should maintain adequate hydration (consider continuous IV hydration) to help prevent acute kidney injury secondary to crystal nephropathy. Foscarnet 120 to 200 mg/kg/day divided every 8 to 12 hours for 2 to 3 weeks is the treatment of choice for acyclovir-resistant HSV.

**Opportunistic CNS Infections**

**Cerebral Toxoplasmosis** Across the globe, cerebral toxoplasmosis represents the most common focal brain infection in HIV-infected patients. Infection rates in the United States vary but are reported to be approximately 15% among patients with AIDS. The majority of cases occur in patients with CD4+ cell counts less than 100 cells/mm³ (100 × 10⁹/L). Potent antiretroviral therapy and primary prophylaxis (first-line option is sulfamethoxazole-trimethoprim) in IgG-positive patients has greatly reduced the disease burden. First-line therapy in toxoplasmosis encephalitis is pyrimethamine plus sulfadiazine, given concomitantly with leucovorin to prevent severe hematologic adverse effects secondary to pyrimethamine (see tables for dosing). Clindamycin may be substituted for sulfadiazine in cases of contraindications to sulfa-based therapy. Sulfamethoxazole-trimethoprim may also be an option, specifically in patients unable to take oral therapy. Adjunctive corticosteroids and anticonvulsant therapy should be considered to reduce sequelae from the inflammatory process and control active seizures, respectively.

**Cryptococcal Meningitis** CNS disease secondary to *Cryptococcus neoformans* is primarily observed in severely immunocompromised hosts, such as those with HIV infection. Potent antiretroviral therapy has significantly reduced the disease burden from preantiretroviral therapy rates of 5% to 8% in developed countries. The majority of disease occurs in patients with CD4+ cell counts less than 50 cells/mm³ (50 × 10⁹/L). First-line therapy is considered amphotericin B deoxycholate 0.7 mg/kg IV daily plus flucytosine 100 mg/kg/day orally in four divided doses for a minimum of 2 weeks. Therapeutic drug monitoring may be considered for flucytosine to help reduce the risk of adverse effects. Development of renal dysfunction as a result of disease and/or drug toxicity should be closely monitored and may prompt dose reduction or possible switch to alternative lipid formulations of amphotericin, which may be less nephrotoxic. High-dose fluconazole is considered an alternative first-line therapy, especially in resource-limited areas. Secondary prophylaxis with fluconazole for an indefinite period is recommended following the completion of at least 2 weeks of induction therapy and 8 weeks of maintenance therapy with fluconazole.

**Adjunctive Dexamethasone Therapy**

The adjunctive agent dexamethasone improves outcomes in selected patient populations with bacterial meningitis. Dexamethasone inhibits the release of proinflammatory cytokines and limits the CNS inflammatory response stimulated by infection and antibiotic therapy.

Clinical benefit in reducing neurologic deficits (primarily by reducing hearing loss) has been observed in infants and children, if dexamethasone is initiated prior to antibiotic therapy. The American Academy of Pediatrics recommends dexamethasone (0.15 mg/kg IV every 6 hours for 2 to 4 days) for infants and children at least 6 weeks of age with Hib meningitis and consideration of dexamethasone in pneumococcal meningitis. In contrast to this recommendation, a large multicenter cohort study failed to show any mortality benefit of adjunctive dexamethasone therapy regardless of age or responsible pathogen (*S. pneumoniae* or *N. meningitidis*). Dexamethasone should be initiated 10 to 20 minutes before or no later than the time of initiation of antibiotic therapy; it is not recommended for infants and children who have already received antibiotic therapy because
it is unlikely to improve treatment outcome in these patients. There are insufficient data to make a recommendation regarding the use of adjunctive dexamethasone therapy in neonatal meningitis.

In adults, a significant benefit was observed with dexamethasone in reducing meningitis complications, including death, particularly in patients with pneumococcal meningitis. The IDSA recommends dexamethasone 0.15 mg/kg IV every 6 hours for 2 to 4 days (with the first dose administered 10 to 20 minutes before or with the first dose of antibiotics) in adults with suspected or proven pneumococcal meningitis. Dexamethasone is not recommended for adults who have already received antibiotic therapy. Some clinicians would administer dexamethasone to all adults with meningitis pending results of laboratory tests. Benefit of dexamethasone in bacterial meningitis in a HIV-positive population has not been clearly established.

There is controversy regarding the administration of dexamethasone to patients requiring vancomycin for pneumococcal meningitis. Animal models indicate that concurrent steroid use reduces vancomycin penetration into the CSF by 42% to 77% and delays CSF sterilization. A prospective evaluation in patients with pneumococcal meningitis receiving vancomycin and adjunctive dexamethasone demonstrated that adequate concentrations of vancomycin (nearly 30% of serum concentrations) were achievable in the CSF, provided appropriate vancomycin dosage was utilized. Treatment failures have been reported in adults with resistant pneumococcal meningitis who were treated with dexamethasone, but the risk–benefit of using dexamethasone in these patients cannot be defined at this time. Animal models indicate a benefit of adding rifampin in patients with resistant pneumococcal meningitis whenever dexamethasone is used.

OUTCOME EVALUATION

Monitor patients with CNS infections continuously throughout their treatment course to evaluate their progress toward achieving treatment goals, including relief of symptoms, eradication of infection, and reduction of inflammation to prevent death and the development of neurologic deficits. These treatment goals are best achieved by appropriate parenteral antimicrobial therapy, including empirical therapy to cover the most likely pathogens, followed by directed therapy after culture and sensitivity results are known. Components of a monitoring plan to assess efficacy and safety of antimicrobial therapy of CNS infections include clinical signs and symptoms and laboratory data (eg, CSF findings, culture, sensitivity data).

Patient Care Process

**Patient Assessment:**
- Assess patient allergies, including severity of reactions
- Determine if patient has received recent antibiotics that may influence LP results or treatment decisions
- Determine from a medication history if any medicines may be associated with drug-induced aseptic meningitis

**Therapy Evaluation:**
- Assess LP results, results of antigenic testing, and culture and susceptibility for additional data to help streamline therapy
- Monitor patient for any antimicrobial-related adverse events. Provide recommendations for necessary prophylaxis based on causative pathogen and exposure history

**Care Plan Development:**
- Based on patient-specific factors and local susceptibility patterns, determine appropriate empirical antimicrobial treatment plan
- Collaborate with treatment team to ensure timely administration of antibiotic in relation to performing LP and obtaining blood cultures
- Collaborate with treatment team to determine appropriate administration of adjunctive corticosteroid therapy

**Follow-up Evaluation:**
- Determine appropriate length of therapy for diagnosed CNS infection
- Provide recommendations for outpatient parenteral therapy as needed upon discharge from acute care facility

During the patient’s treatment course, monitor clinical signs and symptoms at least three times daily. Trends are more important than one-time assessments. Expect fever, headache, nausea and vomiting, and malaise to begin to improve within 24 to 48 hours of initiation of antimicrobial therapy and supportive care. Evaluate the patient for resolution of neurologic signs and symptoms, such as altered mental status and nuchal rigidity, as the infection is eradicated and inflammation is reduced within the CNS. Expect improvement and subsequent resolution of signs and symptoms as the treatment course continues. At the time of hospital discharge, arrange outpatient follow-up for several weeks to months depending on the causative pathogen, clinical treatment course, and patient’s underlying comorbidities.

Monitoring of laboratory tests is important in patients receiving treatment for CNS infections. Monitor CSF and blood cultures so that antimicrobial therapy can be tailored to the etiologic organisms. Follow-up cultures may be obtained to prove eradication of the organism(s) or treatment failure. Although repeat LP generally is not performed, consider repeat LP for patients who do not respond clinically after 48 hours of appropriate antimicrobial therapy, especially those with resistant pneumococcus who receive dexamethasone. Other candidates for repeat LP include those with infection with gram-negative bacilli, prolonged fever, and recurrent meningitis. Repeat the

---

**Patient Encounter 2, Part 3**

As noted, BB had not received any vaccinations since birth. The parents are concerned and inquire about the need for antibiotic prophylaxis for the family and now are considering vaccination for BB.

**Who should receive antimicrobial prophylaxis for H. influenzae?**

**Who should receive vaccination against Hib disease?**

**How is vaccination important in the prevention of Hib disease, especially for BB?**
LP in neonates to determine the duration of therapy. Repeat LP also may be performed to relieve elevated intracranial pressure. Expect repeat blood cultures to become negative quickly during therapy and the serum WBC count to improve and normalize with appropriate antimicrobial therapy.

Evaluate antimicrobial dosing regimens to ensure efficacy of the treatment regimen. Trough vancomycin concentrations of 15 to 20 mg/L (10–14 μmol/L) are recommended for the treatment of CNS infections.14 Monitor patients for drug adverse effects, drug allergies, and drug interactions. The specific safety monitoring plan will depend on the antibiotic(s) used (Table 70–3). Pay close attention to concomitant medications in patients on rifampin for treatment or prophylaxis. Rifampin is a potent inducer of hepatic metabolism and may reduce the efficacy of other drugs metabolized by the cytochrome P-450 enzyme pathway.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the common pathogens that cause community-acquired pneumonia (CAP), aspiration pneumonia, ventilator-associated pneumonia (VAP; early versus late onset), and health care–associated pneumonia.
2. Explain the host defenses that protect against infection.
3. Explain the pathophysiology of pneumonia.
4. List the signs and symptoms associated with CAP and VAP.
5. Identify patient and organism factors required to guide the selection of a specific antimicrobial regimen for an individual patient.
6. Design an appropriate empirical antimicrobial regimen based on patient-specific data for an individual with CAP, aspiration pneumonia, and VAP or health care–associated pneumonia (early vs late onset).
7. Design an appropriate antimicrobial regimen based on both patient- and organism-specific data.
8. Develop a monitoring plan based on patient-specific information for a patient with CAP and health care–associated pneumonia or VAP.
9. Formulate appropriate educational information to be provided to a patient with pneumonia.

INTRODUCTION

Pneumonia is inflammation of the lung with consolidation. The cause of the inflammation is infection, which can be caused by a wide range of organisms. There are five classifications of pneumonia: community-acquired, aspiration, hospital-acquired, ventilator-associated, and health care-associated. Patients who develop pneumonia in the outpatient setting and have not been in any health care facilities, which include wound care and hemodialysis clinics, have community-acquired pneumonia (CAP). Pneumonia can be caused by aspiration of either oropharyngeal or gastrointestinal contents. Hospital-acquired pneumonia (HAP) is defined as pneumonia that occurs 48 hours or more after admission. Ventilator-associated pneumonia (VAP) requires endotracheal intubation for at least 48 to 72 hours before the onset of pneumonia. Health care–associated pneumonia (HCAP), which is defined as pneumonia occurring in any patient hospitalized for at least 2 days within 90 days of the onset of the infection; residing in a nursing home or long-term care facility; received IV antibiotic therapy, wound care, or chemotherapy within the last 30 days prior to the onset of the infection; or having attended a hemodialysis clinic.

EPIDEMIOLOGY AND ETIOLOGY

Etiology and Mortality Rates

The etiology of bacterial pneumonia varies in accordance with the type of pneumonia. Table 71–1 lists the more common pathogens associated with the various types or classifications of pneumonia. Streptococcus pneumoniae colonizes the nasopharyngeal flora in up to 50% of healthy adults and may colonize the lower airways in individuals with chronic bronchitis. It possesses many virulence factors, enhancing its ability to cause infection in the respiratory tract. Therefore, it is not surprising that S. pneumoniae is the predominant bacterial pathogen associated with CAP. The second most common pathogen is one of the atypical organisms, Mycoplasma pneumoniae. Nontypeable Haemophilus influenzae intermittently colonizes about 80% of the population, and the incidence of permanent colonization increases in chronic obstructive pulmonary disease (COPD) patients and those with cystic fibrosis. Therefore, the likelihood of nontypeable H. influenzae causing pneumonia increases in COPD patients. Moraxella catarrhalis is a more common cause of pneumonia in the very young and the very old. Chlamydia pneumoniae and Legionella pneumophila are less frequent causes than the other bacterial and atypical organisms. Community-acquired methicillin-resistant Staphylococcus aureus (CA-MRSA) is associated with necrotizing and severe pneumonia in healthy children and young adults. Less than 2% of all CA-MRSA infections are pneumonia (most are skin and soft tissue); however, the number of reports of pneumonia are increasing.

Viruses are a common cause of CAP in children (about 65%) and in adults ranges from 12% to 29%. Mixed infections of viruses and bacteria have been increasingly identified in 11% to 56% of cases. Viruses most often associated with pneumonia in adults include influenza A and B and rhinoviruses, but can be caused by adenoviruses, enteroviruses, cytomegalovirus,

PATHOPHYSIOLOGY

Local Host Defenses

Local host defenses of both the upper and lower respiratory tract along with the anatomy of the airways are important in preventing infection. Upper respiratory defenses include the mucociliary apparatus of the nasopharynx, nasal hair, normal bacterial flora, IgA, and complement. Local host defenses of the lower respiratory tract include cough, mucociliary apparatus of the trachea and bronchi, antibodies (IgA, IgM, and IgG), complement, and alveolar macrophages. Mucous lines the cells of the respiratory tract, forming a protective barrier for the cells. This minimizes the ability of organisms to attach to the cells and initiate the infectious process. The squamous epithelial cells of the upper respiratory tract are not ciliated, but those of the columnar epithelial cells of the lower tract are. The cilia beat in a uniform fashion upward, moving particles up and out of the lower respiratory tract.

Particles greater than 10 microns (μm) are efficiently trapped by mechanisms of the upper airway and are removed from the nasopharynx either by swallowing or by expulsion. The mucociliary apparatus of the trachea and bronchi along with the sharp angles of the bronchi often are effective at trapping and eliminating particles that are 2 to 10 μm in size. Particles in the range of 0.5 to 1 μm may consistently reach the alveolar sacs of the lung. Microorganisms fall within this size range, and if they reach the alveolar sacs, then infection may result if alveolar macrophages and other defenses cannot contain the organisms.

Aspiration

Aspiration of the oropharyngeal or gastric contents may lead to aspiration pneumonia or chemical (acid) pneumonitis. Risk factors for aspiration include dysphagia, change in oropharyngeal colonization, gastroesophageal reflux (GER), and decreased host defenses.

Dysphagia can be caused by stroke or other neurologic disorders, seizures, alcoholism, and aging. Oropharyngeal colonization may be altered by oral/dental disease, poor oral hygiene, tube feedings, or medications. This could result in a higher number

Patient Encounter 1

A 65-year-old man, who only speaks Spanish, presents to your ED complaining of difficulty breathing and shortness of breath. He is accompanied by his daughter and she serves as his translator. His physical examination reveals that he is alert and oriented ×3, has decreased breath sounds on the left side compared with the right, and has rales and crackles in the left lower lobe. His temperature is 38.3°C (100.9°F), respiratory rate is 16 breaths/min, and blood pressure is 120/80 mm Hg. She indicates he is a bit confused and this is not normal for him.

**What are his signs and symptoms of pneumonia?**

**What are the top two bacterial organisms that could be causing the pneumonia?**

**What are the top two atypical organisms and top two viruses that could be causing the pneumonia?**

**What are the advantages and disadvantages of having a family member serve as an interpreter for the patient?**
of anaerobic organisms in the oral cavity or colonization with enteric gram-negative bacilli. Acid suppression is an important factor in the treatment of GER disease, which may allow enteric gram-negative bacilli to colonize the gastric contents. Finally, impaired mucous production or cilia function, decreased immunoglobulin in secretions, and altered cough reflex may increase the likelihood of infection following an aspiration. The infection can result in a necrotizing pneumonia or lung abscess.

HAP, VAP, HCAP

Risk factors for the development of HAP fall into four general categories: intubation and mechanical ventilation, aspiration, oropharyngeal colonization, and hyperglycemia.

Intubation and mechanical ventilation increase the risk of HAP/VAP. VAP may also be related to colonization of the ventilator circuit. Risk of aspiration is increased in these patients due to the supine positioning of the patient, the presence of the endotracheal tube preventing the closure of the epiglottis over the glottis, enteral feedings, GER, and medications. Oropharyngeal colonization is affected by the use of antibiotics, oral antiseptics, and poor infection control measures, which may decrease normal commensal flora and allow pathogenic organisms to colonize the oral cavity. Hyperglycemia may directly or indirectly promote infection; two proposed mechanisms are inhibiting phagocytosis and providing additional nutrients for bacteria.

Once breakdown of the local host defenses occurs and organisms invade the lung tissue, an inflammatory response is generated either by the organisms causing tissue damage or by the immune response to the presence of the organisms. This inflammatory response either can remain localized in the infected tissue or can become systemic. The role of the alveolar macrophages is twofold. First, to engulf the organisms and to contain the infection, and second, to process the antigens for presentation in order to generate a specific immune response by either the patient’s symptoms, minimize or prevent complications, and decrease mortality. Potential complications secondary to pneumonia include further decline in pulmonary function in patients with underlying pulmonary disease, prolonged mechanical ventilation, bacteremia/sepsis/septic shock, and death. Use of an antimicrobial agent with the narrowest spectrum of activity that covers the suspected pathogen(s) without having activity against organisms not involved in the infection is preferred to minimize the development of resistance.

Patient Encounter 2

A 68-year-old woman was admitted to the hospital secondary to a motor vehicle accident. One day after admission she developed respiratory failure and was intubated. She has remained intubated and on day 9 the chest x-ray revealed bilateral lower lobe infiltrates. She is sedated but does respond to commands. Her temperature is 38.9°C (102°F), her blood pressure is 110/75 mm Hg, and her WBC is 20.4 × 10³/mm³ (20.4 × 10⁹/L) with a cell differential of 75% (0.75) neutrophils, 7% (0.07) bands, 15% (0.15) lymphocytes, and 3% (0.03) monocytes.

What are her signs and symptoms of pneumonia? What are the top three bacterial organisms that could be causing the pneumonia?

Clinical Presentation and Diagnosis

Several scoring systems are available for assessing the severity of the pneumonia: the Pneumonia Severity Index (PSI); confusion, uremia, respiratory rate, blood pressure (CURB); CURB-65 (for those greater than equal to 65 years of age), and systolic BP, oxygenation, age, and respiratory rate (SOAR). PSI or CURB-65 scores less than or equal to 70 and less than 2 respectively, correlate with mild disease that should be treated in the outpatient setting. These models are used by physicians to help determine the severity of illness, prognosis (mortality risk), and the need for hospitalization and then to help guide in the selection of antimicrobial therapy, along with the use of published guidelines.

Treatment

The goal of antibiotic therapy is to eliminate the patient’s symptoms, minimize or prevent complications, and decrease mortality. Potential complications secondary to pneumonia include further decline in pulmonary function in patients with underlying pulmonary disease, prolonged mechanical ventilation, bacteremia/sepsis/septic shock, and death. Use of an antimicrobial agent with the narrowest spectrum of activity that covers the suspected pathogen(s) without having activity against organisms not involved in the infection is preferred to minimize the development of resistance.

General Approach to Treatment

Designing a therapeutic regimen for any patient with any type of pneumonia begins with three general categories of consideration:

1. Patient-specific factors that will impact therapy.
2. The top two to three organisms likely causing the infection and resistance issues associated with each organism.
3. The antimicrobials that will cover these organisms. The spectrum should not be too broad or narrow; they should penetrate into the site of infection and be the most cost effective.

Patient factors that need to be considered include age, renal function, drug allergies and/or drug intolerances, immune status (diabetes, neutropenia, or immunocompromised host), cardiopulmonary disease, pregnancy, medical insurance and prescription coverage, exposure to resistant organisms, and prior antibiotic exposure(s).

- The most common pathogens vary with the type of pneumonia, and they are listed in Table 71–1. M. pneumoniae lacks a cell wall; therefore, β-lactam drugs have no activity against this organism. The atypical organisms have not changed in recent years with respect to antibiotic resistance. β-Lactamase production in H. influenzae has remained relatively steady over the last 5 to 10 years, and the rate is approximately 25%. S. pneumoniae has developed resistance mechanisms against many classes of antimicrobials, and the mechanisms include the following:
  - Alteration of the penicillin-binding proteins (PBPs), inactivating β-lactams
  - Efflux or methylation of the ribosome-inactivating macrolides
Clinical Presentation of CAP or Aspiration Pneumonia

General
Patients may experience nonrespiratory symptoms in addition to respiratory symptoms. With increasing age, both respiratory and nonrespiratory symptoms decrease in frequency.

Key Concept: Symptoms
- Respiratory—cough (productive or nonproductive), shortness of breath, and difficulty breathing
- Nonrespiratory—fever, fatigue, sweats, headache, myalgias, mental status changes

Key Concept: Signs
- Temperature may increase or decrease from baseline, but most often it is elevated. The temperature may be sustained or intermittent.
- Respiratory rate is often increased. Cyanosis, increased respiratory rate, and use of accessory muscles of respiration are suggestive of severe respiratory compromise.
- Breath sounds may be diminished. Rales or rhonchi may be heard.
- Confusion, lethargy, and disorientation are relatively common in elderly patients.

Diagnostic Tests
- Chest x-ray should reveal single or multiple infiltrates.
- Oxygen saturation should be more than 90% (0.90), as determined by pulse oximetry.
- Arterial blood gases are beneficial primarily in patients with severe pneumonia.

Laboratory Tests
- The WBC may or may not be elevated. In elderly patients, a drop in WBCs also can be a sign of infection. The differential should show a predominance of neutrophils if a bacterial infection is present. The presence of bands also could be an indicator of bacterial infection. Elevated lymphocytes are an indication of viral infection.
- Blood urea nitrogen (BUN) and serum creatinine are needed to dose antibiotics appropriately and to minimize or prevent drug toxicity (especially in the elderly patient).

Microbiology Tests
- Sputum Gram stain should demonstrate the presence of WBCs and the absence of squamous epithelial cells. It may or may not show a predominance of one type of organism.
- Sputum culture and susceptibility are not obtained in the outpatient setting. The value of culturing is debated owing to the rapidity in which S. pneumoniae dies in transport media and the inability to reliably or routinely culture atypical organisms.
- Bronchoscopy may be performed to improve the ability to diagnose pneumonia. Tracheal secretions often are better specimens than sputum owing to the lack of oral contamination.
- Serology (IgM and IgG) is useful in determining the presence of atypical organisms such as Mycoplasma and Chlamydia.
- Urinary Legionella antigen is used to diagnose L. pneumophila.
- Polymerase chain reaction (PCR) is being used more frequently to detect the DNA of respiratory pathogens.
- Blood cultures should be obtained in all patients admitted to the ICU with pneumonia. Positive blood cultures are present in about 1% to 20% of patients with CAP.

Clinical Presentation of Severe CAP or Aspiration Pneumonia

General
In approximately 10% of patients, CAP will be severe enough to require intensive care or mechanical ventilation.

Key Concept: Symptoms
- Respiratory—cough (productive or nonproductive), shortness of breath, difficulty breathing
- Nonrespiratory—fever, fatigue, sweats, headache, myalgias, mental status changes

Signs
- Temperature may increase or decrease from baseline, but most often it is elevated. The temperature may be sustained or intermittent.
- Respiratory rate greater than 30 breaths/min. Cyanosis and use of accessory muscles of respiration along with the increased respiratory rate are suggestive of severe respiratory compromise.
- Hypotension (systolic blood pressure less than 90 mm Hg or diastolic blood pressure less than 60 mm Hg).
- Requirement for vasopressors.
- Breath sounds may be diminished. Rales or rhonchi may be heard.
- Urine output less than 20 mL/hour or less than 80 mL over 4 hours.
- Confusion, lethargy, and disorientation are relatively common in elderly patients.

Diagnostic Tests
As stated in the clinical presentation of community-acquired or aspiration pneumonia.

Laboratory Tests
As stated in the clinical presentation of community-acquired or aspiration pneumonia.

Microbiology Tests
As stated in the clinical presentation of community-acquired or aspiration pneumonia.
Diagnosis of VAP

Clinical Strategy
- Chest x-ray should reveal a new infiltrate plus two of the following:
  - Temperature greater than 38.0°C (100.4°F)
  - Leukocytosis or leukopenia
  - Purulent secretions
  - Semiquantitative cultures are obtained to identify the pathogen(s)
  - Tracheal aspirates grow more organisms than invasive quantitative cultures and often result in overuse of antibiotics
- The major limitation of the clinical strategy is the consistent overprescribing of antibiotics

Recommended Diagnostic Strategy
- Combination of the preceding two methods:
  - Obtain either a quantitative or semiquantitative culture of a lower respiratory sample. Initiate empirical broad-spectrum antibiotic therapy
  - Days 2 and 3: Check culture results, and assess clinical response to therapy: temperature, WBCs, chest x-ray, oxygenation, purulent sputum, hemodynamic changes, and organ function
- Assess clinical improvement at 48 to 72 hours:
  - Improvement and culture negative—stop antibiotics
  - Improvement and culture positive—narrow antibiotic therapy
  - No improvement and culture negative—consider other pathogens, complications, or other diagnosis
  - No improvement and culture positive—change antibiotic therapy and consider other pathogens, complications, or other diagnosis

Bacteriologic Strategy
- Uses quantitative culture of endotracheal aspirates, bronchoalveolar lavage (BAL), or protected specimen brush (PSB)
  - Greater than or equal to $10^6$ cfu/mL ($10^9$ cfu/L) for endotracheal aspirates
  - Greater than or equal to $10^4$ to $10^5$ cfu/mL ($10^7$–$10^8$ cfu/L) for BAL
  - Greater than or equal to $10^3$ cfu/mL ($10^6$ cfu/L) for PSB
- The advantage of this method is that it separates colonization from infection better than culturing tracheal aspirates
- The limitation is the potential misinterpretation of negative culture results. These samples should be obtained prior to antibiotics being started

Patient Encounter 3, Part 1: Medical History, Physical Examination, and Diagnostic Tests

A 65-year-old man presents to your ED complaining of difficulty breathing and shortness of breath.

PMH: Hypertension for 8 years, COPD for 5 years, currently controlled

FH: Father died of lung cancer at the age of 68 years; mother died of natural causes

SH: Denies alcohol use, smokes 1 pack per day for 15 years. Lives alone and has 2 children. He is 5’8” (173 cm) and weighs 140 lb (63.6 kg)

Allergies: NKDA

Meds: Hydrochlorothiazide 25 mg orally once daily; fluticasone propionate/salmeterol 250/50 mcg one inhalation twice daily; albuterol inhaler 1 to 2 inhalations every 4 hours as needed for shortness of breath

ROS: (+) difficulty breathing and shortness of breath; (–) chest pain, N/V/D, change in appetite

PE:
VS: BP 120/80, P 82, RR 22, T 38.6°C (101.5°F)
CV: RRR, normal $S_1$, $S_2$; no murmurs, rubs, or gallops

Lungs: Decreased breath sounds on the left side compared with the right with rales and crackles in the left lower lobe

Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly, heme (–) stool

Neuro: Oriented to name and place, confused

Diagnostic Tests: Chest x-ray: left lower lobe infiltrates; oxygen saturation 84% (0.84) on room air

Labs: WBCs $14.2 \times 10^3$/mm$^3$ ($14.2 \times 10^9$/L) with a cell differential of 70% (0.70) neutrophils, 2% (0.02) bands, 20% (0.20) lymphocytes, and 8% (0.08) monocytes; BUN 9 mg/dL (3.2 mmol/L), SCr 0.9 mg/dL (80 μmol/L), glucose 90 mg/dL (5.0 mmol/L); sputum Gram stain: moderate gram-positive cocci, few gram-negative bacilli, many WBCs; sputum culture is pending

Given this additional information, what is your assessment of the patient’s condition?

Identify your treatment goals for the patient.

What organisms should you include in your list of potential pathogens?

What pharmacologic agents are available for treating this patient?
• Ribosome protection (tetM gene) inactivating tetracyclines
• Alteration of DNA gyrase or topoisomerase IV inactivating fluoroquinolones

*S. pneumoniae* resistance to commonly prescribed antimicrobials such as the penicillins and macrolides/azalides dramatically increased in the late 1980s through the mid- to late 1990s and has remained relatively flat in the 2000s. Resistance information collected nationally along with susceptibility testing for a new antimicrobials, demonstrates that average national rates of resistance to penicillin and macrolides were approximately 13% and 38%, respectively. Resistance to trimethoprim/sulfamethoxazole is approximately 25%, and fluoroquinolone resistance remains less than 0.5%.26

For HCAP, HAP, and VAP, the risk of infection from an MDR pathogen is relatively high. The number and type of organisms that are MDR vary from hospital to hospital, making it more difficult to generate guidelines for treatment. Therefore, the treatment recommendations may be too broad or too narrow for any given institution. Treating patients with HCAP, HAP, or VAP is more complex than treating patients with CAP. There are many factors to consider, and one of those relates to the timing of infection to the most likely pathogens. Early-onset infection is less likely to be caused by MDR pathogens than late-onset infection. In early-onset infection, community pathogens such as pneumococcus, *Legionella*, and *Mycoplasma* need to be considered as well as some of the hospital pathogens. Patients developing late-onset pneumonia are at increased risk for resistant pathogens or MDR pathogens such as MRSA, enteric gram-negative bacilli, *Pseudomonas*, and *Acinetobacter*. Risk factors for developing infection caused by a resistant pathogen are as follows:

• Antimicrobial therapy in preceding 90 days
• Current hospitalization of at least 5 days
• High occurrence of antibiotic resistance in the community or in the specific hospital unit
• Immunosuppressive disease and/or therapy

• Presence of risk factors for HCAP:
  • Hospitalization for 2 days or more in the preceding 90 days
  • Residence in a nursing home or extended-care facility
  • Home infusion therapy (including antibiotics)
  • Peritoneal or hemodialysis within 30 days
  • Home wound care
  • Close contact family member with MDR pathogen

Once these issues are addressed, antimicrobial therapy can be selected and initiated. The patient- and drug-related categories are common to all types of pneumonia, but the organisms vary with the type of pneumonia. Guidelines have been generated by experts in the field for all types of pneumonia. These guidelines were generated to provide practitioners with evidence-based therapeutic options for the management of patients with pneumonia. The evidence-based guidelines generated by the American Thoracic Society and Infectious Diseases Society of America were derived from VAP and applied to HCAP and HAP.

**Pharmacologic Therapy for CAP**

*Treatment of CAP is predominantly empiric, that is, treatment is started without knowing the causative pathogen.* The most recent guidelines are the result of a collaboration between the Infectious Diseases Society of America and the American Thoracic Society.27 The approach to patient care is based on the classification of patients into two broad categories, outpatient and inpatient, and then further dividing the groups by comorbid conditions and location in the hospital, respectively. These guidelines use patient-specific data along with predominant pathogen information to design appropriate empirical antimicrobial regimens. Table 71–2 summarizes these therapeutic options.

**► Adult Outpatient Previously Healthy**

First-line therapeutic options for treating previously healthy adults include use of a macrolide (erythromycin, clarithromycin)

---

**Patient Encounter 3, Part 2: Medical History, Physical Examination, and Diagnostic Tests**

A 68-year-old woman was admitted to the hospital secondary to a motor vehicle accident. One day after admission she developed respiratory failure and was intubated. She has remained intubated and on day 9 the chest x-ray revealed bilateral lower lobe infiltrates. She is sedated but does respond to commands.

**PMH:** Hypertension for 15 years, currently controlled

**FH:** Father and mother deceased from natural causes. Both had hypertension, mother had hypothyroidism

**SH:** Denies tobacco, social alcohol one to two glasses of wine per week. She lives with her husband; retired teacher. She is 5’6” in (168 cm) and weighs 68.2 kg (150 lb)

**Allergies:** Penicillin—hives

**Meds:** Losartan 50 mg orally once daily

**PE:**

**VS:** BP 100/70, P 78, T 38.7°C (101.6°F)

**CV:** RRR, normal S1, S2; no murmurs, rubs, or gallops

**Abd:** Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly

**Diagnostic Tests:** Chest x-ray: bilateral lower lobe infiltrates; oxygen saturation 98% (0.98) on ventilator

**Labs:** WBC is 20.4 × 10^9/mm^3 (20.4 × 10^3/L) with a cell differential of 75% (0.75) neutrophils, 7% (0.07) bands, 15% (0.15) lymphocytes, and 3% (0.03) monocytes; BUN 10 mg/dL (3.6 mmol/L), SCr 0.9 mg/dL (80 μmol/L); BAL Gram stain: many gram-negative bacilli, moderate gram-positive cocci in clusters, many WBCs; culture is pending

*Given this additional information, what is your assessment of the patient’s condition?*

**Identify your treatment goals for the patient.**

**What organisms should you include in your list of potential pathogens?**

**What pharmacologic agents are available for treating this patient?**
or an azalide (azithromycin) or doxycycline. If a patient has failed therapy with a macrolide, azalide, or doxycycline, one has to consider why the patient failed. The most common reasons are either medication adherence issues or the presence of resistant organisms. If a resistant organism is suspected, then use of one of the respiratory fluoroquinolones active against S. pneumoniae (gemifloxacin, levofloxacin, or moxifloxacin) is warranted.

### Adult Outpatient with Comorbid Conditions

The comorbid conditions that can impact therapy and outcomes in patients with CAP include diabetes mellitus, COPD, chronic heart, liver, or renal disease, alcoholism, malignancy, asplenia, and immunosuppressive condition or use of immunosuppressive drugs. If the patient did not receive antibiotics in the last 3 months, then either a respiratory fluoroquinolone alone or a combination of an oral β-lactam agent plus a macrolide or azalide is recommended. If the patient received an antibiotic in the last 3 months, the recommendation is to use an agent from a different class. Doxycycline is an acceptable alternative to a macrolide or azalide.

### Adult Inpatient Not in the ICU

For patients admitted to the hospital with CAP, the severity of illness is generally increased (caused either by the organism itself or the comorbidity). If the patient did not receive antibiotics in the last 3 months, the recommendation is to use an agent from a different class. Doxycycline is an acceptable alternative to a macrolide or azalide.
or underlying comorbidities in the patient), and the pathogens are essentially the same as in the outpatient setting. Recommendations are to use either a respiratory fluoroquinolone alone or a combination of an IV β-lactam antimicrobial agent plus an advanced macrolide/azalide (clarithromycin/azithromycin) or doxycycline. The recommended β-lactams include cefotaxime, ceftriaxone, ampicillin-sulbactam, or ertapenem.27 The first antibiotic dose should be administered within the first 24 hours of admission. Conversion to oral therapy should occur when the patient is hemodynamically stable, improving clinically, and able to take oral medications, which often is within 48 to 72 hours for most patients. Discharge from the hospital should be as soon as the patient is stable and without other medical complications. The need to observe the patient in the hospital on their oral antibiotic is not necessary.27

► Adult Inpatient in the ICU

Patients admitted to the ICU have severe pneumonia, and the likely etiology includes *S. pneumoniae* and *H. influenzae* as in the other categories; however, the incidence of *L. pneumophila* increases in this setting and should be considered a potential pathogen. In addition, enteric gram-negative bacilli and *S. aureus* are more frequently the cause of the pneumonia in these patients. The recommendations are to treat with an IV β-lactam plus either azithromycin or a respiratory fluoroquinolone. These combination therapies minimize the risk of treatment failure due to a resistant pathogen as well as provide broad coverage.27 The β-lactams are the same as for inpatient non-ICU treatment. If the patient is allergic to β-lactams, then aztreonam plus a respiratory fluoroquinolone are preferred.

If *P. aeruginosa* is suspected, then the antimicrobial treatment must be broadened to cover *Pseudomonas* as well as the organisms listed previously. Owing to the high resistance rates observed with *Pseudomonas*, the recommended regimens empirically double cover the *Pseudomonas* to ensure at least one of the antibiotics is active against it. The regimens include the use of an antipseudomonal cephalosporin, an antipseudomonal β-lactam (cefepime, ceftazidime, piperacillin/tazobactam, imipenem, or meropenem), plus either ciprofloxacin or levofloxacin or an aminoglycoside. If the aminoglycoside is chosen, then either IV azithromycin or a respiratory fluoroquinolone should be added to cover *S. pneumoniae* and the atypical bacterial organisms.27

If CA-MRSA is suspected in the patient, then the addition of vancomycin or linezolid to the preceding regimen should be considered. Daptomycin cannot be used because surfactant in the lung inactivates the drug, thus rendering it ineffective for pneumonia. CA-MRSA can cause a necrotizing pneumonia, and the cause is believed to be due to its many virulence factors, including the Panton-Valentine leukocidin toxin.6 In these patients the use of an agent that decreases toxin production may be beneficial. Linezolid decreases toxin production; the other recommended agents to decrease toxin production and added to vancomycin therapy are clindamycin or a respiratory fluoroquinolone.27

► Influenza

Influenza viruses A and B can cause pneumonia in pediatric and adult patients. Amantadine and rimantadine are available oral agents with activity against influenza virus type A. If started within 48 hours of the onset of the first symptoms, they reduce the duration of the illness by about 1.3 days. Oseltamivir and zanamivir are oral agents active against both type A and B influenza that reduce the duration of the illness by about 1.3 days if initiated within 40 to 48 hours of the first symptoms.28 For active infection beyond the first 48 hours, none of these agents are effective in treating infection, and supportive care is the best treatment for these patients.

► Aspiration

Anaerobes and *Streptococcus* spp. are the primary pathogens if a patient aspirates their oral contents and develops pneumonia. Antibiotics active against these organisms include penicillin G, ampicillin/sulbactam, and clindamycin. If the patient aspirates oral and gastric contents, then anaerobes and gram-negative bacilli are the primary pathogens. The preferred treatment regimen is a β-lactam/β-lactamase inhibitor combination (amoxicillin/sulbactam, amoxicillin/clavulanate, piperacillin/tazobactam, or ticarcillin/clavulanate).27

► Pediatric Outpatient

Guidelines have been published for treating CAP in children. The most predominant pathogens in preschool children in the outpatient setting are viruses, and often supportive therapy (maintaining hydration, antipyretics) is all that is needed.29 For appropriately immunized infants, children, and adolescents with mild-to-moderate pneumonia in an area lacking high-level penicillin-resistant pneumococcus, high-dose amoxicillin is the recommended first-line therapy. If atypical organisms are considered likely, then a macrolide is recommended. If moderate to severe CAP is diagnosed and it is during influenza season, then treatment with oseltamivir, zanamivir (Relenza), amantadine, or rimantadine is recommended.29 Fluoroquinolones and tetracyclines should not be used in children younger than 5 years. Dosing of antibiotics for pediatric patients is presented in Table 71–3.

► Pediatric Inpatient

If the infant or child is fully immunized, then the guidelines recommend the use of IV penicillin G or ampicillin. Alternative β-lactams include IV cefotaxime or ceftriaxone. If the infant or child is not fully immunized, then the third-generation cephalosporins (cefotaxime or ceftriaxone) should be administered.28 If atypical organisms are suspected, add azithromycin to the β-lactam. If community-acquired MRSA is suspected, then vancomycin or clindamycin should be added to the regimen.29

Pharmacologic Therapy for HCAP/HAP/VAP

Nosocomial pneumonia has since been replaced by the terms *health care–associated pneumonia, hospital-associated pneumonia,* and *ventilator-associated pneumonia.* **Key Concept** Empirical selection of antimicrobial therapy for ventilator-, health care-, and hospital-associated pneumonia is broad spectrum; however, once culture and susceptibility information are available, the therapy should be narrowed (de-escalation) to cover the identified...
Pathogen(s). Two factors important to the empirical selection of antibiotics for these types of pneumonia are onset time after admission and risk factors for MDR organisms. If it is early onset (less than equal to 5 days since admission), and there are no risk factors for MDR organisms, then the most frequent pathogens include *S. pneumoniae*, *H. influenzae*, methicillin-susceptible *Staphylococcus aureus* (MSSA), and enteric gram-negative bacilli. Recommendations for therapy include third-generation cephalosporins such as ceftriaxone or cefotaxime; a respiratory fluoroquinolone such as gemifloxacin, levofloxacin, or moxifloxacin; ampicillin/sulbactam; or ertapenem. If it is late-onset pneumonia and/or there are risk factors for MDR organisms, then the pathogen list includes *P. aeruginosa*, extended-spectrum β-lactamase–producing *K. pneumoniae*, *Acinetobacter* spp., and MRSA. Empirical antibiotic selection must cover *P. aeruginosa*, which often then covers the other gram-negative pathogens. Available antibiotics include ceftazidime, imipenem, meropenem, piperacillin/tazobactam, ticarcillin/clavulinate, levofloxacin, ciprofloxacin, gentamicin, tobramycin, and amikacin. Empirical therapy for late-onset pneumonia (listed in Table 71–4) could include any of the β-lactams, carbapenems, or fluoroquinolones alone or in combination with one of the aminoglycosides. If MRSA is suspected, then either vancomycin or linezolid should be added to the regimen. Recommendations for vancomycin trough concentrations of 15 to 20 mcg/mL (15–20 mg/L; 10–14 μmol/L) were based on expert opinion, not evidence from clinical trials.

Currently there is debate over whether or not double coverage for *Pseudomonas* is required. In vitro studies have shown that aminoglycosides exhibit synergistic killing against gram-negative bacilli when combined with β-lactams. Dosing of the aminoglycosides is dependent on the patient’s renal function. A high-dose once-daily regimen (eg, 4–7 mg/kg gentamicin or tobramycin or 15–20 mg/kg amikacin) can be utilized in patients with good renal function. Most of the studies enrolled patients with estimated creatinine clearances of at least 70 mL/min (1.17 mL/s). Meta-analyses have shown high-dose once-daily regimens to be as efficacious as and less toxic than divided daily dosing. Divided daily dosing (eg, 1 to 2 mg/kg gentamicin or tobramycin or 7.5 mg/kg amikacin) has been utilized since the 1970s, and the dosing interval is based on the patient’s renal function to achieve a trough concentration of less than 2 mcg/mL (2 mg/L; 4 μmol/L) for gentamicin and tobramycin and less than 5 mcg/mL (5 mg/L; 9 μmol/L) for amikacin.

In addition to obtaining a synergistic effect, another reason for double coverage when treating VAP, HAP, or HCAP is to broaden the coverage empirically to increase the likelihood of covering the majority of resistant pathogens. VAP is the most studied of these types of pneumonias and is often the most severe. There is an increase in mortality when inadequate therapy is initiated for VAP. Crude mortality ranges are quite large (35%–92%) compared with estimates of attributable mortality (approximately 9%); however, attributable mortality studies are limited by the large sample size needed to accurately measure this outcome.35–37

*Dosages are based on normal renal and hepatic function and should be adjusted as appropriate for each patient.

Trough concentrations ideally should be nondetectable; less than 1 mcg/mL for gentamicin and tobramycin (1 mg/L; 2 μmol/L) and less than 4 to 5 mcg/mL (4–5 mg/L; 7–9 μmol/L) for amikacin.
Duration of Antimicrobial Therapy

**KEY CONCEPT** The duration of therapy for pneumonia should be kept as short as possible and depends on several factors: type of pneumonia, inpatient or outpatient status, patient comorbidities, bacteremia/sepsis, and the antibiotic chosen. If the duration of therapy is too prolonged, then it can have a negative impact on the patient’s normal flora in the respiratory and gastrointestinal tracts, vaginal tract of women, and on the skin. This can result in colonization with resistant pathogens, *Clostridium difficile* colitis, or overgrowth of yeast. In addition, the longer antibiotics are administered, the greater the chance for toxicity from the agent, as well as an increase in cost.

For treating adult outpatient CAP, two antibiotics are approved for a 5-day duration of therapy, levofloxacin (the 750-mg dose) and azithromycin. The recommended duration of therapy for all other therapies is 7 to 10 days. For treatment of CAP in adult patients admitted to the hospital, the duration is independent on whether or not blood cultures were positive. In the absence of positive blood cultures, the duration of therapy is 7 to 10 days. If blood cultures were positive, the duration of therapy should be 2 weeks from the day blood cultures first became negative. The duration of therapy in pediatric patients is 10 days for uncomplicated CAP, with the exception of azithromycin, which is approved for 5 days.29

The duration of therapy cited in the literature for HCAP, HAP, or VAP ranges from 10 to 21 days. Efforts should be made to shorten the duration of therapy from the traditional 14 to 21 days to periods as short as 7 days, provided that the etiologic pathogen is not *P. aeruginosa* and that the patient has a good clinical response with resolution of clinical features of infection. Shortening the duration of therapy is beneficial because of the colonization, toxicity, and cost issues. Several studies evaluated mortality, clinical success, recurrence, or the development of resistance with shorter courses of therapy for VAP and found no differences when compared with longer courses of therapy.36,38 The Clinical Pulmonary Infection Score (CPIS) has been used to determine when to end therapy for VAP. Using CPIS, patients who survived VAP and were treated with adequate therapy clinically improved within 3 to 5 days.39 This study was instrumental in recommending a shortened duration of therapy of 6 days.

**OUTCOME EVALUATION**

For CAP, outcomes include preventing hospitalization, shortening the duration of hospitalization, and minimizing mortality. Improvement of symptoms should occur within 24 to 72 hours after initiation of therapy for most patients with CAP. Response to therapy could be slowed in patients with underlying pulmonary disease such as moderate to severe asthma, COPD, or emphysema. In patients not responding to therapy consider patient comorbid conditions, other infectious and noninfectious reasons, and a drug-resistant pathogen must be considered. Noninfectious reasons to consider include pulmonary embolus, congestive heart failure, carcinoma, lymphoma, intrapulmonary hemorrhage, and certain inflammatory lung diseases.

Outcome parameters for VAP, HAP, and HCAP are similar to those with CAP. Clinical improvement should occur within 48 to 72 hours of the start of therapy. If a patient is not responding to therapy, then, again, consider infectious and noninfectious reasons. Infectious explanations are the same as for CAP stated above, but noninfectious reasons are not. They include atelectasis, acute respiratory distress syndrome (ARDS), pulmonary embolism or hemorrhage, cancer, empyema, or lung abscess.

**PREVENTION**

**KEY CONCEPT** Prevention of both pneumococcal and influenza pneumonia by use of vaccination is a national goal. Vaccination is used to prevent or minimize the severity of pneumonia caused by *S. pneumoniae* or the influenza virus.

The influenza vaccine is available in two forms, injectable and nasal inhalation. There are two forms of the injectable inactivated vaccine (containing killed virus). The regular influenza vaccine is approved for use in people older than 6 months of age, including healthy people and people with chronic medical conditions. Fluzone intradermal vaccine is indicated for adults 18 through 64 years of age against influenza disease caused by virus subtypes A and type B. The high-dose influenza vaccine

---

**Patient Care Process**

**KEY CONCEPT** Monitoring response to therapy is essential for determining efficacy, identifying adverse reactions, and determining the duration of therapy.

**Patient Assessment:**
- Symptoms and status (ie, inpatient, outpatient, or intubated) to determine the type of pneumonia.
- Comorbid conditions of asthma, COPD, or emphysema, smoking history.
- Chest x-ray, pulse oximetry.
- Allergies and drug intolerances, noting the severity of the reaction.

**Therapy Evaluation:**
- What are the top two to three organisms associated with the type of pneumonia the patient has?
- Select an appropriate empirical antibiotic regimen for the patient and type of pneumonia, ensuring that the doses are correct for renal function (see Tables 71–2 and 71–3).

**Care Plan:**
- Assess the effectiveness of the antibiotic therapy after 24 to 72 hours looking for improvement in signs and symptoms.
- If the patient is not improving, then reevaluate the diagnosis and pathogen list, and make appropriate changes to therapy.
- Assess the patient for conversion from IV to oral therapy.
- Assess the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.

**Follow-up Evaluation:**
- If the patient responds to therapy within the first 72 hours consider a short course of therapy.
is recommended for those 65 years of age and older. The nasal-spray influenza vaccine is made with live, weakened influenza viruses that do not cause the influenza (live attenuated influenza vaccine). This formulation is approved for use in healthy people 2 to 49 years of age who are not pregnant. The ability of influenza vaccine to protect a person depends on two key factors: the age and chronic status of the person getting the vaccine, and the similarity or “match” between the virus strains in the vaccine and those in circulation. Protective antibodies are detected approximately 2 weeks after vaccination. In February 2010, the Centers for Disease Control and Prevention (CDC) adopted a universal influenza vaccination policy, thus recommending all persons 6 months of age and older to be vaccinated annually. The CDC identified high-risk groups in whom vaccination is especially important:

1. Pregnant women
2. Children younger than 5, but especially children younger than 2 years old
3. People 50 years of age and older
4. People of any age with certain chronic medical conditions
5. People who live in nursing homes and other long-term care facilities
6. People who live or care for those at high risk for complications from flu, including:
   - Health care workers
   - Household contacts of persons at high risk for complications from the flu
   - Household contacts and out-of-home caregivers of children less than 6 months (these children are too young to be vaccinated)

The 13-valent conjugated pneumococcal vaccine (PCV13) is recommended for children younger than 5 years (6 years if chronic health conditions are present) and the 23-purified-capsular polysaccharide antigen vaccine (PPSV23) for children 5 years of age and older and adults. The serotypes in the PCV13 are the most common disease-causing strains of pneumococcus. The minimum age to receive the PCV is 6 weeks, and the recommended age range is between 12 and 15 months. A reliable immunologic response to the PCV13 has been demonstrated, along with a favorable safety profile. The PCV13 is also recommended for adults aged 19 years or older with immunocompromising conditions, functional or anatomic asplenia, cerebrospinal fluid (CSF) leaks, or cochlear implants in addition to receiving the PPSV23 vaccine. The 23 capsular types in the PPSV23 represent at least 85% to 90% of the serotypes that cause invasive pneumococcal infections among children and adults in the United States. Ten years after vaccination, a sample of elderly individuals demonstrated significant quantity of protective antibodies. Those who should receive the polysaccharide vaccine include the following:

1. All adults 65 years or older should receive one dose.
2. Anyone older than 6 years who has a long-term health problem such as heart disease, lung disease, sickle cell disease, diabetes, alcoholism, cirrhosis, and leakage of cerebrospinal fluid.
3. Anyone older than 6 years who has a disease or condition or is taking any drug that lowers the body’s resistance to infection, such as Hodgkin disease, lymphoma, leukemia, kidney failure, multiple myeloma, nephrotic syndrome, HIV infection or AIDS, damaged spleen or no spleen, organ transplant, long-term steroids, certain cancer drugs, or radiation therapy.

For patients who meet the qualifications, discuss the value of vaccination against *S. pneumoniae* and/or influenza.

### Abbreviations Introduced in This Chapter

- **ARDS**: Acute respiratory distress syndrome
- **ATS**: American Thoracic Society
- **BUN**: Blood urea nitrogen
- **CA-MRSA**: Community-acquired methicillin-resistant *Staphylococcus aureus*
- **CAP**: Community-acquired pneumonia
- **CDC**: Center for Disease Control and Prevention
- **COPD**: Chronic obstructive pulmonary disease
- **CPIS**: Clinical Pulmonary Infection Score
- **DFA**: Direct fluorescence antigen
- **GER(D)**: Gastroesophageal reflux (disease)
- **H**: Hemagglutinin
- **HAP**: Hospital-acquired pneumonia
- **HCAP**: Health-care–associated pneumonia
- **IDDM**: Insulin-dependent diabetes mellitus
- **IDSA**: Infectious Diseases Society of America
- **MDR**: Multidrug resistant
- **MRSA**: Methicillin-resistant *Staphylococcus aureus*
- **MSSA**: Methicillin-susceptible *Staphylococcus aureus*
- **N**: Neuraminidase
- **Pao_{2}/FiO_{2}**: Arterial oxygen pressure/fraction of inspired oxygen
- **PB**: Penicillin-binding protein
- **PCR**: Polymerase chain reaction
- **PCV13**: Pneumococcal 13-valent conjugated vaccine
- **PPSV23**: Purified-capsular polysaccharide 23 antigen vaccine
- **TNF-α**: Tumor necrosis factor alpha
- **VAP**: Ventilator-associated pneumonia

### REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List common bacteria that cause acute otitis media (AOM), acute bacterial rhinosinusitis (ABRS), and acute pharyngitis.
2. Explain the pathophysiology of and risk factors for AOM, bacterial rhinosinusitis, and streptococcal pharyngitis.
3. Identify clinical signs and symptoms associated with AOM, bacterial rhinosinusitis, streptococcal pharyngitis, and the common cold.
4. List treatment goals for AOM, bacterial rhinosinusitis, streptococcal pharyngitis, and the common cold.
5. Develop a treatment plan for a patient with an upper respiratory tract infection (URI) based on patient-specific information.
6. Create a monitoring plan for a patient being treated for a URI using patient-specific information and prescribed therapy.
7. Educate patients about URIs and proper antibiotic use.

INTRODUCTION

Upper respiratory tract infection (URI) is a comprehensive term for upper airway infections, including otitis media, sinusitis, pharyngitis, laryngitis, and the common cold. Over 1 billion URIs occur annually in the United States, triggering millions of ambulatory care visits and antibiotic prescriptions each year. Most URIs are caused by viruses, have non-specific symptoms, and resolve spontaneously. Antibiotics are not effective for viral URIs, and their excessive use has contributed to resistance, which has prompted development of clinical guidelines to reduce inappropriate prescribing. This chapter focuses on acute otitis media (AOM), sinusitis, and pharyngitis which are frequently caused by bacteria. Proper management of the common cold is also reviewed.

OTITIS MEDIA

Otitis media, or middle ear inflammation, is the most common childhood illness treated with antibiotics. It usually results from a nasopharyngeal viral infection and can be subclassified as AOM or otitis media with effusion (OME). AOM is a rapid, symptomatic infection with effusion, or fluid, in the middle ear. OME is not an acute illness but is characterized by middle ear effusion. Antibiotics are only useful for the treatment of AOM.

EPIDEMIOLOGY AND ETIOLOGY

AOM occurs in all ages but is most common between 6 months and 2 years of age. By 3 years of age, more than 80% of children have at least one episode, and up to 65% have recurrent infections by 5 years of age. Many risk factors (Table 72–1) predispose children to otitis media. While the use of antibiotics for otitis media has declined since the mid-1990s, the proportion of health care visits resulting in antibiotic prescriptions remains close to 60%.

Although AOM occurs frequently with viral URIs, bacteria are isolated from middle ear fluid in up to 90% of children with AOM. Historically, Streptococcus pneumoniae was the most common organism, responsible for up to half of bacterial cases. Haemophilus influenzae and Moraxella catarrhalis caused up to 30% and 20% of cases, respectively. Routine childhood pneumococcal vaccination has altered the microbiology such that the prevalence of H. influenzae and S. pneumoniae is now nearly equal. Viruses are isolated from middle ear fluid with or without concomitant bacteria in up to half of cases. Lack of improvement with antibiotics is usually a result of viral infection and subsequent inflammation rather than antibiotic resistance. Antibiotic resistance heavily influences the treatment options for AOM. Penicillin-resistant S. pneumoniae (PRSP) exhibit intermediate resistance (minimum inhibitory concentrations between 0.12 and 1.0 mcg/mL [0.12 and 1.0 mg/L]) or high-level resistance (minimum inhibitory concentration of 2.0 mcg/mL [2.0 mg/L] and higher). Altered penicillin-binding proteins cause resistance in approximately 44% of pneumococci, where one-third are highly penicillin-resistant. Amoxicillin resistance is less common, occurring in approximately 19% of pneumococci. PRSP are frequently resistant to other drug classes, including sulfonamides, macrolides, and clindamycin, but are usually susceptible to levofloxacin. Treatment should be aimed at S. pneumoniae because pneumococcal AOM is unlikely to
resolve spontaneously and commonly result in recurrent infections.\textsuperscript{5,9} β-Lactamase production occurs in nearly 30% and 90% of \textit{H. influenzae} and \textit{M. catarrhalis}, respectively.\textsuperscript{14} Although infections caused by these organisms are more likely to resolve without treatment, they should be considered when failure occurs.

**PATHOPHYSIOLOGY**

- AOM is caused by an interplay of factors. Viral URIs impair eustachian tube function and cause mucosal inflammation, impairing mucociliary clearance and promoting bacterial proliferation and infection. Children are predisposed because they have shorter, more flaccid, and more horizontal eustachian tubes than adults, which are less functional for middle ear drainage and protection. Clinical manifestations of AOM result from host immune response and cellular damage from inflammatory mediators released by bacteria.
- Viscous effusions caused by allergy or irritant exposure contribute to impaired mucociliary clearance and AOM in susceptible individuals. Effusions can persist for up to 6 months after an episode of AOM. Atopic children experience chronic OME that may require tympanostomy tube placement to reduce complications such as hearing and speech impairment and recurrent AOM.

**TREATMENT**

- The goals of treatment are to alleviate ear pain and fever, if present; eradicate infection; prevent complications; and avoid unnecessary antibiotic use.

### General Approach to Treatment

**KEY CONCEPT** The majority of uncomplicated cases resolve spontaneously. Untreated AOM improves in over 80% of children between days 2 and 7 of illness without increasing complications.\textsuperscript{15} Antibiotics improve otalgia in only 5% of children between days 2 and 7 of therapy while increasing the risk of adverse events by 7%.\textsuperscript{15} Antibiotics significantly improve recovery in children younger than 2 years with bilateral AOM and in those with AOM and otorrhea.\textsuperscript{15} Children younger than 2 years have a higher incidence of PRSP infections, and children between 6 months and 3 years have higher clinical and bacteriologic failure rates and complications without initial antibiotic treatment as compared with older children.\textsuperscript{14,16} Patients with severe AOM have lower spontaneous recovery rates than those with less severe disease, particularly in children less than 2 years.\textsuperscript{3,9} \textbf{KEY CONCEPT} Therefore, antibiotics should be reserved for patients most likely to benefit, which is dependent on proper diagnosis, patient age, and illness severity. Current guidelines stratify patients using these criteria in order to identify those most likely to benefit from antibiotics.\textsuperscript{9}

### Nonpharmacologic Therapy

Watchful waiting and “safety-net” antibiotic prescriptions (prescription given to the patient but only filled if symptoms persist or worsen within 48–72 hours after diagnosis) are approaches used to attenuate microbial resistance and avoid unnecessary antibiotic adverse events and costs. Initial observation and use of delayed prescriptions in older children and those with less severe disease can reduce antibiotic use by 67% without increasing complications.\textsuperscript{13,18} These approaches should only be considered in otherwise healthy children (Figure 72–1) as a joint decision between the clinician and the parent/caregiver and only if close follow-up and good communication exist.\textsuperscript{13,18}

Children with recurrent AOM or chronic OME with impaired hearing or speech may benefit from surgery (tympanostomy tube placement with or without adenoidectomy).

### Pharmacologic Therapy

**Antibiotic Therapy**

When antibiotics are necessary, clinicians must consider drug factors (eg, antimicrobial spectrum, likelihood of response, middle ear fluid penetration, side effects, drug interactions, cost) and patient factors (eg, risk factors for resistance, allergies, regimen complexity, medication palatability, and presence of other medical conditions). Studies in uncomplicated AOM have not revealed significant differences between antibiotics in clinical response rates, but most were confounded by spontaneous resolution in children likely to have had viral URIs. Bacteriologic response varies among antibiotics and does not always correlate well with clinical response but is considered important when selecting therapy.\textsuperscript{3,9}

The American Academy of Pediatrics (AAP) developed clinical guidelines for healthy children between 6 months and 12 years of age with uncomplicated AOM (Figure 72–2).\textsuperscript{5} Amoxicillin is the drug of choice in most patients because of its proven effectiveness, high middle ear concentrations, excellent safety profile, low cost, good-tasting suspension, and relatively narrow spectrum (Table 72–2).\textsuperscript{5} High-dose amoxicillin (80–90 mg/kg/day) is preferred over conventional doses (40–45 mg/kg/day) because higher middle ear fluid concentrations can overcome pneumococcal penicillin resistance without substantially increasing adverse effects.\textsuperscript{11} High dose amoxicillin-clavulanate is preferred for children who received amoxicillin in the previous days 2 and 7 of illness without increasing complications.\textsuperscript{15}
Patients with AOM usually have cold symptoms, including rhinorrhea, cough, or nasal congestion, before or at diagnosis.

**Symptoms**
- Young children: ear tugging or rubbing, irritable, poor sleeping and eating
- Older patients: ear pain, ear fullness, hearing impairment

**Signs**
- Fever: present in fewer than 25% of patients; often in younger children
- Middle ear effusion
- Otorrhea with tympanic membrane perforation
- Bulging tympanic membrane
- Limited or absent mobility of tympanic membrane
- Distinct erythema of tympanic membrane
- Opaque tympanic membrane that obscures middle ear visibility

**Laboratory Tests**
- Gram stain, culture, and sensitivities of ear fluid if draining spontaneously or obtained via tympanocentesis (not performed routinely in practice)

**Complications**
- Infectious: mastoiditis, meningitis, osteomyelitis, intracranial abscess
- Structural: perforated eardrum, cholesteatoma
- Hearing and/or speech impairment

**Diagnosis**
AOM should be diagnosed if any of the following are met:
- Moderate to severe bulging of tympanic membrane (usually with impaired mobility as assessed by pneumatic otoscopy)
- Mild bulging of tympanic membrane and recent onset (less than 48 hours) of otalgia (or ear rubbing/tugging in nonverbal child) or intense erythema of tympanic membrane
- New onset otorrhea not caused by acute otitis externa

Severe AOM: Moderate to severe otalgia or otalgia for at least 48 hours or temperature of 39.0°C (102.2°F) or greater

30 days, have concurrent purulent conjunctivitis, have a history of recurrent AOM unresponsive to amoxicillin, and when coverage for β-lactamase-producing organisms is desired. Patients with penicillin allergies require alternative therapy (see Figure 72–2). There is limited cross-reactivity between penicillins and newer cephalosporins which supports AAP recommendations to use cephalosporins in penicillin-allergic patients because they are more effective than alternatives.9,20 Trimethoprim-sulfamethoxazole and macrolides have limited efficacy against S. pneumoniae and H. influenzae, making them less desirable for most

**FIGURE 72–1.** Treatment algorithm for initial antibiotics or observation in children 6 months to 12 years of age with uncomplicated AOM. (Data from Lieberthal AS, Carroll AE, Chonmaitree T, et al. The diagnosis and management of acute otitis media. Pediatrics. 2013;131(3):e964–e999.)

**FIGURE 72–2.** Treatment algorithm for uncomplicated AOM in children 6 months to 12 years of age. (Data from Lieberthal AS, Carroll AE, Chonmaitree T, et al. The diagnosis and management of acute otitis media. Pediatrics 2013;131(3):e964–e999.)
### Usual Dose and Schedule

A tympanic incision is typically made when children have otitis media, often referred to as acute otitis media (AOM). The usual dose of antibiotics is crucial in achieving a cure for AOM, with most antibiotics administered twice daily to ensure effective concentration at the site of infection. For instance, amoxicillin is often prescribed at a dose of 80–90 mg/kg/day in two doses, while amoxicillin-clavulanate is given at a dose of 90 mg/kg/day in two doses. Other antibiotics, such as cefuroxime axetil and cefdinir, are also commonly used, with typical dosages being 30 mg/kg/day in two doses and 14 mg/kg/day in one to two doses, respectively. The selection of these antibiotics not only depends on the initial resistance pattern but also on the patient's age, weight, and the duration of the treatment course.

### Adjunctive Therapy

Analgesics provide relief within 24 hours and should be used regardless of antibiotic therapy. Ibuprofen provides longer relief than acetaminophen but should be avoided in children younger than 6 months because of increased toxicity concerns. Alternating ibuprofen with acetaminophen is not recommended because of the potential for dosing error in ambulatory settings and a lack of safety and efficacy data. Topical anesthetic drops provide pain relief within 30 minutes of administration, but their effects are short-lived. Myringotomy, an incision made in the tympanic membrane, provides immediate relief but is rarely performed. Decongestants, antihistamines, and corticosteroids have no role in AOM treatment and can prolong effusion duration.

### Prevention

Vaccinations may prevent AOM in certain patients. Influenza vaccine is more effective in children older than 2 years because of impaired immune responses and immature host defenses in infants and toddlers. The live attenuated influenza vaccine is more effective than the injectable inactivated vaccine for protecting children older than 2 years against influenza-associated AOM. Pneumococcal conjugate vaccine is most protective against infection from pneumococcal serotypes contained in the vaccine and in infants at low-risk for AOM. Antibiotic prophylaxis is not recommended because of antibiotic resistance trends. Exclusive breast-feeding for the first 6 months of life and avoidance of tobacco smoke are advised, but the effects of these interventions remain unproven.

*Other FDA-approved antibiotics for AOM not recommended in AAP guidelines: azithromycin, cefaclor, cefixime, cefprozil, ceftibuten, cephalexin, clarithromycin, erythromycin-sulfisoxazole, and trimethoprim-sulfamethoxazole.

Approximate cost per course: $ (under $25), $$ ($25–$50), $$$ ($50–$100), $$$$ (over $100).

AOM, acute otitis media; Fe, iron; IM, intramuscular; IV, intravenous, PRSP, penicillin-resistant S. pneumoniae.

patients. Single-dose intramuscular ceftriaxone is effective for children who cannot tolerate oral medications, but a 3-day course may be preferred because of increasing pneumococcal resistance and reports of treatment failure with single doses. Ototopical antibiotics are an alternative to systemic agents for patients with otitis media or tympanostomy tubes. If there is no improvement or worsening with initial therapy during the first 48 to 72 hours, proper diagnosis and antibiotic selection must be reassessed. Tympanocentesis can assist with guiding therapy in difficult cases.

Duration of antimicrobial therapy depends on antibiotic selection, patient characteristics, and acceptability of failure if a short treatment course is used. Failure rates with short-course therapy (less than 10 days) are significantly higher in children with perforated eardrums and in children less than 2 years treated with azithromycin. Short-course antibiotics may result in fewer gastrointestinal side effects but only when compared with 10-day courses of amoxicillin-clavulanate. Standard 10-day regimens are recommended for all severe infections and for children less than 2 years. Seven-day regimens and five- to seven-day regimens can be considered for mild to moderate AOM in children 2 to 5 years and children 6 years and older, respectively.

#### Adjunctive Therapy

Pain is a central feature of AOM but it is often overlooked. Ibuprofen provides longer relief than acetaminophen but should be avoided in children younger than 6 months because of increased toxicity concerns. Alternating ibuprofen with acetaminophen is not recommended because of the potential for dosing error in ambulatory settings and a lack of safety and efficacy data. Topical anesthetic drops provide pain relief within 30 minutes of administration, but their effects are short-lived. Myringotomy, an incision made in the tympanic membrane, provides immediate relief but is rarely performed. Decongestants, antihistamines, and corticosteroids have no role in AOM treatment and can prolong effusion duration. Data are lacking on the safety and efficacy of complementary and alternative treatments.

#### Prevention

Vaccinations may prevent AOM in certain patients. Influenza vaccine is more effective in children older than 2 years because of impaired immune responses and immature host defenses in infants and toddlers. The live attenuated influenza vaccine is more effective than the injectable inactivated vaccine for protecting children older than 2 years against influenza-associated AOM. Pneumococcal conjugate vaccine is most protective against infection from pneumococcal serotypes contained in the vaccine and in infants at low-risk for AOM. Antibiotic prophylaxis is not recommended because of antibiotic resistance trends. Exclusive breast-feeding for the first 6 months of life and avoidance of tobacco smoke are advised, but the effects of these interventions remain unproven.
Patient Care Process for Acute Otitis Media

Patient Assessment:
- Based on patient history, review of systems, and physical examination (including pneumatic otoscopy findings), determine if the patient has AOM and if it is severe.
- Perform a medical review and conduct a medication history (including prescription and nonprescription medications and natural products). Does the patient have any medication allergies or adverse reactions? Is the patient up-to-date on immunizations?

Therapy Evaluation:
- If the patient is receiving pharmacotherapy, assess efficacy, safety, and adherence.
- Determine if antibiotic therapy is indicated or if observation can be employed (see Figure 72–1).
- Determine whether the patient has prescription coverage and if the desired antibiotic is covered by their insurance.

Care Plan Development:
- If appropriate, select analgesic therapy that will provide optimal pain relief.
- If appropriate, select antibiotic therapy that is likely to be effective and safe (see Figure 72–2).
- Select an optimal antibiotic dose (see Table 72–2) and an appropriate duration of treatment based on patient age and illness severity.
- Discuss potential adverse effects and how to manage them.
- Discuss importance of medication adherence to treat infection and pain.
- Determine the need for influenza and pneumococcal vaccinations to reduce risk for future infection.

Follow-up Evaluation:
- Reevaluate patient within 48 to 72 hours if symptoms persist or worsen.
- Monitor for middle ear effusion resolution at an appropriate interval based on age and presence of conditions that interfere with recognition of hearing impairment.

OUTCOME EVALUATION

Improvement of signs and symptoms (ie, pain, fever, and tympanic membrane inflammation) should be evident by 72 hours of proper therapy. Children can appear clinically worse during the first 24 hours but often stabilize during the second day. If symptoms persist or worsen, reevaluate the patient for the proper diagnosis and treatment. Counsel patients and caregivers regarding common antibiotic adverse effects such as rash, diarrhea, and vomiting that may prompt additional medical attention.

Presence of middle ear effusion in the absence of symptoms is not an indicator of treatment failure. Evaluate hearing in children who are otherwise healthy and have persistent effusion lasting 3 months in duration. Preschool-aged and younger children or those at risk for developmental difficulties may need reexamination earlier because speech and hearing impairment is more difficult to assess in these populations.

SINUSITIS

Sinusitis, or paranasal sinus inflammation, is often described as rhinosinusitis because it involves contiguous nasal mucosa and occurs in nearly all viral URIs. Acute rhinosinusitis is characterized by symptoms that persist for up to 4 weeks, whereas chronic rhinosinusitis lasts for more than 12 weeks. Acute bacterial rhinosinusitis (ABRS) refers to an acute bacterial sinus infection that occurs independently of or is superimposed on chronic sinusitis. This section will focus on ABRS.

EPI EPIDEMIOLOGY AND ETIOLOGY

Rhinosinusitis affects about 1 billion people annually in the United States.\(^1\) It is caused mainly by respiratory viruses but can also be triggered by allergies or environmental irritants. Viral rhinosinusitis is complicated by secondary bacterial infection in 0.2% to 2% of adults and 5% to 13% of children.\(^1,18\) URIs of less than 7 days’ duration are usually viral, whereas more prolonged or severe symptoms are often caused by bacteria. Risk factors for ABRS include prior viral URI, allergic rhinitis, and anatomic defects (Table 72–3).\(^29,30\)

Bacteria that cause sinusitis are similar to those in AOM. \(S.\ pneumoniae\) and \(H. influenzae\) cause more than half of ABRS cases, with an additional 8% to 16% of cases caused by \(M. catarrhalis\).\(^29,30\) Similar to AOM, an increased prevalence of \(H. influenzae\) has been reported in ABRS, and certain factors predict the presence of drug-resistant pathogens.\(^1,30\)

PATHOPHYSIOLOGY

Rhinosinusitis is caused by mucosal inflammation and mucociliary dysfunction from viral infection or allergy. Increased mucus production and reduced clearance lead to blockage of the sinus

Patient Encounter 1, Part 2

On further questioning, his mother states that he is ‘allergic’ to trimethoprim/sulfamethoxazole. He was treated for a urinary tract infection 7 months ago and experienced diarrhea while taking this antibiotic. He has not received antibiotics since that time, and this is his first ear infection. Immunizations: up-to-date

Meds: Acetaminophen drops 120 mg orally every 4 to 6 hours as needed for fever

ROS: (+) rhinorrhea and fever, (–) vomiting, diarrhea, or cough

PE:

Gen: Irritable child but consolable

VS: BP 100/64 mm Hg, P 130 beats/min, RR 22 breaths/min, T 39.1°C (102.4°F)

HEENT: Erythema and severe bulging of the left tympanic membrane with the presence of middle ear fluid; the right tympanic membrane is obscured with cerumen.

Identify your treatment goals for this child. Given this information, what nonpharmacologic and pharmacologic therapy do you recommend?
Intranasal medications or illicit drugs.

**Antibiotic Therapy**

Clinical diagnosis: Viral respiratory tract infection or traumatic head injury.

Radiographic studies: Adjunctive Therapy

Laboratory studies/nasopharyngeal cultures:

Children with persistent nasal discharge for at least 10 days report significantly more adverse events with antibiotics. Studies in adults with clinically diagnosed nonsevere sinusitis report cure rates of nearly 50% by usually is viral and self-limited. Studies in patients with mild persistent illness for at least 10 days, observation for another 3 days can be employed if there is adequate follow-up.

**Nonpharmacologic Therapy**

- Humidifiers and saline nasal sprays or drops moisturize the nasal canal, impair crusting of secretions, and promote ciliary function. Although many patients report benefit from such therapies, there are no controlled studies that support their efficacy. Nasal irrigation with isotonic or hypertonic saline may reduce medication use and improve symptoms, especially in patients with recurrent or chronic sinusitis.

**Pharmacologic Therapy**

- **Adjuvantive Therapy**

 Medications that target symptoms are commonly used in rhinosinusitis despite a lack of evidence demonstrating their efficacy. Analgesics/antipyretics should be used to treat facial pain and fever. Oral decongestants relieve congestion but should be avoided in children younger than 4 years and patients with ischemic heart disease or uncontrolled hypertension. Intranasal decongestants can be used for severe congestion in patients 6 years of age or older, but use should be limited to 3 days to avoid rebound nasal congestion. Avoid antihistamines because they thicken mucus and impair clearance, but they may be useful in patients with allergic rhinitis or chronic sinusitis. Similarly, intranasal corticosteroids usually are reserved for patients with allergies or chronic sinusitis, but they may be beneficial as monotherapy or with antibiotics in ABRS.

- **Antibiotic Therapy**

No randomized, double-blind, placebo-controlled antibiotic studies have used pre- and posttreatment sinus aspirate cultures as an outcome measure. In some studies, antibiotics resulted in modest benefits with antibiotic therapy.

Ostia. This environment is ideal for bacterial growth and promotes a cycle of local inflammation and mucosal injury characterized by increased concentrations of interleukins, histamine, and tumor necrosis factor. Damage to the host defense system perpetuates bacterial overgrowth and persistence of infection.

**TREATMENT**

The goals of treatment are to relieve symptoms, promote sinus drainage, use antibiotics when appropriate that minimize resistance, and prevent development of chronic disease or complications.

**General Approach to Treatment**

Initial management focuses on symptom relief. Clinicians often inappropriately prescribe antibiotics for rhinosinusitis, which usually is viral and self-limited. Studies in adults with clinically diagnosed nonsevere sinusitis report cure rates of nearly 50% by day 10 with no differences between antibiotics and placebo but significantly more adverse events with antibiotics.

Studies in children with persistent nasal discharge for at least 10 days report

<table>
<thead>
<tr>
<th>Complications</th>
<th>Diagnosis</th>
</tr>
</thead>
</table>
| Orbital cellulitis or abscess, periorbital cellulitis, meningitis, cavernous sinus thrombosis, ethmoid or frontal sinus erosion, chronic sinusitis, and exacerbation of asthma or bronchitis | Clinical diagnosis: Most common method; signs and symptoms that persist for more than 10 days with no improvement or that worsen after initial improvement, or severe symptoms (fever greater than or equal to 39.0°C [102.2°F] and purulent nasal discharge) for at least 3 to 4 days at illness onset. Respiratory secretion color is unreliable for diagnosis because neutrophil presence causes color and is found in viral sinusitis.
| Radiographic studies: Useful for assessing presence of complications | Paranasal sinus puncture: “Gold standard”; not routine but can be useful in complicated or chronic cases.
| Laboratory studies/nasopharyngeal cultures: not recommended |
faster symptom resolution with lower failure rates compared with no treatment, particularly with more severe infection. Because diagnosis is usually based on clinical presentation, clinicians must differentiate ABRS from viral rhinosinusitis in order to minimize inappropriate antibiotic use. Empiric antibiotic selection is usually used and should target commonly infecting bacteria. Treatment guidelines outline antibiotic choices that are likely to result in favorable clinical and bacteriologic outcomes based on causative pathogens and nationwide resistance patterns (Figure 72–3). Severe disease should be treated in conjunction with specialists such as otolaryngologists or infectious disease physicians.

Antibiotics (Table 72–4) should target S. pneumoniae and H. influenzae, but consideration must also be given to other bacteria and local resistance patterns. Standard dose amoxicillin or amoxicillin-clavulanate is recommended for most patients. Amoxicillin is effective for most infections and is less expensive and better tolerated than amoxicillin-clavulanate, which provides expanded coverage against β-lactamase–producers. High-dose amoxicillin or amoxicillin-clavulanate is recommended for patients who are at risk for infection from resistant bacteria, such as those who attend daycare, and when PRSP and other resistant bacteria are frequent in a community (see Figure 72–3). Patients with penicillin allergies can be treated with an appropriate cephalosporin, doxycycline, or a respiratory fluoroquinolone depending on age and allergy severity. Cephalosporin monotherapy is less desirable because of increased pneumococcal resistance, so combination therapy may be required to optimize coverage for PRSP and β-lactamase producers. Macrolides and trimethoprim-sulfamethoxazole are not recommended because of high pneumococcal and H. influenzae resistance. For uncomplicated infections, treatment duration ranges from 5 to 10 days in adults and 10 to 14 days in children. While short-course therapy with some fluoroquinolones and β-lactams are as effective as longer courses in adults with uncomplicated acute maxillary sinusitis, data are lacking to support shorter courses in more severe infections or in children.

Failure to improve within 3 to 5 days of therapy or worsening at any time requires reevaluation to confirm the diagnosis, consider changing antibiotics, and examine for complications.

OUTCOME EVALUATION

Clinical improvement (eg, defervescence, reduced nasal congestion and discharge, improvements in pain or facial pressure) should be evident within 5 days of therapy. Monitor for common adverse effects and refer to a specialist if clinical response is not obtained with first- or second-line therapy. Referral is also important for severe, recurrent, or chronic infection. Surgery may be indicated in complicated cases.

PHARYNGITIS

Pharyngitis is an inflammation of the throat often caused by infection. Acute pharyngitis is responsible for 1% to 2% of physician visits in adults and 6% to 8% of pediatric visits, but it is generally self-limited. Antibiotics are frequently prescribed because it can be difficult to clinically distinguish between viral and bacterial infection and the fear of untreated streptococcal illness.
**EPIDEMIOLOGY AND ETIOLOGY**

Pharyngitis is a common manifestation of viral URIs. *Streptococcus pyogenes* (Group A streptococci) is the most common bacterial cause, responsible for 20% to 30% of cases in children and 5% to 15% of adult infections. It is most common in late winter and early spring and spreads easily through direct contact with contaminated secretions. Clusters of infection are common and prevent complications of untreated streptococcal infection.

**PATHOPHYSIOLOGY**

Group A streptococci colonize the pharynx in up to 20% of children and is a risk factor for developing pharyngitis if there is disruption in mucosal integrity. Symptoms of streptococcal pharyngitis usually are self-limited and resolve within a few days of onset without antibiotic treatment. Historically, untreated or inappropriately treated infection caused acute rheumatic fever, heart valve damage, and other infectious complications. Delayed antibiotic therapy given up to 9 days after symptom onset can prevent these sequelae, so proper diagnosis is important to minimize unnecessary antibiotic use for viral pharyngitis and prevent complications of untreated streptococcal infection.

**TREATMENT**

- **KEY CONCEPT** The goals of therapy for streptococcal pharyngitis are to shorten the disease course, reduce spread, and prevent complications, including peritonsillar or retropharyngeal abscesses, cervical lymphadenitis, and rheumatic fever. Immune-mediated, nonsuppurative complications such as glomerulonephritis and reactive arthritis are not impacted by antibiotics.

**Pharmacologic Therapy**

Pain is a key feature of pharyngitis. Oral analgesics provide pain relief and can allow patients to maintain normal eating and drinking habits. **KEY CONCEPT** Antibiotics should be used only in cases of laboratory-confirmed streptococcal pharyngitis with associated clinical symptoms (Figure 72–4). Effective therapy (Table 72–5) reduces the infectious period from approximately 10 days to 24 hours and shortens symptom duration by 1 to 2 days. Penicillin is the drug of choice because of its narrow spectrum, documented safety and efficacy in nasopharyngeal streptococcal eradication, and low cost. Amoxicillin is an alternative agent, particularly for children because of its improved taste and its enhanced adherence with once-daily dosing.

aMaximum dose not to exceed adult dose.

ABRS, acute bacterial rhinosinusitis; IDSA, Infectious Diseases Society of America; PRSP, penicillin-resistant *S. pneumoniae*; IM, intramuscular.
Cephalosporins may be more effective than penicillin for relapse prevention and nasopharyngeal eradication, particularly in asymptomatic carriers.\textsuperscript{40,41} Usual duration of therapy is 10 days, but 5-day courses of some cephalosporins are as effective for streptococcal eradication as 10 days of penicillin.\textsuperscript{43} Resistant strains of group A streptococci cause the majority of streptococcal pharyngitis. Resistant strains are more likely to cause complications, such as rheumatic fever and glomerulonephritis.

Resistance plays a smaller role in pharyngitis treatment compared with other URIs. \textbf{KEY CONCEPT} Penicillin resistance has not been documented in group A streptococci, but resistance and clinical failures occur more frequently with tetracyclines, trimethoprim-sulfamethoxazole, and to a lesser degree macrolides. Patients with penicillin allergies should be treated with a first-generation cephalosporin (if non–type I allergy), a macrolide/azalide, or clindamycin.\textsuperscript{40,41} Recurrent infections or treatment failures can be retreated with the same initial antibiotic or treated with amoxicillin-clavulanate, a first-generation cephalosporin, clindamycin, or penicillin G benzathine.\textsuperscript{40,41}
Clinical Presentation and Diagnosis of Streptococcal Pharyngitis

Children between 5 and 15 years have the highest incidence of streptococcal pharyngitis.

Signs and Symptoms of Streptococcal Pharyngitis³⁰,⁴¹
- Sudden sore throat with severe pain while swallowing
- Fever
- Headache, abdominal pain, nausea, or vomiting (especially children)
- Tonsillopharyngeal erythema with or without exudates
- Tender, anterior cervical lymphadenitis
- Swollen red uvula
- Halitosis
- Soft palate petechiae
- Scarletiform rash
- Absence of conjunctivitis, hoarseness, cough, rhinorrhea, discrete ulcerations, and diarrhea (suggestive of viral etiology)

Diagnosis³⁸,⁴⁰,⁴¹
- Rapid antigen detection test (RADT): 70% to 90% sensitivity; results available within minutes.
- Throat culture: “gold standard”; results available within 24 to 48 hours. Should be performed after all negative RADTs in children and adolescents, and adults with significant pediatric contact. Also recommended in outbreaks and to monitor for resistance.
- Tests should be performed only when there is clinical suspicion for streptococcal pharyngitis. Pharyngeal carriage occurs in up to 20% of healthy children.

must be aware of evidence regarding the use of cough and cold products in order to make appropriate recommendations for this commonly encountered condition.

EPIDEMIOLOGY AND ETIOLOGY

Many viruses cause the common cold, including rhinoviruses (most common), coronaviruses, parainfluenza viruses, respiratory syncytial virus, and adenoviruses. Infection rates increase during the fall through spring seasons and are highest in the winter months. Adults experience 2 to 4 colds each year, whereas children have 6 to 10 colds per year.⁴⁶ Colds usually resolve over 10 to 14 days but can be complicated by bacterial superinfections, including AOM and ABRS. Factors associated with an increased incidence of colds are young age, contact with school-age children, crowded conditions and poorly ventilated areas, and cigarette smoking. Children are more likely than adults to transmit viruses because of poorer hand hygiene, closer casual contacts, and sharing of toys.⁴₅ Viral antigenic drifts and host immune system evasion contribute to the persistence of URIs in the community.

*Other FDA-approved agents include amoxicillin-clavulanate, cefixime, cefaclor, cefprozil, cefpodoxime, erythromycin, clarithromycin, and others.

**IM, intramuscular.**

**PATHOPHYSIOLOGY**

Viruses enter the respiratory tract mucosa via inhalation of aerosols or infected droplets or direct contact with contaminated secretions. After cell entry, viral replication and shedding occur for several days to weeks. Symptoms arise from epithelial cell damage, inflammation, vasodilation, local tissue edema, increased mucous production, and impaired mucociliary clearance. Tracheobronchial inflammation and irritation induce cough via afferent nerve impulse transmission to the medulla. Antibody production halts viral replication and inflammation as symptoms diminish.

**TREATMENT**

The treatment goal is to minimize discomfort from symptoms to allow patients to function as normally as possible. Preventative measures are also important to limit the spread of infection. Antibiotics are not effective, but they are often prescribed to patients with viral URIs and purulent secretions, which have contributed to increased resistance. Treatment should focus on symptom relief.

Supportive measures include air humidification, intranasal saline drops or sprays with or without bulb suctioning, increased fluid intake, throat lozenges or saline gargles, and rest. Nasal strips may relieve congestion by lifting the nares and opening the anterior nasal passages. These nondrug measures are particularly important for children younger than 6 years and pregnant women, for whom medication safety is a significant concern. Although studies proving their benefits are lacking, these non-drug treatments are safe.

Nonprescription cough and cold preparations are used frequently despite a lack of evidence to support their safety and efficacy. Reports of serious adverse events and deaths led to efforts to eliminate use of these medications in young children. Manufacturers have removed product labeling for all children younger than 4 years. Hundreds of products are available to manage cold symptoms. **KEY CONCEPT** Choice of therapy is influenced by patient age, presence of comorbid conditions, and balance of effectiveness and safety. Single-ingredient agents are preferred to target only symptoms that are present and to minimize toxicity that can result from confusion and lack of knowledge about active ingredients in multiple ingredient formulations. Cautious use of nonprescription products is warranted in certain patient populations: pregnant or lactating women, elderly, and patients with cardiovascular disease, diabetes, or glaucoma. Table 72–6 summarizes some of the available agents used for cold symptoms. Antipyretics and analgesics can be used for fever, pain, and discomfort. Local anesthetics (eg, benzocaine, dyclonine) relieve throat pain and are available in lozenges and sprays. Decongestants cause vasoconstriction that can improve congestion, but use of intranasal products should be limited to 3 days to avoid rebound congestion.44,49
Patient Care Process for Streptococcal Pharyngitis

Patient Assessment:
- Based on patient history, review of systems, and physical examination, determine if streptococcal pharyngitis is likely. If so, perform a rapid antigen detection test and/or follow-up throat culture to confirm the diagnosis.
- Perform a medical review and conduct a medication history (including prescription and nonprescription medications and natural products). Does the patient have any medication allergies or adverse reactions?

Therapy Evaluation:
- If the patient is receiving pharmacotherapy, assess efficacy, safety, and patient adherence.
- Determine if antibiotic therapy is indicated (see Figure 72–4).
- Determine whether the patient has prescription coverage and if the desired antibiotic is covered by their insurance.

Care Plan Development:
- If appropriate, select analgesic therapy that will provide optimal pain relief.
- If appropriate, select antibiotic therapy that is likely to be effective and safe (Table 72–5). Select an optimal dose and appropriate duration of treatment.
- Discuss potential adverse effects and how to manage them.
- Discuss importance of medication adherence to treat infection, minimize spread, and reduce chances of recurrence.
- Discuss the need to avoid close contact with others for 24 hours to minimize spread.

Follow-up Evaluation:
- Reevaluate patient if symptoms persist after 72 hours or worsen.
- Reevaluate patient if infection recurs after completion of therapy.

Clinical Presentation and Diagnosis of the Common Cold

Symptoms begin 24 to 72 hours after infectious contact. They peak at day 3 to 4, begin to wane by day 7, and resolve by day 10 to 14.

Signs and Symptoms
- Onset: Malaise, fatigue, headache, pharyngitis, low-grade fever (can be higher in infants and children)
- Secondary: Nasal and/or postnasal drainage (often clear at onset, but can become thick and purulent); congestion; cough and/or throat clearing; sneezing; conjunctivitis; irritability; impaired smell or taste

Complications
- AOM, ABRS, chronic bronchitis, bronchiolitis (in infants and children less than 2 years), pneumonia, asthma exacerbation

Diagnosis
- Clinical diagnosis: Most common method; based on history, presence of symptoms, and physical examination
- Radiographic studies: Useful for assessing complications such as pneumonia
- Laboratory studies: Rapid viral antigen tests and nasopharyngeal cultures helpful for epidemiology and diagnosis in acutely ill young infants

Patient Encounter 4

A 20-year-old woman presents to the university health center clinic with a "sinus infection." Three days ago, she developed a sore throat and a "runny nose." Today, her nasal discharge is thicker and yellow in color, she is congested, and she has a headache. She took acetaminophen 500 mg this morning, which provided some relief. She has exercise-induced asthma. She attends college and lives in an apartment with two friends who also have similar symptoms.

Immunizations:
- Up-to-date; needs influenza vaccine this season

Meds:
- Ortho Tri-Cyclen orally daily, albuterol inhaler as needed before exercise

Allergies:
- Cephalexin (rash)

PE:
- Gen: No apparent distress
- VS: BP 118/66 mm Hg, P 66 beats/min, RR 16 breaths/min, T 37.3°C (99.2°F), Wt 54.5 kg (120 lb)
- HEENT: Conjunctiva clear; no photophobia; yellow nasal discharge with swollen nasal mucosa; erythematous pharynx; no facial pain upon palpation; tympanic membranes normal appearing
- Lungs: Clear to auscultation; no crackles

What signs and symptoms are suggestive of the common cold? Which are suggestive of ABRS?

What diagnostic studies should be performed?

Create a care plan that includes nonpharmacologic and pharmacologic therapies and a monitoring plan. Include preventative measures in your plan.

Patient Encounter 3

A 7-year-old girl presents to the pediatrician with a sore throat and fever of 39.1°C (102.4°F) for the past 12 hours. She has pain while swallowing, so she is unable to eat or drink as much as usual. She also complains of a “belly ache.” She has no other symptoms and takes no medications. She is allergic to amoxicillin (rash). Her mother reports that two children in her daughter's class had “strep throat” recently. Physical examination reveals halitosis, pharyngeal and tonsillar erythema with exudates, and cervical lymphadenopathy.

Does this child have streptococcal pharyngitis?
- Is antibiotic therapy indicated? If so, what agent should be initiated and for how long?
- What education should be provided to her mother regarding treatment?

</tbody>
</table>

<sup>a</sup>Also for children older than 12 years.
<sup>b</sup>For children 6 to 12 years of age.
<sup>c</sup>Preferred antipyretic/analgesic for children; can be used in newborns.
<sup>d</sup>Safe to use in pregnancy.
<sup>e</sup>Can be used in children older than 6 months of age.

Antihistamines should be avoided: first-generation agents may dry secretions through their anticholinergic effects, but they impair mucociliary clearance of thick mucus, which can worsen congestion, and there is not a clear benefit for cough or cold symptoms when these agents are used alone. Cough suppressant use is not supported by strong evidence showing benefit. They can cause significant neurologic adverse effects and have been linked to abuse by teens for their euphoric effects in high doses. Guaifenesin, an expectorant, may reduce sputum thickness in adults, but it has been poorly studied in children. High-dose vitamin C (greater than 200 mg/day) supplementation does not significantly impact cold severity or duration, but it may be useful for prevention in patients exposed to severe physical exercise or cold stress. Echinacea has limited benefit for treatment in adults, and its use is discouraged for prevention and in all children because of adverse effects. Zinc lozenges are not consistently effective, and concerns exist regarding the loss of smell with intranasal preparations, so they should be avoided.

**PREVENTION**

Prevention of the common cold is best achieved by minimizing contact with infected people and secretions. Frequent hand-washing with soap and water or use of alcohol-based products is vital. Coughing and sneezing into the arm sleeve should be taught rather than using tissues or covering the mouth and nose with hands. Other methods that are advocated for preventing the spread include smoking cessation, maintenance of a healthy lifestyle through diet and exercise, and minimizing stress.
OUTCOME EVALUATION

Most colds resolve within 7 to 10 days. Monitor patients for persistent symptoms lasting longer than 10 to 14 days, worsening symptoms, and complications such as wheezing, difficulty breathing, significant facial or ear pain, and high fevers. If complications are suspected, refer to a clinician for evaluation.

Abbreviations Introduced in This Chapter

ABRS  Acute bacterial rhinosinusitis
AOM   Acute otitis media
OME   Otitis media with effusion
PRSP  Penicillin-resistant *S. pneumoniae*
RADT  Rapid antigen detection test
URI   Upper respiratory tract infection

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss characteristics of the skin that render it resistant to infection.
2. Describe the epidemiology, etiology, pathogenesis, clinical manifestations, diagnostic criteria, and complications associated with skin and soft tissue infections (SSTIs).
3. Identify the desired therapeutic outcomes for patients with SSTIs.
4. Recommend appropriate empirical and definitive antimicrobial regimens when given a diagnosis, patient history, physical examination, and laboratory findings.
5. Monitor chosen antimicrobial therapy for safety and efficacy.

INTRODUCTION

Skin and soft tissue infections (SSTIs) are frequently encountered in both acute and ambulatory care settings. They can range in severity from mild, superficial, and self-limiting, to life-threatening deep tissue infections that require intensive care, surgical intervention, and IV broad-spectrum antibiotics. Gram-positive pathogens, primarily *Staphylococcus aureus* and *Streptococcus* species, are the most common causative bacteria. Polymicrobial infections are more likely in complicated infections involving deeper layers of the skin, fascia, or muscle in persons with immune suppression, diabetes, and vascular insufficiency, and in postsurgical patients.

The role of methicillin-resistant *S. aureus* (MRSA), particularly community-acquired methicillin-resistant *S. aureus* (CA-MRSA), in SSTI is of increasing importance. In many US cities, MRSA is the most frequently isolated pathogen from patients presenting to emergency departments with SSTI, and antimicrobial prescribing has largely shifted to empiric use of MRSA-active agents. MRSA infections were historically associated with exposures to health care settings and more defined populations such as injection drug users or athletes; however, the prevalence of MRSA in the community and its rise in otherwise healthy individuals means that historical high-risk groups have little clinical relevance in most areas. In areas with high rates of CA-MRSA, and in those with recurrent infections or infections that persist despite appropriate antimicrobial therapy, empiric therapy including antibiotics active against this pathogen must be considered. This chapter covers the epidemiology, pathogenesis, clinical manifestations, and pharmacologic management of the more common and severe bacterial SSTIs.

Intact skin generally is resistant to infection. In addition to providing a mechanical barrier, its relative dryness, slightly acidic pH, colonizing bacteria, frequent desquamation, and production of various antimicrobial defense chemicals, including sweat (which contains IgG and IgA), prevent invasion by various microorganisms. Conditions that predispose a patient to SSTIs include: (a) high bacterial load (greater than $10^5$ microorganisms); (b) excessive skin moisture; (c) decreased skin perfusion; (d) availability of bacterial nutrients; and (e) damage to the corneal layer of the skin.

IMPETIGO

EPIEDEMOLOGY AND ETIOLOGY

**KEY CONCEPT** Impetigo is a common skin infection worldwide that can occur in any age group, but most frequently affects children between 2 and 5 years. β-Hemolytic streptococci and *S. aureus* are the most common causative pathogens. Impetigo is a superficial infection and spreads easily, especially in settings of poor hygiene and crowding, and particularly during the summer months. The offending microorganisms colonize the skin surface and invade through abrasions, insect bites, or other small traumas. The scabby, crusty eruption of impetigo ensues. These lesions may occur anywhere on the body, but are most common on the face and extremities.

CLINICAL PRESENTATION AND DIAGNOSIS

Impetigo lesions are numerous, well localized, and erythematous. **KEY CONCEPT** They begin as small, thin-walled blisters that can quickly evolve into ruptured lesions, with the dried discharge forming a honey-colored crust reminiscent of cornflakes. *S. aureus* and β-hemolytic Strept are most often implicated in impetigo. The lesions of impetigo are rarely painful, but are pruritic. Scratching the lesions can spread the infection to other areas of the body. Scarring is rarely problematic, unless ulceration occurs, as in ecthyma.

In order to avoid further spread and complications, antibiotic therapy is usually indicated. Sequelae of impetigo are uncommon, but rarely, glomerulonephritis secondary to group A
**FOLLICULITIS, FURUNCLES, AND CARBUNCLES**

See Table 73-1 for summary.

**CELLULITIS AND ERYSIPELAS**

**EPIDEMIOLOGY AND ETIOLOGY**

Cellulitis and erysipelas are bacterial infections involving the skin. Cellular is an infection of the dermis and subcutaneous tissue, whereas erysipelas is a more superficial infection of the upper dermis and superficial lymphatics. Although both can occur on any part of the body, many infections involve the leg. These infections develop after a break in skin integrity, resulting from trauma, surgery, ulceration, burns, tinea infection, or other skin disorder. However, they may occur after an inapparent break in the skin, and the skin may appear previously intact. In rare cases, cellulitis develops from bloodborne or contiguous spread of pathogens.

Etiologic microorganisms vary according to the area involved, host factors, and exposures. The predominant pathogens associated with cellulitis are streptococci, mainly group A, and less frequently *S. aureus*, including methicillin-resistant strains. Persons who are immunocompromised have diabetes or vascular insufficiency, or use injection drugs, are at risk for polymicrobial cellulitis.

**TREATMENT**

The primary goals of therapy for impetigo include preventing the spread of infection within the patient and to others, resolution of infection, and preventing recurrence. Secondarily, relief of symptoms associated with impetigo, such as itching, and improving cosmetic appearance are also important. Prevention of the rare, but serious complications of impetigo is an alternative goal.

**Nonpharmacologic Treatment**

Because impetigo is rarely painful, there is often a delay in seeking medical attention. Lesions may improve with time and increased hygiene, and soaking and cleansing the lesions with mild soap and water and the use of skin emollients to dry skin areas may reduce spread.

**Pharmacologic Treatment**

Antibiotic therapy is recommended to achieve the desired outcomes of preventing the spread of infection and complications. Although GAS historically has been the primary causative organism and penicillin is recommended when cultures yield streptococci alone, the incidence of *S. aureus* impetigo is common, and oral penicillinase-stable penicillins (such as dicloxacillin) or first-generation cephalosporins (such as cephalaxin) are preferred. Clindamycin, sulfamethoxazole-trimethoprim, or doxycycline is preferred when MRSA is suspected, or as alternative choices when penicillin allergy is a concern; however, tetracyclines should be avoided in children younger than 8 years. Topical mupirocin or retapamulin twice daily for 5 days may be used alone in mild cases with few lesions or in individual outbreaks.

**CLINICAL PRESENTATION AND DIAGNOSIS**

The manifestations of and diagnostic criteria for erysipelas and cellulitis are presented in Table 73-2.

With early diagnosis and appropriate therapy, the prognoses for cellulitis and erysipelas are excellent. Severe or repeated episodes can cause lymphedema. Rare complications include the spread of infection to deeper skin and soft tissue layers, bacteria, and sepsis. Although rates of bacteremia were traditionally low, prevalence may be increasing and associated with increased length of hospitalization and costs, and higher readmission rates.

Recurrent cellulitis can be problematic. Annual recurrence rates, especially for cellulitis of the leg, can be as high as 20%. Vascular and lymphatic insufficiencies increase the risk of recurrences; obesity, tobacco use, history of cancer, and homelessness also increase risk.

**TREATMENT**

The goals of therapy for cellulitis and erysipelas are rapid and successful eradication of the infection and prevention of related complications.

**Nonpharmacologic Treatment**

Nonpharmacologic treatment includes elevating the involved limb to decrease swelling. Sterile saline dressings may be placed on any open lesions to cleanse them of purulent materials. Surgical débridement may be indicated for severe infection and to rule out any necrotizing process. Drainage of abscesses is imperative to achieving clinical cure and may be the only treatment necessary if the abscess is small (less than 5 cm) with limited cellulitis.

**Pharmacologic Treatment**

Most patients with erysipelas or cellulitis are effectively treated with outpatient therapy. Hospitalization and treatment with IV antibiotics is recommended in the presence of systemic inflammatory response syndrome (SIRS) (eg, temperature greater than 38°C or less than 36°C, tachypnea greater than 24 breaths/min, tachycardia greater than 90 beats/min, or white blood cell count greater than 12 × 10⁹/mm³ [12 × 10⁹/L] or less than 400/mm³ [0.4 × 10⁹/L]), altered mental status, or hemodynamic instability. Outpatient treatment should also be avoided when deep or necrotizing infection is present, in severe immunocompromise or when outpatient treatment is failing or adherence to therapy is poor.

Antibiotic choices for typical cases of cellulitis should have activity against streptococci, and include penicillin, amoxicillin, amoxicillin-clavulenate, dicloxacillin, cephalaxin, or clindamycin. In uncomplicated cases, a 5-day course is as effective as a 10-day course. Monotherapy with a β-lactam is appropriate in uncomplicated cases; however, when purulent drainage, abscess, or ulcer is present, or in cases of penetrating trauma, particularly IV drug use, coverage for MRSA should be initiated. Vancomycin continues to be the drug of choice for severe cellulitis due to MRSA because of its efficacy, safety, and low cost. Daptomycin, linezolid, telavancin, or ceftaroline are also acceptable and should be considered over vancomycin when the isolated organism has a minimum inhibitory concentration (MIC) of greater than 2 mcg/mL (greater than 2 mg/L) (eg, vancomycin-intermediate *S. aureus* [VISA] or vancomycin-resistant *S. aureus* [VRSRA]). Tigecycline is an alternative; however, due to its broad spectrum of activity, it is best reserved for patients with intolerances to the aforementioned drugs or in those with polymicrobial infections. Several new agents for SSTI, including tedizolid,
Folliculitis, Furuncles, and Carbuncles

<table>
<thead>
<tr>
<th>Folliculitis</th>
<th>Furuncles</th>
<th>Carbuncles</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Epidemiology/etiology</strong></td>
<td><strong>Folliculitis is a superficial inflammatory reaction involving the hair follicle. The most familiar form of folliculitis is acne. It can be infectious, caused by microorganisms such as <em>S. aureus</em>, <em>Pseudomonas</em>, and <em>Candida</em>. Folliculitis can also be chemically induced.</strong></td>
<td>Also known as boils, furuncles might be described as a deep form of folliculitis. A furuncle is a bacterial infection that has spread into the subcutaneous skin layers but still only involves individual follicles. Furuncles occur primarily in young men. Diabetes and obesity are other predisposing factors. Staphylococci are the most common cause.</td>
</tr>
<tr>
<td><strong>Presentation and diagnosis</strong></td>
<td>Folliculitis presents as small, pruritic, erythematous papules. Location of the lesions and a good patient history are often all that are required in the diagnosis of folliculitis. Although Gram stain and culture of the papules may be considered to help determine the causative agent, they are not generally required as folliculitis typically resolves spontaneously.</td>
<td>Furuncles most commonly develop on the face, neck, axilla, and buttock. A furuncle typically starts as a small, red, tender nodule. Within a few days, the nodule becomes painful and pustular. Typically, a furuncle will spontaneously discharge pus, heal, and leave a small scar.</td>
</tr>
<tr>
<td><strong>Desired outcomes</strong></td>
<td>The goals of therapy for folliculitis, furuncles, and carbuncles are resolution of infection with no or minimal scarring. A secondary goal of therapy for larger furuncles and all carbuncles is to minimize the risk of endocarditis or osteomyelitis by reducing bloodstream invasion.</td>
<td>Incision and drainage are indicated.</td>
</tr>
<tr>
<td><strong>Nonpharmacologic treatment</strong></td>
<td><strong>KEY CONCEPT</strong> Warm compresses are generally sufficient.</td>
<td>Moist heat is indicated to facilitate drainage. Large furuncles require incision and drainage.</td>
</tr>
<tr>
<td><strong>Pharmacologic treatment</strong></td>
<td><strong>KEY CONCEPT</strong> Often resolves spontaneously. A topical antibiotic or antifungal may be used to control the spread of infection but generally is unnecessary. For staphylococcal or streptococcal folliculitis, antibiotic ointments such as mupirocin might be administered. Antifungal shampoo can be used for dermatophytes.</td>
<td>Carbuncles and furuncles that are purulent with signs of infection (ie, fever) should be treated systemically with an antibiotic that will cover <em>S. aureus</em>, such as dicloxacillin or cephalaxin. Trimethoprim-sulfamethoxazole or doxycycline is preferred if CA-MRSA is suspected or if the patient has a severe allergy to penicillin. Treatment should continue until acute inflammation has resolved, usually a 5- to 10-day course. Immunocompromised patients and severe infections or abscesses in patients who fail incision and drainage plus oral antibiotics should be treated empirically with vancomycin, daptomycin, linezolid, televancin, or ceftaroline. Prevention for recurrent episodes may be warranted, including adequate skin hygiene with the use of soap and water, and handwashing after contact with lesions. Proper care of clothing and dressings is also recommended to prevent autoinoculation.</td>
</tr>

Data from Refs. 4, 10, and 12.

### Patient Encounter 1, Part 1: Cellulitis

A 57-year-old man presents to the ambulatory care clinic with a 3-day history of progressively worsening pain and swelling of his left lower extremity. Upon examination, you notice that in addition to the patient’s complaints, the area is visibly erythematous. Poorly defined areas of redness and streaking extend from just below the knee up toward his hip. A small, nonpurulent scabbed area is present over the kneecap. He reports running a low-grade fever and some feelings of fatigue, but otherwise feels fine. When questioned, he indicates that he recently fell from a ladder while working on the gutters of his home and landed primarily on his left side. His vitals at the clinic reveal a temperature of 38.8°C, pulse 90 beats/min, blood pressure 128/89 mm Hg, and respiratory rate 18 breaths/min. The physician diagnoses the patient with cellulitis.

**What subjective and objective clinical manifestations are suggestive of cellulitis?**

**What additional information do you need before developing a therapeutic plan for this patient?**
The infected area is described as painful or tender. In the case of erysipelas, the patient may complain of “burning pain” at the lesion site. CA-MRSA infections often start as a localized skin lesion and may be described by the patient as looking like a “spider bite.”

Cultures and sensitivities:
Vancomycin plus piperacillin/tazobactam is recommended in these cases. Therapy continuation is recommended in polymicrobial infections, whereas more defined therapy is recommended when a causative pathogen is isolated.

Table 73–2
Presentation of Erysipelas and Cellulitis

Symptoms
- The infected area is described as painful or tender. In the case of erysipelas, the patient may complain of “burning pain” at the lesion site. CA-MRSA infections often start as a localized skin lesion and may be described by the patient as looking like a “spider bite.”

Signs
- Both erysipelas and cellulitis are manifested by rapidly spreading areas of redness, edema, warmth, and tenderness. Lymphangitis and regional lymphadenopathy may be observed.
- The affected area may have an “orange peel” appearance due to superficial skin edema causing skin dimpling around the hair follicles.
- Low-grade fever, flu-like illness, and other systemic symptoms may occur prior to development of the lesion.

Laboratory Tests
- Leukocytosis may be present.
- Cultures and sensitivities:
  - Blood cultures should be obtained for complicated or severe cases, although their yield is often low as bacteremia is an infrequent, but growing, occurrence; facial cellulitis may increase risk. Cultures aspirated from the lesion have a low organism isolation rate, but also may be considered.
  - Abscess drainage and debrided tissue, if obtainable, should be cultured and will frequently yield the causative organism(s).

Imaging Studies
- Imaging studies may identify abscess formation, gas in the soft tissues, or osteomyelitis.

Patient Encounter 1, Part 2: Cellulitis: Medical History, Physical Examination, and Diagnostic Tests

PMH: Hypertension, dyslipidemia, GERD.
FH: Father (age 79) and mother (age 77) are both alive. Father has hypertension and CAD; mother is otherwise healthy. One brother, age 54, also has hypertension.
SH: Denies alcohol or illicit drug use. Married, with two sons who attend the local community college. Works full-time in construction.
Meds: Lisinopril 20 mg daily; simvastatin 20 mg daily; omeprazole 20 mg daily as needed.
Allergies: No known drug allergies.
ROS: (+) pain, edema, and erythema in the left lower extremity; (-) headache, chest pain, shortness of breath, cough, nausea, vomiting, diarrhea, and weight loss.
PE:
Gen: Patient is in no acute distress. Wt 88.2 kg (194 lb); Ht 5’11” (180 cm).
Chest: Lungs bilaterally clear to auscultation.
CV: Regular rate, rhythm. No murmurs/rubs/gallops.
Ext: Left lower extremity with erythema and edema from the knee to just below the hip. Warm to the touch. RLE within normal limits.
Labs: WBC 15.8 × 10^3/mm^3 (15.8 × 10^9/L), serum creatinine 0.8 mg/dL (71 μmol/L).
What are the most likely causative organisms in this case of cellulitis?
What are the goals of therapy for this patient?
What nonpharmacologic interventions would you recommend for him?
What antimicrobial therapy would you recommend? Include drug, dosage, route, interval, and duration of therapy.
How would you monitor your selected regimen for safety and efficacy?
How would your initial choice of an antimicrobial agent change if this patient was at high risk for MRSA?

*aDoses given are for adults with normal renal function. IV therapy can be switched to oral therapy (as for mild infection) when the patient is afebrile and signs of infection are resolving.

*bCA-MRSA isolates resistant to erythromycin should be evaluated for inducible clindamycin resistance via a D-test.

*cLimited clinical data exist for the treatment of MRSA infections. Poor activity against GAS; consider using in combination with clindamycin or cephalaxin if empirical coverage for GAS is desired.

*dIf CA-MRSA suspected, clindamycin, trimethoprim-sulfamethoxazole, or doxycycline must be added to this regimen.

*eP. aeruginosa generally is susceptible to this agent.

*fUse caution in patients with known hypersensitivity to β-lactam antibiotics.

gMRSA coverage indicated for patients with severe cellulitis or systemic illness, who have risk factors for HA-MRSA or CA-MRSA infection, or reside in areas with high CA-MRSA prevalence. Otherwise, the broad-spectrum regimens listed below, without MRSA coverage, are appropriate. Data from Refs. 4, 10 and 14.

---

Recurrent cellulitis can be problematic, especially in the lower extremities. Reducing risk factors may help with preventing recurrences.4 Low-dose antibiotic prophylaxis with penicillin may reduce recurrences, but the benefit subsides when therapy is discontinued.4,13

### NECROTIZING FASCIITIS

#### EPIDEMIOLOGY AND ETIOLOGY

Necrotizing fasciitis (NF) is an uncommon, rapidly progressive, life-threatening infection that causes necrosis of the subcutaneous tissue and fascia. When due to GAS infection, its associated mortality rate approaches 25%.19 NF can affect any age group.

---

#### Patient Encounter 1, Part 3: Cellulitis: Clinical Course

Three days later, the patient returns to the clinic with moderate improvement of his cellulitis, but with a new presentation of a maculopapular skin rash. It is presumed that he has developed an allergy to penicillin.

*What would you suggest for modification of his antimicrobial regimen?*

*How would you monitor his new regimen for safety and efficacy?*

*How would your choice of an agent change if this patient’s cellulitis was severe enough to warrant hospitalization?*
Although the risk of NF is higher in injection drug users and in patients with diabetes or vascular insufficiency, healthy hosts can become infected as well.\(^4\)

NF typically erupts after an initial trauma, which can range from a small abrasion to a deep penetrating wound. The infection begins in the fascia, where bacteria replicate and release toxins that facilitate their spread.\(^4\)

NF may be monomicrobial, most often involving \textit{S. pyogenes}, \textit{S. aureus}, \textit{Vibrio vulnificus}, \textit{Aeromonas hydrophilia}, and anaerobic streptococci (\textit{Peptostreptococcus}). Polymicrobial NF develops in the following clinical settings: after surgery or deep penetrating wounds involving the bowel; from decubitus ulcer, perianal, or vulvovaginal infection; or from the injection site in an IV drug user.\(^4\)

### CLINICAL PRESENTATION AND DIAGNOSIS

Patient outcomes rely on the clinician’s ability to recognize NF early in the course of disease. This is often difficult because early disease tends to be indistinguishable from cellulitis. The clinical presentation of NF is presented in Table 73–4.

NF is perhaps the most devastating SSTI. Left untreated, it can invade the muscles and circulation, resulting in myonecrosis and septic shock, respectively. Half of the cases caused by GAS are accompanied by GAS toxic shock–like syndrome. The syndrome is endotoxin mediated, manifested by hypotension and multiorgan dysfunction, and highly lethal.\(^20\) Amputation is common in patients with extremity infections. Once the patient recovers from acute NF, he or she often requires skin and/or muscle grafting and consequent physical rehabilitation depending on the amount and types of tissues removed during surgical intervention and the duration of hospital stay.\(^22\)

### TREATMENT

The goals of therapy for NF include eradication of infection and reduction of related morbidity and mortality.

#### Nonpharmacologic Treatment

KEY CONCEPT After resuscitation and hemodynamic stabilization, prompt surgical intervention is key in the treatment of NF. Delayed operative débridement increases mortality, and most patients should return to the operating room frequently until débridement is no longer indicated.\(^22\)

#### Pharmacologic Treatment

As an adjunct to surgery, high-dose, broad-spectrum IV antibiotic therapy should be initiated immediately in patients with NF until the patient has improved clinically and is afebrile for 48 to 72 hours, and no further need for débridement exists. Piperacillin-tazobactam, a carbapenem, or ceftriaxone or a fluoroquinolone plus metronidazole is appropriate for empiric therapy. These agents should be used in combination with vancomycin, dapto- mycin, or linezolid until MRSA infection is ruled out.\(^4\) The protein synthesis inhibitors clindamycin or linezolid are often utilized to decrease bacterial toxin production, thereby limiting tissue damage. This is particularly beneficial in streptococcal or clostridial infection.\(^20\)

IV immunoglobulin (IVIG) dosed at 2 g/kg may also be a useful adjunctive treatment in patients with GAS NF who present with shock. Anecdotal evidence and data from small studies strongly support its use in improving 30-day survival and reducing mortality, although additional evidence is needed for a definitive recommendation.\(^4\)

### DIABETIC FOOT INFECTIONS

#### EPIDEMIOLOGY AND ETIOLOGY

Foot ulcers and related infections are among the most common, severe, and costly complications of diabetes mellitus. For the approximately 25 million patients with diabetes in the United States, the lifetime risk of developing at least one foot ulcer is estimated at 25%.\(^22\) In addition to significant morbidity, the health care costs associated with treating infected foot ulcers are enormous.

Infected diabetic foot ulcers typically contain a multitude of microorganisms. KEY CONCEPT Aerobic gram-positive cocci, such as \textit{S. aureus} and \textit{β}-hemolytic streptococci, are the predominant pathogens in acutely infected diabetic foot ulcers. However, severe, or more extensive chronically infected wounds are subject to polymicrobial infection. The clinician should suspect the involvement of gram-negative (such as \textit{P. aeruginosa}) and possibly low-virulence pathogens (including enterococci and \textit{S. epidermidis}) in polymicrobial infections. Foul-smelling, necrotic, or gangrenous wounds are also commonly infected with anaerobic bacteria.

Patients recently hospitalized or treated with broad-spectrum antibiotics, or those with a previous history of MRSA infection are at risk for MRSA as a causative agent.\(^23\)

NF, Necrotizing fasciitis.

Data from Refs. 4 and 20.
PATHOPHYSIOLOGY

Key Concept The pathogenesis of diabetic foot infection stems from two key factors: peripheral neuropathy and ischemia from peripheral vascular disease.22 Neuropathy, the most prominent risk factor for diabetic foot ulcers, develops when continuously high blood glucose levels damage motor, autonomic, and sensory nerves. Damage to motor neurons that supply the small intrinsic muscles of the foot causes deformation, resulting in altered muscular balance, abnormal areas of pressure on tissues and bone, and repetitive injuries. Damage to autonomic neurons results in the shunting of blood through direct arteriole-venous communications, thereby decreasing capillary flow. The secretion of sweat and oil is also diminished, producing dry, cracked skin that is more prone to infection. Finally, damage to sensory neurons produces a loss of protective sensation so that the patient becomes unaware of injury or ulceration.22

Dysfunction of the endothelial cells and abnormalities of the smooth muscles of the peripheral vessels is also the result of high blood glucose concentrations. Vasoconstriction can occur due to decreased levels of endothelium-derived vasodilators, as well as in the presence of other risk factors, including hypertension, dyslipidemia, and smoking. Together, ischemia and skin breakdown can occur as a cumulative result.22

Finally, persons with diabetes have altered immune function that predisposes them to infection. Leukocyte function, and cell-mediated and humoral immunity are compromised in poorly controlled disease.23 Achieving and maintaining controlled blood glucose levels should be a component of the prevention and management of diabetic foot infections.

CLINICAL PRESENTATION AND DIAGNOSIS

Not all diabetic foot ulcers are infected. However, infection is often difficult to detect when perfusion and the inflammatory response are limited in the patient with diabetes. The common signs and symptoms (ie, pain, erythema, and edema) of infection
Clinical Manifestations of Infection

Infection (as above) in a patient who is

Presence of at least two manifestations of

Infection in a patient with systemic illness.

Wound lacking purulence or any manifestations of inflammation

Presence of at least two manifestations of inflammation (purulence or erythema, pain, tenderness, warmth, or induration), but any cellulitis/erythema extends no more than 2 cm around the ulcer, and infection is limited to the skin or superficial subcutaneous tissues; no other local complications or systemic illness

Infection (as above) in a patient who is systemically well and metabolically stable but who has at least one of the following characteristics: cellulitis extending > 2 cm, lymphangitic streaking, spread beneath the superficial fascia, deep tissue abscess, gangrene, and involvement of muscle, tendon, joint, or bone

Infection in a patient with systemic toxicity or metabolic instability (eg, fever, chills, tachycardia, hypotension, confusion, vomiting, leukocytosis, acidosis, severe hyperglycemia, or azotemia)

may be absent. Still, the diagnosis of diabetic foot infection depends mostly on clinical evaluation.

Purulent drainage from the ulcer is indicative of infection. When pus and inflammatory symptoms are not present, the clinician must be astute to more subtle findings. These include delayed healing, increase in lesion size, prolonged exudate production, malodor, and tissue friability. Abnormal granulation tissue also may be present, as evidenced by color change (from bright red to dark red, brown, or gray) and increased bleeding. The ability to probe the ulcer to the underlying bone is highly indicative of osteomyelitis.

Diabetic foot infections are classified into four categories based on clinical presentation using the PEDIS scale (perfusion, extent/size, depth/tissue loss, infection, sensation). Grade 1 signifies no infection; grade 2, involvement of skin and subcutaneous tissue only; grade 3, extensive cellulitis or deeper infection; and grade 4, presence of systemic inflammatory response syndrome. Table 73–5 provides detailed information regarding these grades.

Imaging studies, such as x-ray and magnetic resonance imaging (MRI), can identify osteomyelitis. Blood cultures should be obtained from all patients with signs and symptoms of systemic illness. Deep tissue cultures may help to direct therapy. Bone also may be sent for culture in cases of osteomyelitis. Superficial cultures of ulcers are unreliable and should be avoided.

Spreading soft tissue infection and osteomyelitis are often the first complications that develop from diabetic foot infection. Some patients develop bacteremia and sepsis.

Table 73–6

TREATMENT

The patient received the empiric therapy you recommended for his diabetic foot infection. Two days later, deep wound cultures were reported positive for *P. aeruginosa*. Blood cultures revealed no growth. The patient remained hospitalized for an additional week, during which time his cellulitis improved on directed antimicrobial therapy. He was discharged to complete his antibiotic therapy and to follow up as an outpatient in 1 week.

What modifications would you make to this patient’s antimicrobial regimen knowing that the causative agent is *P. aeruginosa*?

What individualized foot care strategies can you suggest to this patient to prevent further infections?

The most feared complication of infected diabetic foot ulcers is lower extremity amputation. More than 80% of all nontraumatic lower extremity amputations performed each year in the United States are linked to diabetic foot infections, about half of which could be potentially avoided.

**TREATMENT**

The goals of therapy for diabetic foot infection are eradication of the infection and avoidance of soft tissue loss and amputation.

**Prevention**

Comprehensive foot care programs and the utilization of multidisciplinary care teams can improve outcomes and decrease amputation rates. Periodic foot examinations with monofilament testing and patient education regarding proper foot care, optimal glycemic control, and smoking cessation are key preventative strategies.

**Nonpharmacologic Treatment**

The nonpharmacologic treatment of diabetic foot ulcers may include débridement of necrotic or nonviable tissue, wound dressings, vascular or orthopedic surgery, and off-loading pressure from the wound.

**Pharmacologic Treatment**

The severity of a patient’s infection, based on the PEDIS scale, can help guide the selection of empirical antimicrobial therapy. Although most patients with grade 2 diabetic foot infections can be treated as outpatients with oral antimicrobial agents, all grade 4 and many grade 3 infections require hospitalization, stabilization of the patient, and broad-spectrum IV antibiotic therapy.

Multiple antibiotic options exist for the treatment of diabetic wound infections. Table 73–6 provides both general treatment strategies and specific, although not all-inclusive, antibiotic recommendations. The duration of therapy correlates with infection severity. Antibiotics should be continued until the infection has resolved, but not necessarily until the ulcer has healed. Milder infections generally require 7 to 14 days of therapy, whereas more severe infections may necessitate longer treatment durations. Patients with osteomyelitis may require days to weeks of
antibiotic therapy depending on whether infected and necrotic bone is surgically debrided.\textsuperscript{23}

**INFECTED PRESSURE SORES**

**EPIDEMIOLOGY AND ETIOLOGY**

Pressure sores, also known as *decubitus ulcers* or *bedsores*, affect approximately 3 million adults, with an annual prevalence in the United States of about 12.5%. Patients of advanced age and those with spinal cord or orthopedic injuries are at highest risk.\textsuperscript{24}

A pressure sore is a chronic wound that results from continuous pressure on the tissue overlaying a bony prominence. This pressure impedes blood flow to the dermis and subcutaneous fat, resulting in tissue damage and necrosis.\textsuperscript{26} Pressure sore infections develop from breaks in skin integrity and contamination from dirty areas of close proximity, and are often polymicrobial.\textsuperscript{27}

**CLINICAL PRESENTATION AND DIAGNOSIS**

Approximately two-thirds of all pressure sores occur on the sacrum and heels.\textsuperscript{27} Pressure sores are classified according to the extent of tissue destruction.\textsuperscript{28} The most commonly used system for staging of pressure sores is presented in Table 73–7.

Bacterial colonization of pressure sores is common. Because infection impairs wound healing and may require systemic antimicrobial therapy, the clinician must be able to distinguish it from colonization. Table 73–8 describes the clinical presentation of infected pressure sores.

Most complications are infectious. The most common is osteomyelitis; less frequently, NF, clostridial myonecrosis, and sepsis can occur.

**TREATMENT**

The goals of therapy for infected pressure sores include resolution of infection, promotion of wound healing, and establishment of effective infection control.\textsuperscript{30}

**Prevention**

Prevention is the most humane and cost-effective component for the management of pressure sores. Key prevention strategies include monitoring of high-risk patients, reducing skin exposure to pressure and moisture, and promoting good nutritional status. Careful monitoring and preventative care of high-risk patients can begin once these patients are identified. Intrinsic or host-related risk factors for the development of pressure sores include age more than 75 years, limited mobility, loss of sensation, unconsciousness or altered sense of awareness, and malnutrition. Extrinsic or environmental risk factors include pressure, friction, shear stress, and moisture.\textsuperscript{31}

Turning and repositioning the patient at least every 2 hours can reduce skin pressure and prevent pressure sores. However, because this level of care is difficult to achieve in most hospital and nursing home environments, multitudes of pressure-reducing mattresses have been manufactured. Although these can help to decrease pressure on susceptible areas, they do not negate the need for position changes.\textsuperscript{31}

Maintaining a clean, dry environment can prevent skin maceration and subsequent tissue damage. This can be accomplished with
**Staging of Pressure Ulcers**

**Suspected Deep Tissue Injury**
- Intact skin with localized area of purple or maroon discoloration or presence of a blood-filled blister.
- The area may be preceded by tissue that is painful, firm, mushy, boggy, and warmer or cooler as compared with adjacent tissue.

**Stage I**
- Intact skin with localized area of nonblanchable redness, usually over a bony prominence.
- May be difficult to detect in darkly pigmented skin; its color may differ from the surrounding area.

**Stage II**
- Partial-thickness loss of dermis presenting as a shallow open ulcer with a red-pink wound bed or an intact or ruptured serum-filled blister.
- This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation.

**Stage III**
- Full-thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscle is not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling.

**Stage IV**
- Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunneling.

**Unstageable**
- Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed.
- Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as “the body’s natural (biological) cover” and should not be removed.

---

**Presentation of Infected Pressure Sores**

**Symptoms**
- Because many high-risk patients lack sensation, pain may not be a primary symptom.

**Signs**
- Infection generally is diagnosed when erythema and edema of the surrounding skin, purulent drainage, malodor, or delayed wound healing are present.

Patients with bacteremia often develop fever, chills, confusion, and/or hypotension.

**Laboratory Tests**
- Deep tissue cultures may help to direct therapy. Bone also may be sent for culture in cases of osteomyelitis. Superficial cultures are unreliable and should be avoided.

**Imaging Studies**
- Imaging studies, such as CT, MRI, or bone scan, can be used to detect osteomyelitis and to determine the depth and extent of tissue destruction.

---

**INFECTED BITE WOUNDS**

**EPIDEMIOLOGY AND ETIOLOGY**

Many Americans will be bitten by an animal at least once during their lifetimes. Although most of these injuries are minor, some will require medical treatment.

Dogs cause most animal bites, typically open lacerations, of which approximately 20% become infected. Cat bites are the second most common animal bite, most often puncture wounds involving the hand. Because cat bites are deep and penetrating, up to 80% may become infected.32 Human bites are the third most common and the most serious. Before the availability of antibiotics, up to 20% resulted in amputation. Currently, human bite–associated amputation rates remain at 5%, secondary to vascular compromise and infectious complications.33

There are two types of human bite injuries. Occlusal injuries are inflicted by actual biting, whereas clenched-fist injuries are sustained when a person’s closed fist hits another’s teeth. Of the two, clenched-fist injuries typically are more prone to infectious complications.32,33

**KEY CONCEPT** **Bite wound infections generally are polymicrobial.**

Both the normal flora of the biter’s mouth and that of the bite recipient’s skin can be implicated. The bacteriology of the cat and dog mouth is quite similar. *Pasteurella multocida*, a gram-negative aerobe, is one of the predominant pathogens. Viridans streptococci are the most frequently cultured bacteria from human bite wounds, although empiric treatment should also provide coverage for *Eikenella corrodens.*32,33 Table 73–9 provides a comprehensive list of cat-, dog-, and human bite-wound pathogens.
Dog and cat: Pasteurella multocida,
Human: Pain at the wound site is common. Limited range of motion may be present, especially if the hand is bitten. The onset of infectious symptomatology is typically 12–24 hours after the bite. The clinician should obtain anaerobic and aerobic wound cultures only if the wound appears clinically infected.

### Bacterial Pathogens
- **Dog and cat:** Pasteurella multocida, staphylococci, streptococci 
  Moraxella spp., Eikenella corrodens, Capnocytophaga canimorsus, Actinomyces, Fusobacterium, Prevotella, and Porphyromonas spp.
- **Human:** Viridans streptococci, S. aureus, E. corrodens, Haemophilus influenzae, and β-lactamase–producing anaerobic bacteria.

### Signs and Symptoms
- The onset of infectious symptomatology is typically 12–24 hours after the bite.
- Pain at the wound site is common.
- Erythema, edema, and purulent or malodorous drainage at the wound site are manifestations of infected wounds. The patient may be febrile.
- Limited range of motion may be present, especially if the hand is bitten.

### Laboratory Tests
- Leukocytosis may be present.
- The clinician should obtain anaerobic and aerobic wound cultures only if the wound appears clinically infected.

### Imaging Studies
- Radiographs should be obtained if the bite is on the hand, could have damaged bone or joints, or if an embedded object or tooth fragment is suspected.

Data from Refs. 4 and 33.

### CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation of infected bite wounds is presented in Table 73–9. Complications of infected bite wounds include lymphangitis, abscess, septic arthritis, tenosynovitis, and osteomyelitis. Bites to the hand are particularly complication-prone.

### TREATMENT

The goals of therapy for an infected bite wound are rapid and successful eradication of infection and prevention of related complications.

#### Nonpharmacologic Treatment

Thorough irrigation with normal saline is the first step in the care of an infected bite wound. The wound should be elevated and immobilized. Surgical closure may be advocated, especially for facial wounds. Wounds that are infected, at higher risk for infection, or older than 24 hours should be left open because premature closure can lead to disastrous infectious complications.

#### Pharmacologic Treatment

Most bite wounds require antibiotic therapy only when clinical infection is present. However, prophylactic therapy is recommended for wounds at higher risk for infection and bites requiring surgical repair. Bites to the hand and human bites may benefit the most from prophylaxis.

The most effective agent for the treatment (and prophylaxis) of human and animal bite-wound infections is amoxicillin-clavulanate.

Alternatives include second-generation cephalosporins, such as cefuroxime, plus coverage for anaerobes, such as clindamycin or metronidazole. Moxifloxacin, doxycycline, or a carbapenem may also be used. The durations of prophylaxis and treatment are generally 3 to 5 days.

If the wound is associated with significant cellulitis and edema, systemic signs of infection, or possible joint or bone involvement, hospitalization and IV antibiotics (typically ampicillin-sulbactam 3 g IV every 6 hours) should be initiated. Bone and joint infections will require longer durations of therapy of up to 6 weeks.

### OUTCOME EVALUATION

Education of the patient, caregivers, and household members is important to limit further spread of infection and is a key component in SSTI case management. Table 73–10 lists several key prevention messages for patients with SSTIs.

- Patients receiving antibiotic therapy for SSTIs require monitoring for efficacy and safety. Efficacy typically is manifested by reductions in temperature, white blood cell count, erythema, edema, and pain. Initially, signs and symptoms of infection may worsen owing to toxin release from certain organisms (ie, GAS); however, they should begin to resolve within 48 to 72 hours of treatment initiation. If no response or worsening infection is noted after the first 3 days of antibiotics, reevaluate the patient.
  - Lack of response may be due to a noninfectious or nonbacterial diagnosis, a pathogen not covered by or resistant to current antibiotic therapy, poor patient adherence, drug or disease interactions causing decreased antibiotic absorption or increased clearance, immunodeficiency, or the need for surgical intervention. To ensure the safety of the regimen, dose antibiotics according to renal and hepatic function as appropriate, and monitor for or minimize adverse drug reactions, allergic reactions, and drug interactions.

### Prevention Education for Patients with SSTIs

1. Draining wounds should be covered with clean, dry bandages.
2. Hands should be cleaned regularly with soap and water (or with alcohol-based hand gel if not visibly soiled) and immediately after touching infected skin or any item directly contacting a draining wound.
3. General hygiene should be maintained with regular bathing.
4. Items that may become contaminated with wound drainage or that directly touch the skin should not be shared.
5. Wash and dry thoroughly any clothing that has come in contact with wound drainage after each use.
6. If the wound is unable to be covered with a clean, dry bandage at all times, avoid activities with skin-to-skin contact until the wound is healed.
7. Equipment and environmental surfaces with bare skin contact should be cleaned with S. aureus–active detergents or disinfectants.

Community-acquired methicillin-resistant 
Vancomycin-intermediate 
Methicillin-sensitive

Address any patient concerns about SSTIs and their
Review the medical history. Does the patient have any risk factors or chronic conditions that lend to the diagnosis of an SSTI or a particular causative pathogen?
Conduct a medication history (including prescriptions, OTC medications, and dietary supplements). Does the patient have any drug allergies? Is the patient experiencing side effects from therapy?
Review available laboratory tests, especially white blood cell counts and renal function.

Therapy Evaluation:
• Determine whether oral or IV therapy is indicated based on severity of infection.
• If the patient is already receiving pharmacotherapy, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?
• Determine whether the patient has prescription coverage or whether recommended agents are included on the institution’s formulary.

Care Plan Development:
• Select an empirical antibiotic agent based on patient assessment that is likely to be effective and safe.
• Determine whether drug doses, dosing frequency, and duration of therapy are optimal.
• Address any patient concerns about SSTIs and their management.
• In pediatric patients especially, consider method and ease of administration, and palatability and tolerability of oral formulations.

Follow-Up Evaluation:
• Ensure that antimicrobial therapy is effective by monitoring for resolution of local and systemic signs and symptoms of infection.
• Monitor for laboratory evidence of infection resolution.
• Narrow antibiotic coverage when possible with the use of culture and sensitivity data.
• Determine whether patient is experiencing any adverse reactions or drug interactions.

Abbreviations Introduced in This Chapter
CA-MRSA  Community-acquired methicillin-resistant  \textit{S. aureus}
GAS  Group A \textit{Streptococcus} (also known as \textit{Streptococcus pyogenes}, one of the \textit{β}-hemolytic streptococci)
GERD  Gastroesophageal reflux disease
HA-MRSA  Health care-associated methicillin-resistant  \textit{S. aureus}
IVIG  Intravenous immunoglobulin
MIC  Minimum inhibitory concentration
MRI  Magnetic resonance imaging
MRSA  Methicillin-resistant  \textit{S. aureus}
MSSA  Methicillin-sensitive  \textit{S. aureus}
NF  Necrotizing fasciitis
SIRS  Systemic inflammatory response syndrome
SSTI  Skin and soft tissue infection
VISA  Vancomycin-intermediate  \textit{S. aureus}
VRE  Vancomycin-resistant enterococci
VRSA  Vancomycin-resistant  \textit{S. aureus}

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Differentiate the causes and development of infective endocarditis (IE).
2. Identify the clinical presentation and laboratory evaluation for IE.
3. Assess diagnostic criteria used to evaluate a patient suspected of having IE.
4. Describe the most likely causative pathogens of IE, particularly in specific patient populations.
5. Develop appropriate pharmacologic treatment recommendations for patients with IE.
6. Define appropriate patient populations requiring prophylactic treatment, and differentiate appropriate drug regimens.
7. Devise a monitoring plan for patients with IE to determine treatment efficacy and discern any adverse effects.

INTRODUCTION

Infective endocarditis (IE) is a serious infection affecting the lining and valves of the heart. Although this disease is mostly associated with infection of the heart valves, septal defects may become involved in some cases. Infections also occur in patients with prosthetic or mechanical devices or who are intravenous drug users (IVDUs). Bacteria are the primary cause of IE; however, fungi and atypical organisms may also be responsible pathogens.

Typically IE is classified into two categories: acute or subacute. Differences between the two categories are based on the progression and severity of the disease. Acute disease is more aggressive, characterized by high fevers, leukocytosis, and systemic toxicity, with death occurring within a few days to weeks. This type of IE is often caused by more virulent organisms, particularly *Staphylococcus aureus*. Subacute disease is typically caused by less virulent organisms, such as viridans group streptococci, producing a slower and more subtle presentation. It is characterized by weakness, fatigue, low-grade fever, night sweats, weight loss, and other nonspecific symptoms, with death occurring in several months.

Successful management of patients with IE is based on proper diagnosis, treatment with appropriate therapy, and monitoring for complications, adverse events, or development of resistance. The treatment and management of IE are best determined through identification of the causative organism. IE has varied clinical presentations; therefore, patients with this infection may be found in any medical subspecialty (ie, medicine, surgery, critical care, etc).

EPIDEMIOLOGY AND ETIOLOGY

Despite IE being a fairly uncommon infection, in the United States, there are about 10,000 to 20,000 new cases annually, accounting for an incidence of approximately five to seven cases per 100,000 persons-years. Although the exact number of cases is often difficult to determine, owing to the diagnostic criteria and reporting methods for this disease, it continues to rise. IE is now considered the fourth leading cause of serious infectious diseases syndromes following sepsis secondary to urinary tract infection, pneumonia, and intraabdominal sepsis. Although IE occurs at any age, more than 50% of cases occur in patients older than 50 years. IE in children continues to be uncommon and is mainly associated with underlying structural defects, surgical repair of the defects, or nosocomial catheter-related bacteremia. With the increased use of mechanical valves, prosthetic-valve endocarditis (PVE) now accounts for approximately 10% to 30%. Patients who are IVDUs are also at an increased risk for IE, with 150 to 2000 cases per 100,000 persons per year, most being younger adults. Additionally, others at high risk for IE include patients with any congenital or structural cardiac defects, including valvular disease, long-term hemodialysis, diabetes mellitus; poor oral hygiene, major dental treatment, previous endocarditis, hypertrophic cardiomyopathy, and mitral valve prolapse with regurgitation.

Although almost any type of microorganism is capable of causing IE, the majority of cases are caused by gram-positive organisms. These consist primarily of streptococci, staphylococci, and enterococci. Consideration of gram-negative, fungal, and other atypical organisms must be taken into account, particularly in certain patient populations. In Table 74–1, approximate percentages are given for each organism based on the type of IE, including native valve (community-acquired vs health care–associated), prosthetic valve (grouped by months post-surgery), and IVDUs.
organism and vegetation progression, often producing an organism density of $10^4$ to $10^{10}$ colony-forming units (CFU) per gram.

Acquisition of PVE differs in early stages, where direct inoculation may occur during surgery rather than through hematogenous seeding. In addition, causative organisms in early PVE are typically nosocomial, with increased likelihood of being drug resistant. Embolic events are also common. Embolization occurs as portions of the friable vegetation break loose and enter the bloodstream. These infected pieces are called septic emboli. Pulmonary abscesses are commonly formed as a result of septic emboli from right-sided IE (tricuspid and pulmonary valves). However, in late PVE, the process of colonization and vegetation formation is similar to that of native-valve IE, as described earlier.

Typically, vegetations are located on the line along valve closure on the atrial surface of the atroventricular valves (tricuspid and mitral) or on the ventricular surface of the semilunar valves (pulmonary and aortic). The vegetations can vary significantly in size, ranging from millimeters to several centimeters and may be single or multiple masses. Often, destruction of underlying tissue occurs and may cause perforation of the valve leaflet or rupture of the chordae tendineae, interventricular septum, or papillary muscle. Valve ring abscesses may occur, resulting in fistulas penetrating into the myocardium or pericardial sac, particularly with staphylococcal endocarditis.

Embolic events are also common. Embolization occurs as portions of the friable vegetation break loose and enter the bloodstream. These infected pieces are called septic emboli. Pulmonary abscesses are commonly formed as a result of septic emboli from right-sided IE (tricuspid and pulmonary valves). However, left-sided IE (mitral and aortic valves) is more likely to have an embolus travel to any organ, especially kidneys, spleen, and brain. Along with emboli, immune complex deposition may occur in organ systems, causing extracardiac manifestations of the disease. This commonly occurs in the kidneys, producing
abscesses, infarction, or glomerulonephritis. Immune complexes or emboli may also produce skin manifestations of the disease, as seen with petechiae, Osler nodes, and Janeway lesions, or within the eye (eg, Roth spots).

**CLINICAL PRESENTATION AND DIAGNOSIS**

- **A fever is the most frequent and persistent symptom in patients but may be blunted with previous antibiotic use, congestive heart failure, chronic liver or renal failure, or infection caused by a less virulent organism (ie, subacute disease).**
- Other signs and symptoms that may also occur are listed below, with some discussed in further detail.

Heart murmurs are heard frequently on auscultation (greater than 85% of cases), but a new murmur or change in murmurs is only found in 3% to 5% or 5% to 10%, respectively. Additionally, more than 90% of patients who have a new murmur will develop congestive heart failure, which is a major cause of morbidity and mortality. Splenomegaly and mycotic aneurysms are also noted in many cases of IE.

This disease is also characterized by the following peripheral manifestations. Some of these clinical findings are found in up to one-half of adult patients with IE, although recently the prevalence has been decreasing and is rarely seen in children.

- **Skin:** Petechiae are very small (usually less than 3 mm), pinpoint, flat red spots beneath the skin surface caused by microhemorrhaging. They occur in 20% to 40% of patients with chronic IE and are often found on the buccal mucosa, conjunctivae (Figure 74–1A), and extremities. Splinter hemorrhages appear as small dark streaks beneath the fingernails or toenails and occur most commonly proximally with IE, typically as a result of local vasculitis or microemboli in about 20% of patients (Figure 74–1B). Osler nodes are small (usually 2–15 mm), painful, tender subcutaneous nodules located on the pads of the fingers and toes (Figure 74–1D) caused primarily by either septic emboli or vasculitis. These nodes are rare in acute disease but are also nonspecific for IE despite occurring in 10% to 25% of all patients. Janeway lesions are small, painless, hemorrhagic macular plaques on the palms of the hands or soles of the feet due to septic emboli (in ~5% of patients) and more commonly associated with acute S. aureus IE (Figure 74–1E).

- **Extremities:** Clubbing of the finger tips typically occurs in long-standing illness and is present in approximately 10% to 20% of patients (Figure 74–1C).

- **Eye:** Roth spots occur rarely (less than 5% of IE cases) and are oval-shaped retinal hemorrhages with a pale center near the optic disc (Figure 74–1F).

**Laboratory Studies**

- **Blood cultures are the essential laboratory test for the diagnosis and treatment of IE. Typically, patients with IE have a low-grade consistent bacteremia, with approximately 80% of cases having less than 100 CFU/mL (100,000 CFU/L) in the bloodstream.** Blood culture results are critical for determining the **most appropriate therapy.** Three blood culture sets should be drawn within the initial 24 hours to determine the etiologic agent. Approximately 90% of the first two cultures will yield a positive result. If a positive blood culture is not obtained from a patient with suspected IE, the microbiology laboratory should be notified to monitor cultures for growth of fastidious organisms (eg, HACEK) for up to 1 month. Another important tool aiding in the diagnosis of IE is the echocardiogram. This imaging tool is used to visualize vegetations. Two methods of the echocardiogram are used: the transthoracic echocardiogram (TTE) and the transesophageal echocardiogram (TEE).
An erythrocyte sedimentation rate (ESR) may also be obtained to determine the presence of inflammation, although this test is highly nonspecific and almost always elevated in IE.

### Diagnostic Criteria

- A definitive diagnosis of IE would consist of a biopsy or culture directly from pathologic specimens from the endocardium. However, this would be a highly invasive test. Therefore, diagnosis of IE relies on clinical presentation as well as laboratory and echocardiographic results. To guide the clinical diagnosis of IE, major and minor criteria have been established (Table 74–2A). Depending on the number of major or minor criteria a patient demonstrates, leads to a classification of definite, possible, or rejected diagnosis of IE (Table 74–2B).

### Causative Organisms

- Gram-positive bacteria are the most common causative organisms to produce IE. Streptococci and staphylococci species account for the majority of cases at more than 80%. Viridans group streptococci have been considered the primary pathogens in IE. However, staphylococci have been increasing in prevalence and are now the dominant causative organisms in some reports (see Table 74–1). Other gram-positive, gram-negative, atypical, and fungal organisms are less common but still must be considered in certain patient populations.

#### Streptococci

Streptococci causing IE are typically a group of species called viridans group streptococci. The most common of this group are Streptococcus salivarius, Streptococcus mutans, Streptococcus mitis, and Streptococcus sanguis. This group of bacteria, considered normal flora in the human mouth, is α-hemolytic, with most clinical microbiology laboratories not differentiating to the exact species. These organisms may cause bacteremia after dental procedures, which can lead to the development of IE in at-risk patients. Viridans group streptococci are also the predominant pathogen of IE associated with mitral valve prolapse, native valves and in children. Another streptococcal species commonly associated with IE is Streptococcus bovis, classified as group D streptococci and is frequently found in the GI tract. However, owing to the similarities of these streptococci, including microbiologic susceptibility, treatment is similar regardless of species.

IE caused by these streptococci typically have a subacute clinical course. The current cure rate is often greater than 90% unless complications arise, which do occur in more than 30% of patients. The majority of viridans group streptococci remain very susceptible to penicillin, with most strains having a minimum inhibitory concentration (MIC) of less than 0.125 mcg/mL (0.125 mg/L). However, isolation of organisms with decreased susceptibilities is increasing. Therefore, antibiotic susceptibilities need to be assessed in order to determine the most appropriate treatment regimen.

#### Staphylococci

Staphylococcal endocarditis continues to increase in prevalence, causing 30% or more of all cases of IE, with the majority (80%–90%) being due to S. aureus (coagulase-positive staphylococci). This increase in staphylococci has been primarily attributed to expanded use of venous catheters, more frequent valve replacement, and increased IVDU. Coagulase-negative...
## Modified Duke Criteria for IE

### 2A. Definitions of Modified Duke Criteria

#### Major Criteria

**Blood culture positive for IE:**
- Typical microorganisms consistent with IE from two separate blood cultures:
  - Viridans streptococci, *S. bovis*, HACEK group, *S. aureus*, or community-acquired enterococci in the absence of a primary focus, or
- Microorganisms consistent with IE from persistently positive blood cultures, defined as follows:
  - At least two positive cultures of blood samples drawn greater than 12 hours apart, or
  - All of three or a majority of four separate cultures of blood (with first and last sample drawn at least 1 hour apart)

**Single positive blood culture for *C. burnetii* or antiphase I IgG antibody titer greater than 1:800**

**Evidence of endocardial involvement:**
- Echocardiogram positive for IE (TEE recommended in patients with prosthetic valves, rated at least “possible IE” by clinical criteria, or complicated IE [paravalvular abscess] TTE as first test in other patients), defined as follows:
  - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant, or on implanted material in the absence of an alternative anatomic explanation, or
  - Abscess, or
  - New partial dehiscence of prosthetic valve
  - New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

#### Minor Criteria

**Predisposition:** predisposing heart condition or injection drug use

**Fever:** temperature greater than 38°C (100.4°F)

**Vascular phenomena:** major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions

**Immunologic phenomena:** glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor

**Microbiologic evidence:** positive blood culture but does not meet a major criterion as noted above or serologic evidence of active infection with organism consistent with IE

### 2B. Modified Duke Criteria for the Diagnosis of IE

#### Definite IE

**Pathologic criteria:**
- (1) Microorganisms demonstrated by culture or histologic examination of a vegetation that has embolized, or an intracardiac abscess specimen, or
- (2) Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

**Clinical criteria:**
- (1) Two major criteria, or
- (2) One major criterion and three minor criteria, or
- (3) Five minor criteria

#### Possible IE

(1) One major criterion and one minor criterion, or

(2) Three minor criteria

#### Rejected

(1) Firm alternate diagnosis explaining evidence of IE, or

(2) Resolution of IE syndrome with antibiotic therapy for less than or equal to 4 days, or

(3) No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for less than or equal to 4 days, or

(4) Does not meet criteria for possible IE, as above

---

TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

*Excludes single positive cultures for CNS and organisms that do not cause endocarditis.

*See above for definitions of major and minor criteria.

staphylococci (CNS) also cause IE; however, these organisms typically infect prosthetic valves or indwelling catheters.19

Patients with S. aureus bacteremia are at an increased risk of developing IE. S. aureus may infect “normal” heart valves (no prior detected valvular disease) in one-third of cases.1,17 Therefore, it is imperative to assess these patients adequately for the presence of vegetations. Any heart valve may be affected; however, when the mitral or aortic valve is involved, it often results in extensive systemic infection with a mortality rate of approximately 20% to 65%.1,17 When treating S. aureus IE, one must consider whether the isolate displays methicillin-resistance, the location of infection (right or left side), presence of prosthetic valves, and history of IVDU. Despite significant resistance to penicillinase-resistant penicillins (eg, methicillin and nafcillin), most isolates remain susceptible to vancomycin. However, there is an increasing incidence of S. aureus with an elevated MIC of 2 mcg/mL (2 mg/L) which may require use of an alternative agent such as daptomycin.20 Additionally, strains that are intermediate-resistant or fully resistant to vancomycin have been reported.21–23 Fortunately, these strains are not widespread enough to affect empirical antibiotic selection. Susceptibility reports along with clinical response should be assessed to ensure appropriate antimicrobial coverage.

Over the past decade, there has been an increasing emergence of community-acquired methicillin-resistant S. aureus (CA-MRSA) that differs from healthcare-associated MRSA. This organism tends to be less resistant to many antibiotics, with sensitivity to clindamycin, trimethoprim-sulfamethoxazole, and minocycline, as well as vancomycin, linezolid, and daptomycin. In addition, this organism has a virulence gene (Panton-Valentine-leukocidin), which produces a toxin that causes necrosis. To date, this organism primarily causes skin/skin-structure infections or pneumonias (see Chapter 73: Skin and Soft Tissue Infections). There have been a limited number of cases of IE caused by CA-MRSA.24 If CA-MRSA is suspected, treatment with vancomycin with or without gentamicin and/or rifampin remains standard of care.

The predominant coagulase-negative organism causing IE has been S. epidermidis. However, in the past few years there has been an increase in isolation of another coagulase-negative species, S. lugdunensis.25,26 Typically, coagulase-negative staphylococcal IE has a subacute course with numerous complications. Treatment (with or without surgical intervention) is usually successful. On the other hand, S. lugdunensis produces a more virulent infection and, despite similar antibiotic susceptibilities, has a much higher mortality rate.25,26

► Enterococci

Enterococci are normal flora of the human GI tract and sometimes found in the anterior urethra. Affected patients are typically older males who have undergone genitourinary manipulations or younger females who have had obstetric procedures. Although enterococci are a less common cause of IE, there are two predominant species: Enterococcus faecium and Enterococcus faecalis. E. faecalis is the most common and more susceptible of the strains. However, enterococci overall are more intrinsically resistant, with enterococcal IE representing one of the most problematic gram-positive infections to treat and cure. Frequently, enterococci display resistance to multiple antibiotics, including penicillins, vancomycin, aminoglycosides, as well as being described in some of the newer agents (eg, linezolid, quinupristin/dalfopristin, or daptomycin).27

► Gram-Negative Organisms

Gram-negative IE is much less common (~2%) but is typically much more difficult to treat than gram-positive infections.1,28 Fastidious organisms, such as the HACEK group, tend to be seen most commonly, causing approximately 3% of all IE.4,29,30 This group consists of Haemophilus spp. (primarily H. paraprophilus, H. parainfluenzae, and H. arophilus), Aggregatibacter actinomycetemcomitans, Cardio bacterium hominis, Eikenella corrodens, and Kingella kingae. The clinical presentation of IE by these organisms is subacute, with approximately 50% of patients developing complications. These complications are primarily due to the presence of large, friable vegetations and numerous emboli along with development of acute congestive heart failure often requiring valve replacement.30,31 It is important to allow cultures sufficient incubation time (often 2–3 weeks) in order to isolate these organisms. Despite prolonged incubation, these organisms may not be isolated on culture and thus present as culture-negative IE.

Other gram-negative organisms, such as Pseudomonas spp., cause IE, especially in IVDU and patients with prosthetic valves. Additionally, IE may be caused by Salmonella spp., Escherichia coli, Citrobacter spp., Klebsiella spp., Enterobacter spp., Serratia marcescens, Proteus spp., and Providencia spp.1,28

Historically, gram-negative IE typically had a poor prognosis with high mortality rates. However, as nondrug therapy advances to include cardiac surgery in more than half of patients, in-hospital mortality has improved to 24%.32 Treatment usually consists of high-dose combination antimicrobial therapy, with valve replacement often necessary in many patients.

► Culture Negative

Negative blood cultures are reported in approximately 5% of confirmed IE cases, often delaying diagnosis and treatment.1,33 Cultures that do not grow bacteria may be the result of previous antibiotic use, subacute right-sided disease, slow growth of fastidious organisms, nonbacterial endocarditis (eg, fungal or intracellular parasitic infections), noninfective endocarditis, or improper collection of blood cultures. If nonbacterial or fastidious organisms are suspected, additional testing is essential. The choice of treatment regimen depends on patient history and risk factors.

► Other Organisms

Numerous bacteria, including gram-positive bacilli, unusual gram-negative bacteria, atypical bacteria, and anaerobes, as well as spirochetes, may be a rare cause IE.34 Some of the more common organisms include Legionella, Coxiella burnetii (Q fever), and Brucella. These rare organisms occur primarily in at-risk patients such as those with prosthetic valves or IVDU. A comprehensive discussion of these organisms is not feasible for this chapter; for further information, other references sources (particularly references 1–5) should be examined. Treatment of these organisms is difficult, and cure rates are low. Therefore, consulting an infectious diseases specialist is warranted.

► Fungi

Fungal endocarditis is quite uncommon but has significant mortality, typically affecting patients who have had cardiovascular surgery, received total parenteral nutrition (TPN) or prolonged course of broad-spectrum antibiotics, have long-term catheter placement, immunocompromised, or IVDU.3,33 Survival rates remain poor, at approximately 15%, but improvements (survival rates ~30%) have been reported owing to advances in diagnosis
and treatment. Poor prognosis has been attributed to large vegetations, propensity for organism invasion into the myocardium, extensive septic emboli, poor antifungal penetration into vegetations, and low toxic-to-therapeutic ratio and lack of cidal activity of certain antifungals. The two most commonly associated organisms are *Candida* spp. and *Aspergillus* spp. Lack of clinical studies makes treatment decisions difficult. Typically, combination and/or high-dose therapy in conjunction with surgery is required.

**TREATMENT**

**Therapeutic Considerations**

Treatment of IE often is complicated and difficult. Numerous factors involving vegetations influence the effectiveness of antimicrobial agents. Vegetations consist of a fibrin matrix (as discussed earlier) that provides an environment where organisms are relatively free to replicate unimpeded, allowing the microbial density to reach very high concentrations ($10^5$–$10^9$ CFU/g). Once organism density has reached this level, the organisms are virtually in a static growth phase. These factors hinder host defenses, as well as the ability of antimicrobials to produce sufficient kill. This is often seen with β-lactams and glycopeptides as their effectiveness can be significantly affected by bacterial inoculum and stationary growth phase.

**KEY CONCEPT** Selection of an appropriate antimicrobial agent must combine characteristics such as the ability to penetrate into the vegetation, the ability to achieve adequate drug concentrations, and the ability to be minimally affected by high bacterial inoculum in order to achieve adequate kill rates.

**KEY CONCEPT** To accomplish this, antimicrobials typically have to be given parenterally at high doses, with an extended treatment course of 4 to 6 weeks (in most cases). Other desirable drug characteristics include bactericidal and synergistic activity.

**Empirical Therapy**

**KEY CONCEPT** The overall goal of therapy is to eradicate the infection and minimize/prevent any complications. Patients with suspected IE should be evaluated for risk factors that may provide some indication of the most likely causative organism. If no risk factors can be determined, empirical therapy should primarily cover gram-positive organisms. Generally, if streptococci are suspected, empirical treatment should consist of penicillin plus gentamicin. However, if staphylococci or enterococci are suspected, empirical treatment should consist of vancomycin plus gentamicin. It is important to monitor the patient’s response to therapy closely until cultures and susceptibilities are determined to ensure adequate treatment.

**Specific Therapy**

The American Heart Association (AHA) has published guidelines for the management of IE, including specific treatment recommendations. A summary of these treatments for the most common organisms (streptococci, staphylococci, and enterococci) is provided in Tables 74–3 through 74–6. However, for more detailed information, refer to the complete guidelines.

**Streptococci**

Most isolates are highly susceptible to penicillin; therefore, penicillin G remains the regimen of choice. However, ceftriaxone may be used as an alternative agent if the patient is allergic or penicillin resistance is suspected. Typically, length of treatment is 4 weeks and remains the most common duration. However, a shorter course (ie, 2 weeks) may be employed for a patient with uncomplicated IE due to highly penicillin-susceptible strains with no extracardiac infection or whose creatinine clearance is greater than 20 mL/min (0.33 mL/s). If the shorter length of therapy is chosen, gentamicin should be added to the previous regimens for the entire course (ie, 2 weeks). Recommended therapies for highly penicillin-susceptible viridans streptococci are summarized in Table 74–3.

When penicillin MICs for viridans group streptococci are greater than 0.12 mcg/mL [0.12 mg/L] but less than or equal to 0.5 mcg/mL [0.5 mg/L], antimicrobial doses should be increased with 4 weeks therapy suggested. In addition, combination therapy with gentamicin is recommended during the first 2 weeks. In patients who are allergic or intolerant to β-lactams, vancomycin is an alternative treatment option. In patients with resistant strains of viridans group streptococci (MIC greater than 0.5 mcg/mL [0.5 mg/L]), treatment should include antimicrobial agents for enterococcal IE (precise agents determined by the susceptibility report).

Patients with PVE caused by penicillin-susceptible strains of viridans streptococci require treatment for 6 weeks with penicillin G or ceftriaxone with or without gentamicin during the initial 2 weeks of therapy. However, if the organism demonstrates less susceptibility to penicillin (MIC greater than > 0.12 mcg/mL [0.12 mg/L]), combination therapy with penicillin G or ceftriaxone plus gentamicin should be given for the entire 6 weeks. Vancomycin remains the primary alternative for β-lactam (eg, penicillins, cephalosporins) allergic patients.

---

**Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests**

**PMH:** ESRD on hemodialysis (MWF), type 2 diabetes

**FH:** Mother had a history of hypertension and died at the age of 70 from a stroke; father’s history is unknown

**SH:** She began dialysis 6 months ago. She denied alcohol, illicit drug, and tobacco usage

**Meds:** Novolog (insulin aspart) 90 units/24 hour basal rate with 20 units bolus prior to each meal via an insulin pump; sevelamer 800 mg three times daily; epogen 10,000 units post-HD

**Allergies:** No known allergies

**ROS:** Fatigue, decreased appetite

**PE:**

- **VS:** BP 105/65 mm Hg, P 115 beats/min, RR 22 breaths/min, T 39.5°C

- **Cardiovascular:** Tachycardia, positive new murmur

- **Abd:** Normal weight, soft, nontender, nondistended; (–) bowel sounds

- **Labs:** Within normal limits, except WBC = 18.6 × 10^9/μL (18.6 × 10^9/L), SCR = 4.2 mg/dL (371 μmol/L)

**Given this additional information, what is your assessment of the patient’s condition?**

**Identify your empirical treatment recommendations for this patient.**

**What other information would be beneficial to obtain?**

<td>Vancomycin therapy recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to obtain peak (1 hour after infusion completed) serum concentration of 30–35 mcg/mL (30–35 mg/L; 21–24 μmol/L) and a trough concentration range of 10–15 mcg/mL (10–15 mg/L; 6.9–10.4 μmol/L)</td>
</tr>
</tbody>
</table>

IM, intramuscularly; MIC, minimum inhibitory concentration.
*Dosage recommended are for patients with normal renal function.

IA, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from multiple randomized clinical trials; IB, condition with evidence and/or general agreement that a procedure or treatment is useful and effective based on data from a single randomized trial or nonrandomized studies.

Pediatric dose should not exceed that of a normal adult.

Other potentially nephrotoxic drugs (eg, nonsteroidal anti-inflammatory drugs) should be used with caution in patients receiving gentamicin therapy.

Data for once-daily dosing of aminoglycosides for children exist, but no data for treatment of IE exist.

Vancomycin dosages should be infused during course of at least 1 hour to reduce risk of histamine-release "red man" syndrome.

**Notes:**
- IM, intramuscular.
- *Dosages recommended are for patients with normal renal function.
- IA, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from multiple randomized clinical trials; IB, condition with evidence and/or general agreement that a procedure or treatment is useful and effective based on data from a single randomized trial or nonrandomized studies.
- Penicillin G 24 million units/24 hour IV in four to six equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin-susceptible (MIC less than or equal to 0.1 mcg/mL [0.1 mg/L]) and does not produce β-lactamase.
- Gentamicin should be administered in close temporal proximity to vancomycin, nafcillin, or oxacillin dosing.
- Pediatric dose should not exceed that of a normal adult.
- For specific dosing adjustment and issues concerning vancomycin, see Table 74–3 footnotes.

**Staphylococci**

It is important to determine (a) whether the isolate is methicillin-susceptible versus methicillin-resistant and (b) whether the patient has a native versus prosthetic valve. For patients with no prosthetic material, methicillin-susceptible staphylococcal treatment should consist of a penicillinase-resistant penicillin (eg, nafcillin or oxacillin) or cefazolin with or without gentamicin, and for methicillin-resistant strains, therapy should consist of vancomycin (see Table 74–4). Combination therapy with aminoglycosides, when used in these patients, typically is given only during the first 3 to 5 days of therapy to decrease bacterial burden. In the absence of prosthetic material, some treatment guidelines do not recommend combination therapy against MRSA. However, many clinicians may combine either gentamicin or rifampin with vancomycin if the patient is unresponsive to monotherapy.

Increasing resistance of staphylococci necessitates the expanded use of alternative therapies. Daptomycin demonstrated similar efficacy when compared with standard therapy (ie, penicillinase-resistant penicillin for methicillin-sensitive *S. aureus* [MSSA] or vancomycin for MRSA) in patients with staphylococcal IE and is FDA approved for the treatment of right-sided IE or bacteremia caused by *S. aureus*. Additional daptomycin dosing for these indications is 6 mg/kg/day (unless renal adjustments are necessary); although dosages of 8 to 10 mg/kg/day have been suggested in IE. Daptomycin was shown to be safe and well tolerated. Additionally, other antibiotics, such as ceftaroline, linezolid, quinupristin/dalfopristin, telavancin, or tigecycline alone or in combination, have been used in patients who were unresponsive to standard therapy, although they have had variable response rates. These therapies often are reserved for patients who have been unresponsive to traditional therapy (eg, β-lactams or vancomycin) or for organisms that remain susceptible to these agents when resistant to traditional therapy.

<sup>a</sup>Dosages recommended are for patients with normal renal function.

<sup>b</sup>IB, condition with evidence and/or general agreement that a procedure or treatment is useful and effective, based on data from a single randomized trial or nonrandomized studies.

<sup>c</sup>Gentamicin should be administered in close proximity to vancomycin, nafcillin, or oxacillin dosing.

<sup>d</sup>Pediatric dose should not exceed that of a normal adult.

For staphylococcal PVE, treatment length increases significantly, typically requiring a minimum of 6 weeks (see Table 74–5). For MSSA, a penicillinase-resistant penicillin should still be used, as well as vancomycin for MRSA. However, with either regimen, addition of gentamicin for first 2 weeks and rifampin for the entire length of treatment is recommended. Infectious Diseases consultation is recommended for all patients with S. aureus IE, irrespective of methicillin-susceptibility, due to an observed reduction in mortality in this patient population.

### Enterococci

For enterococci, it is imperative to determine species and antibiotic susceptibilities. If the organism is susceptible to penicillin and vancomycin, treatment may consist of high-dose penicillin G, ampicillin, or vancomycin plus an aminoglycoside (gentamicin [see Table 74–6] or streptomycin for gentamicin-resistant strains). Treatment length is usually 4 to 6 weeks, with the aminoglycoside used over the entire course. As resistance develops to penicillin, ampicillin and vancomycin remain treatment options. If the isolate becomes resistant to ampicillin, vancomycin is considered the treatment of choice. If the isolate is determined to be vancomycin-resistant, it is crucial to know the exact species because some treatment options, such as quinupristin/dalfopristin, are not active against E. faecalis. Treatment options for vancomycin-resistant enterococci (VRE) have not been well established. Currently,
recommendations for treating vancomycin-resistant *E. faecium* include linezolid or quinupristin/dalfopristin for a minimum of 8 weeks. However, newer agents, such as daptomycin, provide another option for treatment for either enterococci species (*E. faecium* and *E. faecalis*). The guidelines also suggest the use of imipenem/cilastatin plus ampicillin or ceftriaxone plus ampicillin for the treatment of *E. faecalis*, with a minimum of 8 weeks of therapy; although these regimens are not commonly used. Even with newer agents, combination therapy is often warranted; therefore, consultation with an infectious diseases specialist is recommended if VRE is identified.

### Gram-Negative Organisms

Identification of the exact pathogen is crucial in gram-negative IE as treatment decisions depend on which organism is isolated. Therapy is usually targeted to the most susceptible antibiotics. Combination therapy (usually the addition of an aminoglycoside) is commonly used. For example, *Pseudomonas* spp. are treated with an antipseudomonal β-lactam (eg, piperacillin/tazobactam, cefepime, imipenem/cilastatin) plus high-dose aminoglycoside (typically tobramycin 8 mg/kg/day). However, exact dosing of antibiotics depends on the organism isolated. Length of treatment is usually a minimum of 6 weeks.

### HACEK Group

The HACEK group bacteria are difficult to isolate, often taking weeks for identification. If one of these organisms is suspected, it is important to initiate appropriate empirical treatment. The preferred regimen is ceftriaxone (or another third- or fourth-generation cephalosporin), followed by ampicillin-sulbactam. However, for patients who are intolerant of these treatments, ciprofloxacin may be used. The length of treatment typically is 4 weeks for these organisms.

### Culture-Negative

Treatment for culture-negative IE presents a significant dilemma. Therapeutic regimens are guided by isolated organisms. When cultures fail to identify a specific organism, decisions regarding treatment should cover the most common causative pathogens. If the patient is unresponsive to this initial treatment, additional coverage for less common organisms becomes warranted. An infectious diseases specialist should be consulted for managing culture-negative IE.

### Fungi

Treatment of fungal IE is exceptionally difficult. There is a significant lack of evidence to identify the most appropriate therapy. Currently, amphotericin B is the most common treatment. However, valve replacement surgery is often considered a necessary adjunctive therapy. Intravenous antifungal therapy requires high doses for a minimum of 8 weeks of treatment. Oral azoles (eg, fluconazole) are used as long-term suppressive therapy to prevent relapse. Newer antifungals may be effective options, including the echinocandins (eg, caspofungin) and voriconazole, depending on the organism and susceptibilities.

### Surgery

Surgical intervention has become an integral therapy in combination with pharmacologic management of IE. Valve replacement is the predominant intervention, and is used in almost one-half of all cases of IE. Surgery may be indicated if the patient has unresolved infection, ineffective antimicrobial therapy, more than one episode of serious emboli, refractory congestive heart failure, significant valvular dysfunction, mycotic aneurysm requiring resection, local complications (perivalvular or myocardial abscesses), or prosthetic-valve infection associated with a pathogen demonstrating higher antimicrobial resistance. Often a patient’s hemodynamic status (ie, blood pressure, heart rate, pulmonary artery pressure, etc) is used to determine when surgical intervention is warranted. Despite appropriate medical management and cure, a significant number of people who develop native-valve endocarditis require valve replacement surgery. Involvement of the aorta or development of IE complications is considered an indication for surgery in the majority of patients with PVE.

### Antimicrobial Dosing Considerations

The majority of antibiotic and antifungal agents used for the treatment of IE require dosing modifications based on renal or hepatic function. However, the most closely monitored are vancomycin and aminoglycosides. This is due in part because (a) serum levels are normally monitored to guide therapy, and (b) there is an increased likelihood of developing toxicities (ie, nephrotoxicity, ototoxicity) if the level is too high or adverse outcomes (ie, clinical failure or resistance development) if level is too low. General dosing considerations are included in Table 74–7 for...
the most commonly used drugs for treating IE. However, specific dosing adjustments for individual patients should be determined by referring to an appropriate drug dosing reference.

**Prophylaxis**

**KEY CONCEPT** Certain conditions have been associated more commonly with IE due to preexisting cardiac disease in the presence of a transient bacteremia. In an effort to prevent the development of IE, prophylactic treatment is generally considered appropriate for these at-risk patients. Although there are no well-controlled clinical studies of these recommendations, it is thought that if antibiotics are given just prior to a procedure, the number of bacteria may be decreased in the bloodstream and prevent the bacteria from adhering to the valves.

Cardiac conditions in which prophylaxis is reasonable include presence of prosthetic valves or material, prior IE, congenital cardiac disease (specific forms only), and cardiac transplant patients with cardiac valvulopathy (Table 74–8). Although many patients have other cardiac dysfunction, only patients with these conditions are considered to be at a high risk of developing IE. No prophylaxis is advised in other patients.

Transient bacteremia may occur due to many types of dental and surgical procedures. However, the AHA guidelines significantly limit the types of procedures where prophylaxis is appropriate. Only dental procedures involving manipulation of gingival tissue or periapical region of teeth or perforation of the oral mucosa are considered to increase the likelihood that high-risk patients will develop IE. Viridans group streptococci are the primary bacteria targeted for prophylaxis in this circumstance. On the other hand, prophylaxis for GI or genitourinary surgeries primarily targets enterococci.

The AHA guidelines include suggested antibiotic regimens for dental procedures for which prophylaxis is warranted. Recommended regimens for dental procedures are listed in Table 74–9.

AE, adverse event; CPK, creatinine phosphokinase; CrCl, creatinine clearance.

*Gram-negative bacteria, fungal, or atypical treatments are not listed. It is suggested that an Infectious Diseases Consult be obtained if a patient has IE caused by one of these organisms due to the complexity and difficulty in managing these patients.
These guidelines recommend a single oral or intramuscular/intravenous dose initiated shortly before the procedure. The regimen for dental procedures consists primarily of a penicillin as first choice, with a cephalosporin for penicillin-allergic patients who have not had an anaphylactic reaction and clindamycin or a macrolide for penicillin-allergic patients. A second prophylactic dose is not recommended. However, if an infection develops at the procedure site, additional antibiotics (ie, a therapeutic course) may be required.

**OUTCOME EVALUATION**

**Key Concept** Monitoring for successful therapy is critical for this serious infection to prevent complications, prevent development of resistance, and decrease mortality. Routine assessment of clinical signs and symptoms, as well as laboratory tests (ie, repeat blood cultures), microbiologic testing, and serum drug concentrations (if appropriate), must be performed.

Resolution of signs and symptoms typically occurs within a few days to a week in most cases. Monitor the patient daily for febrile episodes, as well as other vital signs, with expected normal values within 2 to 3 days of initiating antimicrobial therapy. Persistent signs or symptoms could be indicative of inadequate treatment or development of resistance.

Blood cultures are the primary laboratory evaluation to assess response to therapy. Typically, with appropriate treatment, they should become negative within 3 to 7 days. Perform additional blood cultures if the patient appears unresponsive to current therapy or upon treatment completion to confirm eradication of infection. Evaluate all susceptibility reports to assess for appropriateness of antimicrobial therapy.

IM, intramuscular.

*Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.

*Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

Patient Care Process

Patient Assessment:
- Review patient history (social, medical, and surgical), physical exam, laboratory tests (especially blood cultures) and diagnostic imaging (particularly echocardiogram results), assess whether patient has clinical features of IE utilizing modified Duke criteria (see Table 74–2).
- Review patient past medical and medication history. Does patient have any allergies which could limit antimicrobial therapy? Does patient have any risk factors for resistant-pathogens (prior use of broad-spectrum antibiotics, multiple hospital admissions, hemodialysis patient, etc)?
- Conduct a personal history to identify possible causes of IE.

Therapy Evaluation:
- Once blood culture identification/susceptibility reported, determine if patient is on appropriate antimicrobial therapy.
- If bacteremia not cleared after repeat blood cultures, reassess appropriateness of antimicrobial(s) including new cultures/susceptibility and drug dosage and/or frequency.
- Monitor subsequent blood cultures for growth. Determine end of therapy based on first negative blood culture.
- Monitor vital signs/symptoms for return to baseline. If continued to be abnormal, reassessment of therapy/other diagnostic testing is necessary.

Follow-Up Evaluation:
- Is patient experiencing any adverse effects from their antimicrobial(s)? Are there any potential drug–drug interactions from this medication?
- Determine whether recommended agent is on institution’s formulary. If not, is there a formulary alternative? If no alternative, is there anything specific to institution to utilize nonformulary agent?
- Determine whether patient has prescription coverage. Is patient able to afford medication if completing therapy as an outpatient?

Care Plan Development:
- Determine whether drug doses are optimal. Change therapy if pathogen not susceptible to current antimicrobial(s) or if patient not improving on current therapy.
- Address any patient concerns about IE and its management.
- Discuss importance of lifestyle modifications if applicable.

Additionally, counsel patients at risk on the necessity of prophylactic antibiotics prior to major dental treatments in order to prevent recurrent infections. This is critical in patients with risk factors that predispose them to developing IE, such as prosthetic heart valves, other valvular defects, or previous IE.

Develop a follow-up plan to determine whether the patient has achieved a cure, which includes a clinical evaluation of signs/symptoms, repeat blood cultures, and possibly a repeat echocardiogram. The patient should also be assessed for any adverse events. This should be performed usually within a few weeks after the completion of therapy.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Compare the risk for active tuberculosis (TB) disease among patients based on their age, immune status, place of birth, and time since exposure to an active case.
2. Design an appropriate therapeutic plan for a patient with active TB disease.
3. Distinguish among the diagnostic tests used for patients potentially infected with TB.
4. Assess the effectiveness of therapy in TB patients.
5. Describe the common and important adverse drug effects caused by TB drugs.
6. Select patients for whom therapeutic drug monitoring (TDM) may be valuable and identify the necessary laboratory monitoring parameters for patients on antituberculosis medications.
7. Design appropriate antimicrobial regimens for the treatment of latent TB infection.

INTRODUCTION

Tuberculosis (TB) remains one of the leading infectious causes of death worldwide. In 2012, about 8.6 million people developed TB and 1.3 million people died from the disease. Most deaths are preventable if access to health care for diagnosis and correct treatment are provided.

EPIDEMIOLOGY AND ETIOLOGY

Roughly one-third of the world’s population is infected and drug resistance is increasing in many areas. The majority of cases worldwide are found in South-East Asia and Africa. In the United States, about 13 million people have latent TB infection (LTBI), evidenced by a positive skin test (purified protein derivative [PPD]) but no signs or symptoms of disease. The PPD is the antigen derived from Mycobacterium tuberculosis used to determine the presence of an immune response in patients with previous exposure. Patients testing positive have roughly a 1 in 10 chance of active disease during their lives, with the greatest risk in the first 2 years after infection. In 2013, 9588 new TB cases were reported in the United States; a 4.2% decline from 2012.

The most recent data from the Centers for Disease Control and Prevention (CDC) indicate that TB deaths in the United States have increased slightly to 7.6%, from 529 deaths in 2009 to 569 deaths in 2010. (For details, visit the CDC website at www.cdc.gov/nchstp/tb.)

Risk Factors for Infection

Location and Place of Birth

California, New York, Florida, and Texas accounted for approximately 50% of all TB cases in 2013. These higher numbers may reflect the high immigration rates into these states. Mexico, the Philippines, Vietnam, India, and China account for the largest numbers of these immigrants. TB is most prevalent in large urban areas and is exacerbated by crowded living conditions. Those in close contact with patients with active pulmonary TB are most likely to become infected.

Race, Ethnicity, Age, and Gender

In 2012, Asians accounted for 30% of new TB cases, followed by Hispanics (28%) and African Americans (22%), whereas non-Hispanic whites accounted for 16% of new TB cases in the United States. TB is most common among people 25 to 44 years of age, and those 45 to 64 years of age.

Risk Factors for Disease

Once infected, a person’s lifetime risk of active TB is about 10%, with about half this risk during the first 2 years. Young children, the elderly, and immunocompromised patients have greater risks. HIV is the most important risk factor for active TB because the immune deficit prevents patients from containing the initial infection. HIV-infected patients with M. tuberculosis infection are roughly 100 times more likely to develop active TB than normal hosts.

TB is caused by M. tuberculosis, a rod-shaped thin aerobic bacterium. It presents either as LTBI or as progressive active disease. The latter typically causes progressive destruction of the lungs, leading to death in most patients who do not receive treatment. M. tuberculosis are acid-fast bacilli (AFB). Acid-fast organisms are characterized by wax-like nearly impermeable cells walls which often do not stain with Gram stain and cannot be decolorized by acid alcohol. The cell wall contains a high amount of mycolic acids, long-chain fatty acids, and cell wall lipids which make the wall difficult to attack with conventional antibiotics. The acid-fast stain is a differential stain used to identify acid-fast organisms.
Culture and Susceptibility Testing

Microscopic examination of infected material (“sputum smear” of material on a glass slide) is the most rapid and readily available test to detect AFB in clinical specimens. Three sputum specimens should be collected in patients suspected of pulmonary TB to increase the likelihood of finding AFB. The sensitivity of the sputum smear is only about 40%, so culture based TB diagnosis is the current gold standard.3 Unfortunately, culture is much slower due to the roughly 20-hour doubling time of the bacilli. Furthermore, microscopic examination for AFB through sputum smear alone cannot determine which of over 100 mycobacterial species is present. Depending on the presence of epidemiological risk factors, the usual practice is to isolate the patient and treat empirically until presence of M. tuberculosis is confirmed by genetic probe or positive culture.

Antimicrobial susceptibility testing is essential for directing proper treatment. The most common method utilizing solid growth media, known as the proportion method, takes 3 to 8 weeks to produce results. Growth in liquid media is faster and can detect live mycobacteria in about 2 weeks.5,6 Rapid-identification tests include nucleic acid amplification tests utilizing the polymerase chain reaction (PCR).7,9 Three nucleic acid amplification tests have been approved for use in the United States to detect M. tuberculosis in respiratory secretions. These tests are highly sensitive and specific for smear positive patients and somewhat less sensitive in smear negative patients, but only need as few as 1 to 10 organisms/mL (10–10⁹/L) to give a positive result.7,9

The Cepheid MTB/RIF Assay performed on the Xpert System is a qualitative test designed for rapid detection of M. tuberculosis and rifampin resistance.10 New tests looking for specific mutations such as the katG gene associated with isoniazid resistance may facilitate rapid drug therapy decisions in the future. Nitrate reductase assays and porous ceramic support systems are among other rapid drug susceptibility testing techniques currently being investigated.11 DNA fingerprinting is performed to assist surveillance programs and contact investigations. Various techniques are employed including restriction fragment length polymorphism (RFLP) analysis, spoligotyping, and mycobacterial interspersed repeat units. These techniques exploit conserved fragments in the TB genome that change gradually over time and allow investigators to determine if strains are related to one another. Strains that are related to one another are referred to as clusters. Clusters generally indicate recent transmission and are then targeted for interventions by TB programs.12

PATHOPHYSIOLOGY

Primary Infection

M. tuberculosis is transmitted from person to person by coughing or any other aerosol producing activities.4,13 This produces small particles known as droplet nuclei that float in the air for long periods of time. Primary infection usually results from inhaling droplet nuclei that contain M. tuberculosis.4,13 The progression to clinical disease depends on three factors: (1) the number of M. tuberculosis organisms inhaled (infecting dose), (2) the virulence of these organisms, and (3) the host’s cell-mediated immune response.5,13,14 If pulmonary macrophages inhibit or kill the bacilli, the infection is aborted.15 If not, M. tuberculosis eventually spreads throughout the body through the bloodstream.4,13 M. tuberculosis most commonly infects the posterior apical region of the lungs, where conditions are most favorable for its survival.

T lymphocytes become activated over the course of 3 to 4 weeks, producing interferon-γ (IFN-γ) and other cytokines. These stimulate microbicidal macrophages to surround the tuberculous foci and form granulomas to prevent further extension.16 A granuloma is a nodular aggregation of mononuclear inflammatory cells formed when the immune system attempts to wall off foreign substances. At this point, the infection is largely under control, and bacillary replication falls off dramatically. Any remaining mycobacteria are believed to reside primarily within granulomas or within macrophages that have avoided detection and lysis. Over 1 to 3 months, tissue hypersensitivity occurs, resulting in a positive tuberculin skin test.4,13 Approximately 95% of individuals with an intact immune system will enter into this latent phase. Progressive primary disease occurs in roughly 5% of patients, especially children, the elderly, and immunocompromised patients.14 This presents as a progressive pneumonia and frequently spreads, leading to meningitis and other severe forms of TB, often before patients develop positive skin tests or interferon-γ release assays.15

Reactivation Disease

About 10% of infected patients develop reactivation TB, with half occurring in the first 2 years after infection.14 Reactivation TB results when a previously “dormant” focus is reactivated and causes disease. Progression involves the development of caseating granulomas as a result of a vigorous immune response. Liquefaction leads to local spread and a pulmonary cavity results. This provides a portal to the airways and subsequently ambient
air that enhances person-to-person spread. Bacterial counts in the cavities can be as high as $10^9$/mL ($10^{11}$/L) of cavity fluid.\textsuperscript{4,13} Prior to the chemotherapy era, pulmonary TB usually was associated with hypoxia, respiratory acidosis, and eventually death related to asphyxia; a fate that remains all too common in poor countries where patients do not have access to effective therapy.

### Extrapulmonary and Miliary Tuberculosis

Caseating granulomas, regardless of location, can spread tubercle bacilli, and cause symptoms.\textsuperscript{1} Because of muted or altered symptoms, the diagnosis of TB is difficult and often delayed in immunocompromised hosts.\textsuperscript{4,13} HIV-infected patients may present with only extrapulmonary TB, which is uncommon in HIV-negative persons. A widely disseminated form of the disease called miliary TB can occur, particularly in children and immunocompromised hosts. It can be rapidly fatal and immediate treatment is required.\textsuperscript{13}

#### Influence of HIV Infection on Pathogenesis

HIV infection is the most important risk factor for active TB.\textsuperscript{13} As CD4+ lymphocytes multiply in response to the mycobacterial infection, HIV multiplies within these cells and selectively destroys them, gradually eliminating the TB-fighting lymphocytes.\textsuperscript{16,17} HIV-positive patients often have negative skin tests and fail to produce cavitary lesions, and fever may be absent. Cavitary lesions are present in a wide variety of pathological processes involving the lung and are observed radiographically as gas or fluid filled areas of the lung in the center of a nodule. Approximately 5% of HIV-infected patients with pulmonary TB who are not being treated effectively with antiretroviral medications will have positive results on acid-fast staining, yet have a normal chest radiograph. Patients coinfected with HIV and TB have a substantially higher risk of early mortality compared with HIV-negative patients with TB.\textsuperscript{17}

### CLINICAL PRESENTATION AND DIAGNOSIS

Fever, night sweats, weight loss, fatigue, and a productive cough are the classic symptoms of TB.\textsuperscript{4,13,14} Onset may be gradual, and the diagnosis is easily missed if the symptoms are muted.\textsuperscript{4,13,14} Progressive pulmonary disease leads to cavitary lesions visible on x-ray. Physical examination is nonspecific but may be consistent with pneumonia. Dullness to chest percussion, rales, and increased vocal fremitus may be observed on examination. Laboratory data often are uninformative, but a modest increase in the white blood cell (WBC) count with a lymphocytic predominance can be seen. Frequently however, the physical exam is largely unremarkable.

Atypical presentations are common in patients coinfected with HIV.\textsuperscript{4,13,17} Symptoms for these patients range from classic pulmonary to muted and nonspecific. Extrapulmonary TB typically presents either as a slowly progressive decline in the affected organ’s function or commonly as a mass lesion. Lymphadenopathy is relatively common.\textsuperscript{13,14} Abnormal behavior, headaches, or convulsions suggest tuberculous meningitis, although other acute central nervous system (CNS) infections must be excluded.\textsuperscript{4,14}

#### The Elderly

- Positive skin tests, fevers, night sweats, sputum production, or hemoptysis may be absent, making TB hard to distinguish from other bacterial or viral infections or chronic lung diseases.\textsuperscript{4,13,19} In contrast, mental status changes are twice as common in the elderly, and CNS disease must be considered when TB is entertained. Mortality is six times higher in the elderly, in part owing to delays in diagnosis.\textsuperscript{4,18,19}

### Children

- TB in children may present as atypical bacterial pneumonia, and often involves the lower and middle lobes.\textsuperscript{14,17} Extrapulmonary TB is more common in children. The Bacille Calmette-Guérin (BCG) is a vaccine made from strains of tubercle bacilli and is used to produce immunity against human TB. It is administered in countries where TB remains common appears to stimulate children’s immune systems to ward off the most serious forms of the disease. In fact, BCG is most effective in reducing infant mortality from TB meningitis and miliary disease. BCG does not block infection, and these same children often experience reactivation TB as young adults.

#### Skin Testing

TB skin testing with PPD (commercially available as Tubersol or Aplisol) is one of the oldest diagnostic tests still in clinical use.\textsuperscript{4,14,16} Also known as the tuberculin skin test, the product is injected into the skin (not subcutaneously) with a fine (27-gauge) needle, a technique referred to as the Mantoux method, and produces a small, raised, blanched wheal to be read by an experienced professional in 48 to 72 hours. The chance of a false-negative result is increased when the patient is immunosuppressed. The CDC does not recommend the routine use of energy panels to determine if a patient’s T-cell immune system reacts to common antigens.\textsuperscript{16,20}

Criteria for interpretation are listed in Table 75–1.\textsuperscript{14} The “booster effect” occurs in patients who do not respond to an initial skin test but show a positive reaction if retested 1 to 3 weeks later.\textsuperscript{16,20} In order to reduce the likelihood that a boosted reaction is misinterpreted as a new infection, the two-step method is recommended at the time of initial testing for individuals such as health care workers or nursing home residents who may be tested periodically. If the first PPD skin test is negative, repeat the test in 1 to 3 weeks. If the second test is positive, it is most likely a boosted reaction, and the person should be classified as previously infected.

#### Newer Diagnostic Tests

Newer technology has led to the development of blood tests or interferon-γ release assays (IGRAs) that may replace the PPD test.\textsuperscript{20} These methods measure the release of interferon-γ in blood in response to TB antigens. The sensitivity of IGRAs ranges from 80% to 90%, and specificity of 95% for diagnosis of latent TB. The IGRAs do not cause the booster phenomenon and are unaffected by BCG, or infection by most nontuberculous mycobacteria. Results of the IGRAs are available in less than 24 hours, versus the 3 days required for the traditional PPD skin test. Data are limited for use of IGRAs in children younger than 5 years of age, persons recently exposed to TB, health care workers, and immunodeficient patients.\textsuperscript{20} The CDC has endorsed the use of IGRA tests in all circumstances where the PPD is used. IGRAs are approved for the diagnosis of LTBI in HIV-infected patients, but sensitivity is diminished.\textsuperscript{20} IGRAs are preferred for testing patients who have received BCG and in patients who have poor rates of return for PPD skin test reading. Testing with both PPD and IGRA generally is not recommended, but may be useful in certain situations (eg, if the initial PPD test is negative and the risk for infection, clinical suspicion, or the
risk for poor outcome is high; or if the initial PPD test is positive and additional evidence of infection is required; or the patient has a low risk of infection or progression). For persons who are otherwise at low risk and are tested at the start of employment, a reaction of 15 mm or more of induration is considered positive. Risk of TB in patients treated with corticosteroids increases with higher dose and longer duration.

### TREATMENT

#### General Approaches to Treatment

The primary treatment approach is the use of antimicrobials active against *M. tuberculosis*. Monotherapy can be used only for patients with LTBI, as evidenced by a positive skin test or positive IGRA profile in the absence of signs or symptoms of disease.

Once active disease is present, typically *three or four drugs* must be used simultaneously from the outset of treatment. The shortest duration of treatment is 4 months in the unusual case of smear and culture negative clinical cases of pulmonary TB, and up to 2 years of treatment may be necessary for advanced cases of multidrug-resistant tuberculosis (MDR-TB). Directly observed treatment (DOT) is a method used to ensure adherence in which patients are directly observed by a healthcare worker while taking their antituberculosis medication. This also is a cost-effective way to ensure completion of treatment.

#### Desired Outcomes

- Steps should be taken to (a) prevent the spread of TB (respiratory isolation); (b) find where TB has already spread (contact investigation); and (c) return the patient to a state of normal weight and well-being. Items (a) and (b) are performed by public health departments. Clinicians involved in the treatment of TB should verify that the local health department has been notified of all new cases of TB. In rare instances, surgery may be needed.

#### Pharmacologic Therapy

### Treating LTBI

**KEY CONCEPT** Isoniazid is used for treating LTBI. Typically, isoniazid 300 mg daily (5–10 mg/kg of body weight) is given alone for 9 months. Lower doses usually are less effective. In some instances, a 6 month duration of treatment with isoniazid alone is an acceptable alternative. Pyridoxine (25–50 mg/day in adults) can reduce the risk of peripheral neuropathy. Treatment of LTBI reduces a person’s lifetime risk of active TB from about 10% to about 1%. Rifampin 600 mg daily for 4 months can be used when isoniazid resistance is suspected or when the patient cannot tolerate isoniazid. Rifabutin 300 mg daily might be substituted for rifampin in patients at high risk of drug interactions. The combination of pyrazinamide and rifampin is no longer recommended.

Once-weekly doses of isoniazid 900 mg and rifapentine 900 mg given as DOT for 3 months are as effective as 9 months of self-administered isoniazid 300 mg daily. When resistance to isoniazid and rifampin is suspected, there is no regimen proven to be effective (Table 75–2). Note that patients with LTBI are not infectious and there is no isolate on which to perform susceptibility testing. Susceptibility patterns must be inferred based on the most likely source of infection.

### Treating Active Disease

In the United States, TB patients can receive free treatment through the local health department. Treating active TB disease requires combination chemotherapy. Generally, four drugs are started. In particular, isoniazid and rifampin should be included because they are the best drugs available for preventing drug resistance. Drug susceptibility testing should be done on the initial isolate for all patients. Susceptibility testing is repeated if the patient remains culture-positive 8 weeks or more into therapy.

The standard TB treatment regimen for susceptible TB is isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin for 4 months, for a total of 6 months of treatment. Extending treatment to 9 months of isoniazid and rifampin treatment is recommended for patients at greater risk of failure and relapse, including those with cavitary lesions on initial chest radiograph and positive cultures at the completion of the initial 2-month phase of treatment, as well as for patients treated initially without pyrazinamide. Ideally, treatment should be continued for at least 6 months from the time...

**CXR:** Bilateral upper lobe infiltrates with cavity lesions on left; small left pneumothorax

### Clinical Course

The patient was admitted and placed on respiratory isolation. Three separate sputum AFB stain specimens were reported to contain 3+ AFB. IFN-γ was sent and a PPD tuberculin skin test was placed. Sputum samples were sent for AFB, fungi, and bacterial cultures and sensitivities. After 48 hours, the PPD skin test was read as a 7-mm area of induration.

### Assessment

Active pulmonary TB; pneumothorax; hypertension; type 2 diabetes mellitus; rheumatoid arthritis

Which signs, symptoms, and other findings are consistent with active TB infection?

---

**Key Concept:** That patients convert to a negative culture. When the patients’ sputum smears convert to negative, the risk of infecting others is greatly reduced, but it is not zero. Such patients can be removed from respiratory isolation if they are responding clinically. The decision to discontinue isolation should be done by medical providers experienced in TB control. Table 75–3 shows the recommended treatment regimens. When intermittent therapy is used, DOT is essential. Doses missed during an intermittent TB regimen decrease the efficacy of the regimen and increase the relapse rate.

Adjustments to the regimen should be based upon susceptibility data. Drug resistance should be suspected in patients who have been treated previously for TB. If adjustments are needed, two or more drugs with in vitro activity against the patient’s isolate and that were not used previously should be added to the regimen. When isoniazid and rifampin cannot be used, either because of drug resistance or intolerance, treatment durations typically become 2 years or more, regardless of immune status. TB specialists should be consulted regarding cases of drug-resistant TB, or whenever treatment is uncertain. Therapeutic drug monitoring (TDM) can direct dosing for such patients. One of the proven reasons for treatment failure is malabsorption of orally administered drugs. Due to the risk of further drug resistance, it is critical to avoid adding only a single drug to a failing regimen.

*Strength of recommendation: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given.

†Quality of evidence: I = randomized clinical trial data; II = data from clinical trials that are not randomized or were conducted in other populations; III = expert opinion.

‡Recommended regimen for children younger than 18 years.

§Recommended regimens for pregnant women. Pyrazinamide should be avoided during the first trimester.

‖Rifabutin should not be used with hard-gel saquinavir or delavirdine. When used with other protease inhibitors or NNRTIs, dose adjustment of rifabutin may be required.

Special Populations

Treatment for extrapulmonary TB is the same as for pulmonary disease. Patients with CNS TB usually are treated for 12 months.8,24 Isoniazid and pyrazinamide cross the blood–brain barrier well, but rifampin, ethambutol, and streptomycin can penetrate inflamed meninges. TB osteomyelitis typically is treated for 9 months, occasionally with surgical débridement.15,24 TB of the soft tissues can be treated with conventional regimens.8,24 Patients with diabetes mellitus have been shown to have low 2-hour peak serum concentrations of antimicrobials. TDM can be considered to optimize treatment response.9,24 TB in children may be treated with regimens similar to those used in adults, although some physicians extend treatment to 9 months.8,14,15,16,24 Pediatric doses of isoniazid and rifampin on a milligram per kilogram basis are higher than those used in adults (Table 75–4).24

Pregnant women receive the usual treatment of isoniazid, rifampin, and ethambutol for 9 months.24 Pyrazinamide has not been studied in large numbers of pregnant women, but anecdotal data suggest that it may be safe.24,31 The clinician should always determine risk versus benefit and determine if a drug is safe to administer in pregnancy.

Human Immunodeficiency Virus

HIV-infected adults may receive a 6-month regimen of phase of isoniazid, a rifamycin, pyrazinamide, and ethambutol for the first 2 months followed by isoniazid and a rifamycin for 4 months.8,12 Some clinicians recommend extending treatment to 9 months. Rifabutin is used to reduce drug interactions with protease inhibitors and some non-nucleoside reverse transcriptase inhibitors. Integrated antiretroviral therapy (ART) is superior to sequential ART in the treatment of naïve HIV seropositive patients with TB.31 The optimal timing of integrated HIV and TB therapy is influenced by the patient’s immune status.30 It is recommended to start integrated ART therapy 2 to 12 weeks after initiating anti-TB therapy.30 TB-HIV experts should manage such patients. Highly intermittent regimens (twice or once weekly) are not recommended for HIV-positive TB patients.24,32 Some patients with AIDS malabsorb their oral medications, and drug interactions are common, so TDM can be useful.24,28,29

<sup>a</sup>When DOT is used, drugs may be given 5 days per week and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.

<sup>b</sup>Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive 7-month continuation phase.

<sup>c</sup>Five days a week administration is always given by DOT.

<sup>d</sup>Not recommended for HIV infected patients with CD4 counts < 100 cells/μl (100 × 10<sup>6</sup>/L).

<sup>e</sup>Once weekly options with rifapentine should be used only in HIV negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph. For patients started on this regimen and found to have a positive culture form the 2-month specimen, treatment should be extended an extra 3 months. Centers for Disease Control and Prevention. Treatment of Tuberculosis, American Thoracic Society, CDC, and Infectious Diseases Society of America. MMWR 2003;52(No. RR-11);[inclusive page numbers].

For complete recommendations on management of TB and HIV visit the CDC website: www.cdc.gov/tb/publications/guidelines/HIV_AIDS.htm.

**Multidrug-Resistant TB**

If drug-resistant TB is suspected, the empiric regimen should be modified based on patterns of suspected resistance. Once susceptibilities are confirmed, regimens can be modified appropriately. Patients with MDR-TB are at high risk of failure and should be treated by specialists or centers with experience treating drug resistant TB.

**Renal Failure**

Isoniazid and rifampin usually do not require dose modification in renal failure. Pyrazinamide and ethambutol typically are reduced to three times weekly to avoid accumulation of the parent drug (ethambutol) or metabolites (pyrazinamide). Renally cleared TB drugs include the aminoglycosides, ethambutol, cycloserine, and levofloxacin. With renal impairment, dosing intervals need to be extended for these drugs. TB drugs should be administered after hemodialysis; three times weekly regimens may be more convenient. Serum concentration monitoring should be performed for cycloserine and ethambutol to avoid dose-related toxicities in renal failure patients.

**Patient Encounter, Part 3**

Based on the information provided, what are the goals of therapy for this patient?

Select and recommend a therapeutic plan for treatment of this patient’s TB infection. What drugs, dose, schedule, and duration of therapy are best for this patient? Who else should be tested? How should any contacts infected by this patient be evaluated and treated?

$^a$Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

$^b$For purposes of this document, adult dosing begins at age 15 years.

$^c$The authors of this chapter do not agree with the use of maximum doses, since this arbitrarily caps doses for patients who otherwise might need larger doses. These maximum doses were not based on prospective studies in large or overweight individuals, and do not consider patients with documented malabsorption of their medications. Clinical judgment should be used in such circumstances.

$^d$Higher doses of rifampin and rifapentine are being studied. Rifabutin dose may need to be adjusted when there is concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.

$^e$The drug can likely be used safely in older children but should be used with caution in children less than 5 years of age, in whom visual acuity cannot be monitored. In younger children, ethambutol at the dose of 15 mg/kg/day can be used if there is suspected or proven resistance to isoniazid or rifampin.

$^f$It should be noted that, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.

$^g$The single daily dose can be given at bedtime or with the main meal.

$^h$Dose: 15 mg/kg/day (1 g), and 10 mg/kg in persons older than 59 years of age (750 mg). Usual dose: 750–1000 mg administered intramuscularly or intravenously, given as a single dose 5–7 days/week and reduced to two or three times per week after the first 2 to 4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.

$^i$The long-term (more than several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both isoniazid and rifampin. The optimal dose is not known.

$^j$The long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

Data from Centers for Disease Control and Prevention. Treatment of tuberculosis. MMWR 2003;52 (RR-11).

► Hepatic Failure

Hepatically cleared TB drugs include isoniazid, rifampin, pyrazinamide, ethionamide, and $p$-aminosalicylic acid. Ciprofloxacin and moxifloxacin are about 50% cleared by the liver. Isoniazid, rifampin, pyrazinamide, and to a lesser degree ethionamide, $p$-aminosalicylic acid, and rarely ethambutol may cause hepatotoxicity. These patients require close monitoring, and serum concentration monitoring may be the most accurate way to dose them.

TB Drugs

Detailed information regarding TB drugs can be accessed at the following references. A summary is provided in Table 75–4. Isoniazid, rifampin, and pyrazinamide are the key drugs. Other drugs are used in selected circumstances. Quinolones eventually may be used as first-line drugs, but currently are not. In 2012, the Food and Drug Administration approved bedaquiline for the treatment of MDR-TB. It should be used with three or more drugs that are active against the patient’s isolate. Bedaquiline carries a black-box warning due to prolongation of QTc interval. Baseline and follow-up electrocardiograms are recommended. Other new therapies include investigational vaccines, and investigational drugs such as PA-824, OPC-67683, and SQ109, which are in clinical trials.

OUTCOME EVALUATION

Effectiveness of TB therapy is determined by AFB smears and cultures. Send sputum samples for AFB staining and microscopic examination (sputum smears) every 1 to 2 weeks until two consecutive smears are negative. This provides early evidence of a response to treatment. Once on maintenance therapy, sputum
cultures can be performed monthly until two consecutive cultures are negative, which generally occurs over 2 to 3 months. If sputum cultures continue to be positive after 2 months, repeat drug susceptibility testing and check serum concentrations of the drugs.

**KEY CONCEPT** The most serious problem with TB therapy is patient nonadherence. There is no reliable way to identify such patients a priori, therefore DOT should be used. DOT also provides increased opportunities to observe the patient for any apparent toxicities, thus improving overall care.

Check serum chemistries, including blood urea nitrogen (BUN), creatinine, aspartate transaminase (AST), and alanine transaminase (ALT) and a complete blood count with platelets at baseline and periodically thereafter depending on the presence of other factors that may increase the likelihood of toxicity (eg, advanced age, alcohol abuse, pregnancy). Suspect hepatotoxicity in patients whose transaminases exceed five times the upper limit of normal (ULN) or whose total bilirubin exceeds 3 mg/dL (51 μmol/L), and in patients with symptoms such as nausea, vomiting, and jaundice with liver enzyme elevations of more than three times ULN. At this point, discontinue the offending agents. Typically, all TB drugs are stopped, followed by the sequential reintroduction of the drugs, along with frequent testing of liver enzymes. This usually is successful in identifying the offending agent; other agents may be continued (see Table 75–4).

**Therapeutic Drug Monitoring**

TDM is the use of serum drug concentrations to optimize therapy. Patients with uncomplicated, drug-susceptible TB generally do well. Pharmacokinetic variability of anti-TB drugs can contribute to poor outcomes despite adherence. TDM can be used to shorten the time to response and to treatment completion. The evidence to support the use of TDM in the treatment of TB is growing. TDM can assist in patients failing appropriate DOT (no clinical improvement after 2 to 4 weeks or smear-positive after 4 to 6 weeks). Patients with AIDS, diabetes, and various GI disorders often fail to absorb these drugs properly and also are candidates for TDM. Drug levels in patients with hepatic or renal disease should be monitored, given their potential for toxicities. In the treatment of MDR-TB, TDM may be particularly useful. Finally, TDM of the TB and HIV drugs is perhaps the most logical way to untangle the complex drug interactions that take place.

For a complete list of drug interactions, visit the CDC website: [www.cdc.gov/tb/publications/guidelines/TB_HIV_DRUGS/default.htm](http://www.cdc.gov/tb/publications/guidelines/TB_HIV_DRUGS/default.htm). In particular, interactions between the rifamycins (eg, rifampin, rifapentine, rifabutin) and the HIV protease inhibitors and non-nucleoside reverse transcriptase inhibitors are common and require dose and frequency modifications in many cases. Because these are constantly being updated, the preceding link is an excellent way to keep current.

**Patient Care Process**

- Rapidly identify a new TB case.
- Assess the patient’s risk factors and signs and symptoms to determine whether the patient might be infected with TB.
- Isolate the patient with active disease to prevent the spread of the disease.
- Collect appropriate samples for smears and cultures.

**Therapy Evaluation:**

- Obtain a thorough medication history.
- Select and recommend appropriate antituberculosis treatment. Consider HIV status, type of TB infection, renal function, liver function, etc.

**Care Plan Development:**

- Ensure adherence to the treatment regimen by the patient.
- Obtain AFB stains to evaluate the effectiveness of treatment.
- Consider TDM if no clinical improvement.

**Follow-up Evaluation:**

- Continue treatment for at least 6 months from the time the patient converts to a negative culture.
- Identify the index case that infected the patient, identify of all persons infected by both the index case and the new case of TB, and the complete of appropriate treatments for those individuals.

**Abbreviations Introduced in This Chapter**

- AFB: Acid-fast bacillus
- AIDS: Acquired immunodeficiency syndrome
- ALT: Alanine transaminase
- ART: Antiretroviral therapy
- AST: Aspartate transaminase
- BCG: Bacille Calmette-Guérin
- CDC: Centers for Disease Control and Prevention
- CNS: Central nervous system
- DOT: Directly observed therapy
- HIV: Human immunodeficiency virus
- HTN: Hypertension
- IGRA: interferon-γ release assay
- INF: Interferon
- LTBI: Latent tuberculosis infection
- MDR-TB: Multidrug-resistant tuberculosis
- MGIT: Mycobacterial growth indicator tube
- NIDDM: Noninsulin-dependent diabetes mellitus
- PCR: Polymerase chain reaction
- PPD: Purified protein derivative
- RFLP: Restriction fragment length polymorphism
- TB: Tuberculosis
- TDM: Therapeutic drug monitoring
- ULN: Upper limit of normal
- WBC: White blood cell

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Describe the epidemiology and clinical presentation of commonly encountered gastrointestinal (GI) infections.
2. Summarize common risk factors associated with the development of a GI infection.
3. Given a patient with a GI infection, develop an individualized treatment plan.
4. Outline the impact of widespread antimicrobial resistance on current treatment recommendations for GI infections.
5. Discuss the effect of host immunosuppression on the risk of disease complications and treatment strategies associated with GI infections.
6. Educate patients on appropriate prevention measures of GI infections.
7. Describe the role of antimicrobial prophylaxis and/or vaccination for GI infections.

INTRODUCTION

One of the primary concerns related to gastrointestinal (GI) infection, regardless of the cause, is dehydration, which is the second leading cause of worldwide morbidity and mortality. Dehydration is especially problematic for children younger than age 5; however, the highest rate of death in the United States occurs among the elderly. Rehydration is the foundation of therapy for GI infections, and oral rehydration therapy (ORT) is usually preferred (Table 76–1). Single-dose oral ondansetron should be considered the first-line antiemetic in children who are dehydrated with significant vomiting. In non-immunocompromised hospitalized pediatric patients, Lactobacillus supplementation may reduce the length of hospitalization.

In the United States, each year 31 major pathogens cause about 9 million episodes of foodborne illness, almost 56,000 hospitalizations, and 1350 deaths. Most illnesses are caused by norovirus, nontyphoidal Salmonella (NTS), Clostridium perfringens, and Campylobacter. The indiscriminate use of proton-pump inhibitor (PPI) therapy leads to GI-tract bacterial colonization and increased susceptibility to enteric bacterial infections.

SHIGELLOSIS

Epidemiology

Shigella causes bacillary dysentery, which refers to diarrheal stool containing pus and blood. Worldwide, there are an estimated 165 million annual cases of shigellosis, with 1 million associated deaths, and approximately 450,000 infections each year in the United States, which results in more than 6000 hospitalizations. Shigellosis usually affects children 6 months to 10 years of age. In the United States, shigellosis is a serious problem in daycare centers and in areas with crowded living conditions or poor sanitation. Most cases of shigellosis are transmitted through the fecal–oral route. Activities that may lead to shigellosis include handling toddlers’ diapers, ingesting pool water, or consuming vegetables from a sewage-contaminated field. Shigella transmission from contaminated food and water, although less common, is associated with large outbreaks.

Pathogenesis

Shigella organisms are nonmotile, nonlactose-fermenting, gram-negative rods and are members of the Enterobacteriaceae family. S. sonnei (serogroup D) is responsible for most shigellosis cases in the United States. Infection with Shigella occurs after ingestion of as few as 10 to 100 organisms, which may explain the ease of person-to-person spread. Symptoms develop in about 3 days (range, 1–7) after contracting the bacteria.

Shigella strains invade intestinal epithelial cells, with subsequent multiplication, inflammation, and destruction. This organism only rarely invades the bloodstream; but, bacteremia can occur in malnourished children and immunocompromised patients and is associated with a mortality rate as high as 20%.

Treatment and Monitoring

Although infection with Shigella is generally self-limited and responds to supportive care, antibiotic therapy is indicated because it shortens the duration of illness and reduces the risk of transmission. Several antimicrobial agents are available for the treatment of shigellosis, although options are increasingly limited due to globally emerging drug resistance. If antimicrobial susceptibility results are not available, the recommended

### SALMONELLOSIS

**Epidemiology**

Salmonella are gram-negative facultative rods that cause a wide variety of disease manifestations. *Salmonella typhi* and *Salmonella paratyphi* cause typhoid (or enteric) fever. Although typhoid fever is now a rare disease in the United States with approximately 300 clinical cases reported per year, these infections cause an estimated 20 million cases and 200,000 deaths annually worldwide. Nontyphoidal *Salmonella* (NTS) are important causes of reportable food-borne infection. There are an estimated 1.4 million cases of NTS illness annually in the United States, and almost 94 million worldwide. The highest incidence is in those younger than 1 year of age and older than 65 years of age or in those with HIV/AIDS. Exotic pets, especially reptiles, are an increasing source of human salmonellosis. NTS strains may also result in bacteremia and focal disease, such as endovascular infections, osteomyelitis, meningitis, and septic arthritis. Antimicrobial-resistant strains are associated with excess bloodstream infections and hospitalizations. Recurrent *Salmonella* bacteremia is an AIDS-defining illness.

**Clinical Presentation and Diagnosis of Shigellosis**

- Biphasic illness
  - Early—high fever, watery diarrhea without blood
  - Later—after approximately 48 hours, colitis develops with urgency, tenesmus, and dysentery
- Low-grade fever
- More frequent small-volume stools (“fractional stools”)
- Vomiting (35%)
- Complications of shigellosis
  - Proctitis or rectal prolapse—more common in infants and young children
  - Intestinal obstruction
- Colonic perforation
- Bacteremia—more common in children
- Metabolic disturbances
- Neurologic disease—most commonly seizures (approximately 10% of patients)
- Hemolytic-uremic syndrome (HUS)
- Microscopic examination of stool is extremely useful and reveals multiple polymorphonuclear leukocytes and red blood cells (RBCs). Diagnosis is usually confirmed by stool culture
Patient Encounter 1

A 3-year-old child who attends daycare four days each week complains that his “stomach hurts” and that he does not want to eat anything. His mother notes that his stools are loose and that the child has a low-grade fever. The next day, his mother notices blood and some pus in his stools.

By what method did this child most likely acquire this infection?

What is the most likely microorganism to be causing this infection?

What antibiotic (if any) should be recommended to treat this child’s infection?

Proper food handling and storage can help prevent *Salmonella* gastroenteritis. Effective handwashing is important, especially when handling eggs and poultry.

**Treatment and Monitoring**

► **Gastroenteritis**

*Salmonella* gastroenteritis is usually self-limited, and antibiotics have no proven value. Patients respond well to ORT. Symptoms typically diminish in 3 to 7 days without sequelae. Antibiotic use may result in a higher rate of chronic carriage and relapse. Antimicrobial use should be limited to preemptive therapy among patients at higher risk for extraintestinal spread or invasive disease (Table 76–2). Antimotility agents should not be used.

► **Enteric Fever**

The current drug of choice for typhoid fever in adults is a fluoroquinolone, such as ciprofloxacin. Azithromycin or ceftriaxone are preferred in children. The recommended adult dose of ciprofloxacin for uncomplicated typhoid fever is 500 mg orally twice daily for 5 to 7 days; however, decreased susceptibility to ciprofloxacin is a significant problem in many parts of the world. In the United States, *S. typhi* with decreased ciprofloxacin susceptibility is associated with travel to the Indian subcontinent. If ciprofloxacin resistance is present, ceftriaxone may be used; however, this agent may be less suitable in some low- and middle-income countries due to cost and route of administration. Azithromycin is an effective alternative for uncomplicated typhoid fever.

Two typhoid vaccines are available for use in the United States. Immunization is recommended for travelers going to endemic areas such as Latin America, Asia, and Africa; household contacts of a chronic carrier; and laboratory personnel who frequently work with *S. typhi*.

► **Bacteremia and Focal Infections**

Treatment of *Salmonella* bacteremia should be initiated with either a fluoroquinolone (eg, levofloxacin, ciprofloxacin) or a third-generation cephalosporin (eg, ceftriaxone). Given increasing antimicrobial resistance, life-threatening infections should be treated with both agents until susceptibilities are available. If there is no evidence of an endovascular infection, therapy for bacteremia should continue for 10 to 14 days. For patients with suspected meningitis, high-dose ceftriaxone is preferred because of its optimal penetration of the blood–brain barrier. Osteomyelitis and joint infections, often associated with sickle-cell anemia, are difficult to eradicate and require longer durations of antimicrobial therapy (at least 4–6 weeks), as do patients who are infected with HIV.

► **Chronic Carrier State**

A chronic carrier state, defined as positive stool or urine cultures for more than 12 months, develops in 1% to 4% of adults with typhoid fever. Effective agents for eradication of chronic carriage include amoxicillin (3 g orally divided three times a day in adults for 3 months), trimethoprim-sulfamethoxazole (one double-strength tablet orally twice a day for 3 months), or ciprofloxacin (750 mg orally twice daily for 4 weeks). Surgery in combination with antibiotic therapy is indicated in patients with biliary tract abnormalities.

**Clinical Presentation and Diagnosis of Salmonellosis**

**Gastroenteritis**

- Onset 8 to 48 hours after ingestion of contaminated food.
- Fever, diarrhea, and cramping.
- Stools are loose, of moderate volume, and without blood.
- Headache, myalgias, and other systemic symptoms can occur.
- Certain underlying conditions (eg, AIDS, inflammatory bowel disease, and prior gastric surgery) predispose the patient to more severe disease.

**Enteric Fever**

- Febrile illness 5 to 21 days after ingestion of contaminated food or water, which may be persistent and high-grade. A relative bradycardia may be noted at the fever peak.
- Chills, diaphoresis, headache, anorexia, cough, weakness, sore throat, dizziness, muscle pain, and diarrhea may be present before onset of fever.
- Rose spots, a coated tongue, and/or hepatosplenomegaly may be noted.
- Intestinal hemorrhage or perforation, leukopenia, anemia, and subclinical disseminated intravascular coagulopathy may occur.
- Culture of stool, blood, or bone marrow for *Salmonella* species is helpful.
CAMPYLOBACTERIOSIS
Epidemiology
Campylobacter jejuni is the most commonly identified cause of bacterial diarrhea worldwide. In the United States, this organism accounts for an estimated 1.4 million infections, 13,000 hospitalizations, and 100 deaths annually.16 Risk factors for Campylobacter infection include consumption of contaminated foods of animal origin, especially undercooked poultry or other foods that are cross-contaminated by raw poultry meat during food preparation; unpasteurized milk; contaminated water; foreign travel; contact with farm animals and pets; and the use of antimicrobial therapy.17 People should be instructed to wash their hands after contact with raw meats and animals.

In developed countries, there are two distinct age peaks for Campylobacter infection: younger than 1 year of age and 15 to 44 years of age, with a mild male predominance. In developing countries, Campylobacter diarrhea is primarily a pediatric disease.

Pathophysiology
Campylobacter spp. are gram-negative bacilli that have a curved or spiral shape. Campylobacter are sensitive to stomach acidity; as a result, diseases or medications that buffer gastric acidity may increase the risk of infection. The infectious inoculum for C. jejuni is low, similar to that for Salmonella spp. After an incubation period, infection is established in the jejunum, ileum, colon, and rectum.

Treatment
Effective fluid and electrolyte replacement is the cornerstone of therapy for patients with Campylobacter infection. In most cases, this can be accomplished with the use of oral glucose–electrolyte solutions. Antibiotic therapy should be considered in patients with high fevers, bloody stools, symptoms lasting longer than 1 week, pregnancy, infection with HIV, and other immunocompromising conditions.

Macrolides are the recommended first-line drug class for the treatment of Campylobacter infections.11 A fluoroquinolone or a tetracycline are alternatives; however, the widespread use of these agents in food animals has resulted in fluoroquinolone-resistant Campylobacter strains worldwide.12 Campylobacter fetus is the most commonly identified species in patients with bacteremia, which primarily occurs in patients who are elderly or immunocompromised. In addition, focal infections such as cellulitis, vascular infections, meningitis, and abscesses may be present. C. fetus has a predilection for the vascular endothelium and implanted medical devices.14 For these serious infections, treatment with a third-generation cephalosporin, gentamicin, ampicillin, or a carbapenem is recommended.11 Antimotility agents should be avoided because they may prolong the duration of symptoms and have been associated with worse outcomes. Postinfectious complications associated with Campylobacter infection include reactive arthritis (1%) and Guillain-Barré syndrome (0.1%).

Patient Encounter 2
A 55-year-old man with a 20-year history of HIV infection has recently purchased a pet snake. About two months after getting the snake, he presents to his local emergency center with a 3-day history of nausea, several episodes of vomiting, abdominal pain, and nonbloody diarrhea. He also complains of episodes of chills and night sweats over the past two days. Upon further questioning, it is noted that he recently lost his health insurance coverage and he has been unable to refill his HIV medications the past two months. STAT blood cultures are positive for nonpyhloidal Salmonella (NTS).
What risk factors does this patient have for a disseminated Salmonella infection?
What treatment do you recommend? Are there any special considerations due to this patient’s HIV infection?

Clinical Presentation and Diagnosis of Campylobacteriosis
- Incubation period of 1 to 7 days.
- A brief prodrome of fever, headache, and myalgias is followed by crampy abdominal pain, a high fever, and several bowel movements per day, which may be watery or bloody.
- The abdominal pain and tenderness may be localized, and pain in the right lower quadrant may mimic acute appendicitis. Abdominal pain is more prevalent in Campylobacter infection than in either Shigella or Salmonella infections.
- Tenesmus occurs in approximately 25% of patients.
- Fecal leukocytes and red blood cells (RBCs) are detected in the stools of 75% of infected individuals. Diagnosis of Campylobacter is established by stool culture.

ENTEROHEMORRHAGIC ESCHERICHIA COLI
Epidemiology
Blood in the stool indicates the possibility of inflammatory mucosal disease of the colon such as enterohemorrhagic Escherichia coli (EHEC), a pathogenic subgroup of shiga toxin-producing organisms and an important cause of bloody diarrhea in the United States. Acute hemorrhagic colitis has been primarily associated with the O157:H7 serotype. This serotype has been responsible for large outbreaks of infection, has higher rates of complications, and appears to be more pathogenic than non-EHEC STEC strains. The spectrum of disease associated with E. coli O157:H7 includes bloody diarrhea, which is seen in up to 95% of patients; nonbloody diarrhea; hemolytic-uremic syndrome (HUS); and thrombotic thrombocytopenic purpura (TTP). The incidence of HUS has declined in recent years and NSAIDs are increasingly recognized as an important contributor to acute kidney injury in children, especially if volume depleted.19

Approximately 70,000 cases of EHEC illness occur every year in the United States and lead to more than 2000 hospitalizations. The highest incidence is in patients aged 5 to 9 years and 50 to 59 years. Both young and old patients are at risk to develop postinfectious complications, TTP, and HUS.20 Outbreaks of diarrhea due to E. coli O157:H7 and other STECs have occurred following ingestion of contaminated beef, unpasteurized milk, vegetables (eg, alfalfa sprouts, coleslaw, and lettuce), and apple juice. The most important reservoir for E. coli O157:H7 is the GI tract of cattle. Person-to-person transmission also occurs,
Clinical Presentation and Diagnosis of EHEC

- Incubation period of 3 to 5 days
- Bloody stools
- Leukocytosis is often present; fever is frequently absent
- Abdominal tenderness
- HUS in 2% to 10% of patients (especially children 1 to 5 years of age and the elderly in nursing homes); develops on average 1 week after the onset of diarrhea.

EHEC belonging to serotype O157:H7 characteristically do not ferment sorbitol, whereas more than 70% of intestinal floral E. coli do. To properly screen EHEC strains in cases of diarrhea, stool should be placed on special sorbitol-MacConkey agar. In addition, stool should be tested directly for the presence of Stx I and II by enzyme immunoassay (EIA).

Pathophysiology

The infectious inoculum of EHEC is very low, between 1 and 100 colony-forming units (CFUs). The major virulence factor for EHEC is the production of two Shiga-like cytotoxins (Shiga toxin [Stx] I and II), which are responsible for vascular damage and systemic effects such as HUS. Adhesion mediates initial attachment of EHEC to intestinal epithelial cells. Following attachment, these organisms produce lesions on individual intestinal epithelial cells in the small or large intestine resulting in diarrhea.

Treatment

The only recommended treatment of EHEC infection is supportive, including fluid and electrolyte replacement, usually in the form of ORT. Most illnesses resolve in 5 to 7 days. Patients should be monitored for the development of HUS. Antibiotics are currently contraindicated because they can induce the expression and release of toxin. Antimotility agents should be avoided because they delay clearance of the pathogen and toxin, which increases the risk of systemic complications. The use of narcotics and nonsteroidal anti-inflammatory drugs (NSAIDs) should also be avoided in acutely infected patients.

Prevention of EHEC infection is especially important because no therapeutic interventions are available to lessen the risk of the development of HUS. Hamburgers should be cooked thoroughly until the temperature of the thickest part of the patty is 72°C. All surfaces and utensils that contact raw meat should be washed thoroughly before reuse. Fruits and vegetables should be washed thoroughly, especially those that will not be cooked. Handwashing is also very important and should include the supervision of handwashing by children in daycare centers.

CHOLERA

Epidemiology

Cholera is an intestinal infection that is caused by the bacterium Vibrio cholerae that leads to a massive loss of fluid through the GI tract and often results in life-threatening dehydration and shock. The biotypes of V. cholerae responsible for pandemics are serogroup O1 (El Tor) and serogroup O139. Worldwide this infection affects 3 to 5 million people and causes more than 100,000 deaths per year. Cholera can be transmitted by water or by food tainted with contaminated water, particularly undercooked seafood. Research on cholera has led to the refinement of general rehydration therapy, including the proper use of IV and oral rehydration solutions.

Pathophysiology

V. cholerae is a gram-negative bacillus. Vibrios pass through the stomach to colonize the upper small intestine. They possess filamentous protein extensions that attach to receptors on the intestinal mucosa, and their motility assists with penetration of the mucus layer. The cholera enterotoxin consists of two subunits, one of which (subunit A) is transported into the cells and causes an increase in cyclic adenosine monophosphate (cAMP), which leads to the secretion of fluid into the small intestine. This large volume of GI fluid results in the watery diarrhea that is characteristic of cholera. The stools consist of an electrolyte-rich isotonic fluid that is highly infectious.

Treatment

The cornerstone of cholera treatment is fluid replacement. Without treatment, the case-fatality rate for severe cholera is approximately 50%. For cholera, rice-based ORT is better than glucose-based ORT because it reduces the number of stools. Antibiotic prophylaxis is not warranted. The current WHO treatment protocol recommends antibiotics for only “severe” symptoms; however, this is controversial and some expert groups argue that antibiotics should be used more liberally in significant outbreaks. With effective antibiotic therapy, the illness is shortened by about 50%, and the duration of excretion of V. cholerae in the stool is shortened to 1 or 2 days. A tetracycline (eg, doxycycline) is recommended as first-line therapy; however, some
Clinical Presentation and Diagnosis of Cholera

- Incubation period of 18 hours to 5 days
- Abrupt, painless onset of watery diarrhea and vomiting. The diarrheal fluid is usually clear and may be as much as 10 to 20 liters per day
- Large volumes of rice-water stools, which may have fishy odor
- Dehydration is often severe and puts patients at risk for death within hours of disease onset. Symptoms of severe dehydration include low blood pressure, poor skin turgor, sunken eyes, and rapid pulse
- Severe muscle cramps in extremities are due to electrolyte imbalances caused by fluid loss. These cramps should resolve with treatment
- Metabolic acidosis

Pathophysiology

Enterotoxigenic E. coli, which is responsible for up to 70% of TD cases in Mexico, produces both heat-labile enterotoxins (LT) and heat-stable enterotoxins (ST). Both toxins demonstrate cellular mechanisms similar to those of cholera toxins and lead to a great increase in both fluid and electrolyte secretion. These E. coli strains are not invasive, as are the Shiga-toxin–producing EHEC strains. These organisms lead to a profuse, watery diarrhea without blood, leukocytes, or abdominal cramping.

Treatment

The goal of treatment is to maintain hydration and functional status and to prevent disruption of travel plans. For travelers with mild cases of diarrhea, oral rehydration salts can prevent and treat dehydration and may be particularly important for children and the elderly.25 Loperamide (to a maximum dose of 16 mg/day) may be used for milder diarrhea; however, this agent is not recommended if bloody diarrhea or fever is present. Antibiotics are effective at reducing the duration of illness to 1 or 2 days. Providing the traveler with a means for empiric self-treatment is an effective method of treating this illness without promoting the inappropriate use of antibiotics. Therapy should be initiated after the first episode of diarrhea that is uncomfortable or interferes with activities.26 In general, levofloxacin or ciprofloxacin are recommended as first-line agents for travel to most parts of the world.29 Azithromycin is an alternative and is preferred in areas where quinolone-resistant Campylobacter is prevalent (eg, Thailand, India).29 Azithromycin can also be used in pregnant women and children (10 mg/kg/day orally for 3 days).31 Rifaximin, a nonabsorbed oral antibiotic, is approved for treatment of TD caused by ETEC in persons at least 12 years old and has been used off-label in younger children at a dose of 20 to 40 mg/kg/day for 4 days. This agent may be a good choice for persons traveling to destinations where ETEC is the predominant pathogen, such as Mexico. Many clinicians will recommend the use of loperamide in dysentery if it is combined with an antibiotic.29

TRAVELER DIARRHEA

Epidemiology

Traveler diarrhea (TD) commonly occurs when visitors from developed countries travel to developing countries. More than 50 million people are at risk for TD each year.27 These infections arise following the consumption of food or water contaminated with bacteria, viruses, or parasites. Bacteria such as Shigella, Salmonella, Campylobacter, and enterotoxigenic E. coli (ETEC) are responsible for 60% to 85% of TD cases.25 Noroviruses are increasingly recognized as a significant cause of TD as well.28 Most of these illnesses occur during the first 2 weeks of travel and last about 4 days without therapy.29 Protozoans are an uncommon cause but should be suspected if diarrhea lasts for more than 2 weeks.

Food and water contaminated with fecal matter are the main sources of pathogens that lead to TD. Particularly problematic foods and beverages include salads, unpeeled fruits, raw or poorly cooked meats and seafood, unpasteurized dairy products, and tap water (including ice).28 Food from street vendors and buffet-style meals are particularly risky. The consumption of more than five alcoholic drinks per day is a risk factor for TD, especially in males.29 Providing effective education about the types of foods and activities to avoid during travel may decrease the number of cases of TD.

Clinical Presentation and Diagnosis of Traveler Diarrhea

- Frequent, loose stools
- Nausea and vomiting
- Abdominal pain
- Fecal urgency
- Signs and symptoms related to specific causative pathogen

CLINICAL PRESENTATION AND DIAGNOSIS OF TRAVELER DIARRHEA

- Several days after travel
- Nausea and vomiting
- Abdominal pain
- Diarrhea
- Dehydration
- Signs and symptoms related to specific causative pathogen

Food and water contaminated with fecal matter are the main sources of pathogens that lead to TD. Particularly problematic foods and beverages include salads, unpeeled fruits, raw or poorly cooked meats and seafood, unpasteurized dairy products, and tap water (including ice).28 Food from street vendors and buffet-style meals are particularly risky. Providing the traveler with a means for empiric self-treatment is an effective method of treating this illness without promoting the inappropriate use of antibiotics. Therapy should be initiated after the first episode of diarrhea that is uncomfortable or interferes with activities.26 In general, levofloxacin or ciprofloxacin are recommended as first-line agents for travel to most parts of the world.29 Azithromycin is an alternative and is preferred in areas where quinolone-resistant Campylobacter is prevalent (eg, Thailand, India).29 Azithromycin can also be used in pregnant women and children (10 mg/kg/day orally for 3 days).31 Rifaximin, a nonabsorbed oral antibiotic, is approved for treatment of TD caused by ETEC in persons at least 12 years old and has been used off-label in younger children at a dose of 20 to 40 mg/kg/day for 4 days. This agent may be a good choice for persons traveling to destinations where ETEC is the predominant pathogen, such as Mexico. Many clinicians will recommend the use of loperamide in dysentery if it is combined with an antibiotic.29
those who cannot risk temporary incapacitation (eg, athletes, diplomats, business people). A fluoroquinolone antibiotic, such as levofloxacin or ciprofloxacin, is usually used first line for this purpose at a dose of one tablet daily during travel and for 2 days following return.41 Although not approved for prophylaxis, rifaximin may be an option for travelers to Mexico because it is not absorbed and should be less likely to select out resistant organisms than are the fluoroquinolones. Bismuth subsalicylate (Pepto-Bismol; 525 mg orally four times daily for up to 3 weeks) provides a rate of protection of about 60% against TD.39 However, this agent should not be used in persons taking anticoagulants or other salicylates. Probiotics colonize the GI tract and may prevent pathogenic organisms from causing infections. These agents may provide protection rates as high as 50%, but additional studies are needed, and these products suffer from lack of standardization. No effective vaccines are available for TD.

CLOSTRIDIUM DIFFICILE INFECTION
Epidemiology
C. difficile is the primary cause of hospital-acquired infectious diarrhea in hospitalized patients, including children. Both the incidence and severity of C. difficile infection (CDI) have been increasing in the United States.42 The number of C. difficile cases that were reported in 2005 (84 per 100,000) was nearly three times higher than the 1996 rate.35 There has also been a significant increase in severe cases, colectomies, and death related to CDI.16 A more virulent, epidemic strain (NAP1/B1/027) was initially identified in the 1980s and is now commonly associated with outbreaks. These strains are associated with an increased production of toxins A and B, which are the primary virulence determinants for C. difficile.35 An increasing proportion of CDI patients have a community-acquired infection. These patients are often younger, lack traditional risk factors, and generally have less severe disease compared with those with hospital-acquired infections.34 A primary risk factor for these community-acquired infections appears to be therapeutic gastric acid suppression.37 Common risk factors for hospital-acquired CDI include increasing age, severe underlying illness, intensive care unit admission, gastric acid suppression,33 and exposure to antimicrobials, especially broad-spectrum, multiple-drug regimens.35

Nosocomial Clostridium difficile-associated diarrhea (CDAD) is almost always associated with antimicrobial use; therefore, unnecessary and inappropriate antibiotic therapy should be avoided. Clindamycin, cephalosporins, and penicillins are the antibiotics most commonly associated with CDAD, but almost all antibiotics except aminoglycosides have been implicated.6 Fluoroquinolones are also strongly associated with CDAD, especially in community-acquired infections.45

Pathophysiology
C. difficile, a gram-positive, spore-forming anaerobe, is spread by the fecal–oral route, and patient-to-patient spread is an important mode of transmission within the hospital. The organism is ingested either as the vegetative form or spores, which can survive for long periods in the environment and can traverse the acidic stomach. In the small intestine, spores germinate into the vegetative form. Once the GI tract is colonized with spores, disruption of the gut flora, which occurs with antibiotic therapy, allows C. difficile to proliferate. Toxin production is essential for the disease to occur and is responsible for the inflammation, fluid and mucus secretion, and mucosal damage that lead to diarrhea or colitis.

Treatment
- Patients who develop CDI while receiving an antibiotic should have the antibiotic discontinued, if possible. If antimicrobial therapy must continue, an attempt should be made to switch the patient to an agent with a lower risk of CDI.42 The use of concurrent antibiotics during CDI therapy, or soon thereafter, lowers the chances of a clinical cure. Clinical practice guidelines recommend that initial antimicrobial therapy should be based on the severity of illness.43
- Metronidazole (500 mg orally three times daily for 7–14 days; or, 30 mg/kg/day divided into four daily doses for children) is the recommended first-line drug for initial treatment of mild-to-moderate CDI. Oral vancomycin (125 mg four times daily for 7 to 14 days; or, 40 to 50 mg/kg/day divided into four daily doses for children) is the recommended first-line drug therapy for initial treatment of severe CDI,41 which is usually defined as a serum creatinine increase to more than 1.5 times baseline or a white blood cell count greater than 15,000 cells/mm³ (15 × 10³/L). Other risk factors for severe disease include age more than 65 years, hypoalbuminemia, immunosuppression, and severe underlying disease.39 For the treatment of severe, complicated CDI (refractory hypotension, ileus, and/or toxic megacolon), a higher dose of vancomycin (500 mg orally four times daily) may be combined with IV metronidazole (500 mg every 8 hours). Vancomycin may be given as a retention enema (500 mg in 100 mL of normal saline every 6 hours) if a complete ileus is present.43 The use of antimicrobial agents should be avoided because they may precipitate toxic megacolon. Surgical intervention may be lifesaving, particularly in cases complicated by toxic megacolon or colonic perforation. Antimicrobial stewardship programs can decrease the incidence of CDIs and better assure appropriate initial therapy.44

The cost of oral vancomycin capsules (~$1,000 for a 10-day course) is much higher than metronidazole; however, vancomycin for IV use can be prepared for oral use at a much lower cost.39 The FDA has also approved fidaxomicin, an oral macrolide antibiotic, for the treatment of CDI in patients who are at least 18 years old. This drug is minimally absorbed and has no activity against organisms other than clostridia, which allows for preservation of normal gut flora. The recommended dose of fidaxomicin is 200 mg orally twice daily for 10 days. In clinical trials, fidaxomicin resulted in clinical cure rates that were similar to those achieved with oral vancomycin, but there were significantly fewer recurrences in those treated with fidaxomicin. However, recurrence rates were similar among patients infected with the more virulent NAP1/B1/027 strain.45 Fidaxomicin is expensive (~$3000 for a 10-day course) and its place in therapy has not been clearly established.

The recurrence rate after an initial episode of CDI is approximately 20% to 25%, with the highest risk within the first 2 weeks.39 This rate is independent of which agent is used initially. Treatment of the first recurrence of CDI is usually treated with the same regimen used for the initial episode; however, this choice should also depend on the clinical condition of the patient, as recommended for the initial therapy choice.41 Metronidazole should not be used beyond the first recurrence or for long-term chronic treatment due to the risk of neurotoxicity. The treatment of second or later recurrences of CDI should be undertaken with vancomycin using a tapered and/or pulse regimen.35,43 Fidaxomicin may be superior to vancomycin at preventing CDAD recurrences secondary to non-NAP1/B1/027 strains. Rifaximin, administered directly following a course of metronidazole or vancomycin, may be an option for the prevention of recurrent
Clinical Presentation and Diagnosis of CDAD

- Symptoms can start as early as the first day of antimicrobial therapy or several weeks after antibiotic therapy is completed.
- Asymptomatic carriage.
- Diarrhea:
  - Acute watery diarrhea with lower abdominal pain, low-grade fever, and mild or absent leukocytosis.
  - Mild, with only three or four loose watery stools per day.
  - C. difficile toxins are present in stool, but sigmoidoscopic examination is normal.
- Colitis:
  - Profuse, watery diarrhea with 5 to 15 bowel movements per day, abdominal pain, abdominal distention, nausea, and anorexia.
  - Left or right lower quadrant abdominal pain and cramps that are relieved by passage of diarrhea.
- Dehydration and low-grade fever.
- Sigmoidoscopic examination may reveal a nonspecific diffuse or patchy erythematous colitis with or without pseudomembranes.
- Toxic megacolon: Suggested by acute dilation of the colon to a diameter greater than 6 cm, associated systemic toxicity, and the absence of mechanical obstruction. It carries a high mortality rate.
- Fulminant colitis: Acute abdomen and systemic symptoms such as fever, tachycardia, dehydration, and hypotension.

Some patients have marked leukocytosis (up to $40 \times 10^9$ white blood cells/mm$^3$ [$40 \times 10^9/L$]). Diarrhea is usually prominent but may not occur in patients with paralytic ileus and toxic megacolon.

- Recurrent disease:
  - Risk factors include increased age, recent abdominal surgery, increased number of C. difficile diarrheal episodes, and leukocytosis.
  - 20% to 25% of patients develop a second episode of CDAD within 2 months of the initial diagnosis.
  - In most cases, C. difficile toxin testing of a single unformed stool specimen effectively establishes the diagnosis. Stool culture is the most sensitive test, but it is not clinically practical due to slow turnaround time. Enzyme immunoassay (EIA) testing for toxin A and B is used in most labs. This test is rapid, but less sensitive, and repeat testing may be necessary if the initial test is negative. Newer tests, such as EIA detection of glutamate dehydrogenase or use of polymerase chain reaction technology, may ultimately improve diagnostic testing for CDI.
  - Leukocytosis, hypoalbuminemia, and fecal leukocytes are nonspecific but suggestive of C. difficile infection.
  - In selected patients, sigmoidoscopy, colonoscopy, or abdominal CT scan can provide useful diagnostic information.

Patient Encounter 4

A 58-year-old man presents to his local medical clinic complaining of new-onset diarrhea, which he describes as watery and “constant.” He also states that he has some lower abdominal pain. Upon physical examination, the patient is noted to have a low-grade fever and initial lab studies show a mild leukocytosis. Upon further review of this patient’s electronic medical record, you note that he was hospitalized about two months earlier for an acute small bowel obstruction which required surgery. Following surgery, he developed a ventilator-associated pneumonia and was treated with broad-spectrum antibiotics for ten days. Shortly after finishing this course of antibiotics, he was diagnosed with a moderately severe C. difficile infection (CDI) and completed a 10-day course of oral metronidazole (500 mg). About one month ago, he was diagnosed with recurrent CDI that was described as “mild.”

At that time he completed a second 10-day course of oral metronidazole. About 2 weeks before this presentation, this patient was treated with a 10-day course of oral levofloxacin for an episode of acute bacterial rhinosinusitis. He now presents with what is presumed to be a third episode of CDI. His current outpatient medications include lisinopril, carvedilol, citalopram, esomeprazole, albuterol (prn), and ibuprofen (prn).

**What was the primary risk factor that led to this patient’s initial episode of CDI?**

**What risk factors are present for this patient’s recurrent infections?**

**What drug and/or nondrug therapies could be considered for this patient’s third C. difficile infection?**

Strict infection control measures, including contact precautions, should be instituted for all patients with CDAD. Environmental cleaning with chlorine-containing agents should be used to eliminate C. difficile spores. Because alcohol is ineffective in killing spores, it is essential that health care workers wash their hands with soap and water rather than using alcohol-based hand sanitizers. Meticulous handwashing is the single most important strategy to decrease the patient-to-patient transmission of C. difficile. The administration of currently available probiotic agents is not recommended to prevent primary CDI or to treat recurrences.
CRYPTOSPORIDIOSIS

Epidemiology

Cryptosporidiosis has been recognized as a human disease since the 1970s, with increasing importance in the 1980s and 1990s because of its relationship with HIV/AIDS. Cryptosporidium accounts for 2.2% and 6.1% of diarrhea cases in immunocompetent people in developed and developing countries, respectively. In the United States, the number of reported cases of cryptosporidiosis increased from 6479 in 2006 to 10,500 in 2008. This increase was partially attributed to multiple large recreational water outbreaks and likely reflects increased use of communal swimming venues (e.g., lakes, swimming pools, and water parks) by young children. Cryptosporidiosis is spread person-to-person, usually via the fecal–oral route; by animals, particularly cattle and sheep; and through the environment, especially water.

Pathophysiology

Cryptosporidium is an intracellular protozoan parasite that is capable of completing its entire life cycle within one host. Humans become infected upon ingestion of the oocysts, and autoinfection and persistent infections are possible owing to repeated life cycles within the GI tract. As few as 10 to 100 oocysts can cause infection.

Treatment

In general, immunocompetent persons and those with asymptomatic infection do not require antimicrobial therapy. In patients with HIV/AIDS, the optimal therapy is restoration of immune function through the use of antiretroviral therapy (ART). In persons in whom antimicrobial therapy is deemed necessary or in HIV/AIDS patients in whom ART is ineffective, a combination of an antimicrobial and an antidiarrheal agent is recommended.

Nitazoxanide is the only FDA-approved agent for the treatment of cryptosporidiosis in adults and children 1 year and older. This agent has demonstrated efficacy in cryptosporidiosis in immunocompetent persons, malnourished children, and HIV/AIDS patients. Patients who are infected with both HIV and Cryptosporidium usually require longer therapy durations and higher doses than immunocompetent patients. Alternative agents include paromomycin, azithromycin, and clarithromycin.

Prevention of cryptosporidiosis can prove difficult because the oocysts are resilient to many disinfectants and antiseptics, including ammonia, alcohol, and chlorine. Routine screening of drinking water should be considered for water-treatment plants, and severely immunocompromised individuals should be advised to avoid water in lakes and streams and contact with young animals.

VIRAL GASTROENTERITIS

Viruses are the most common cause of diarrheal illness in the world and, in the United States, account for 450,000 illnesses and 160,000 hospitalizations for adults and children, respectively, and more than 4000 deaths. Many viruses may cause gastroenteritis, including rotaviruses, noroviruses, astroviruses, enteric adenoviruses, and coronaviruses (Table 76–3). This chapter focuses on rotaviruses.

Clinical Presentation and Diagnosis of Rotavirus Infection

- Incubation period of 2 days.
- 2- to 3-day prodrome of fever and vomiting.
- Profuse diarrhea without blood or leukocytes (up to 10 to 20 stools per day).
- Severe dehydration.
- Anorexia.
- Fever may be present.
- Presentation in adults may vary from asymptomatic to nonspecific symptoms of headache, malaise, and chills to severe diarrhea, nausea, and vomiting.
- Diagnosis can be made by polymerase chain reaction (PCR) of the stool.

Patient Encounter 5

A 28-year-old woman who has an occasional prescription filled in your community pharmacy, now comes in to ask if she needs to get a flu shot. Since you know she has a 4-month-old child, you ask if her child has started the vaccine series for rotavirus. The mother tells you that she doesn’t believe in giving her child a lot of vaccines because she is concerned that there are a lot of potential long-term effects from vaccines that we don’t know about.

What scientific findings could you discuss with this mother to persuade her to get all recommended vaccinations for her child, especially the rotavirus vaccine?

### Patient Care Process

**Patient Assessment:**
- Based on physical examination, review of systems, and laboratory findings, determine the degree of fluid and electrolyte depletion and estimate current renal function.
- Review the medical history with particular attention to risk factors or medical conditions associated with more severe infection outcomes, such as immunosuppression.
- Conduct a medication history focusing on holding drugs that may worsen the current fluid status or renal function, immunosuppressive therapies, and antibiotic allergies.

**Therapy Evaluation:**
- Review all available tests to determine the etiology and antimicrobial susceptibilities of the suspected pathogen.
- Based on suspected pathogen, patient age, assessment of immune status, and other risk factors for severe complications, determine if antibiotic therapy is indicated.

**Care Plan Development:**
- Determine that appropriate fluids and other supportive measures have been initiated.
- If indicated, select an antibiotic that is appropriate for the pathogen, not unnecessarily broad in its coverage, and is cost-effective for the patient and the health care system.

**Follow-Up Evaluation:**
- Determine that signs of fluid depletion and electrolyte imbalances have been corrected. If acute renal dysfunction was initially present, assess for clinical improvement and reassess medication doses.
- Assess for increase in stool consistency and decrease in stool frequency.
- Assure that all indicated chronic medications that were initially held have been restarted, as appropriate.
- Provide patient counseling on measures to avoid gastrointestinal pathogens and vaccinations, as appropriate.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Define and differentiate between primary and secondary intra-abdominal infections (IAIs).
2. Describe the microbiology typically seen with primary and secondary IAIs.
3. Describe the clinical presentation typically seen with primary and secondary IAIs.
4. Describe the role of culture and susceptibility information for diagnosis and treatment of IAIs.
5. Recommend the most appropriate drug and nondrug measures to treat IAIs.
6. Recommend an appropriate antimicrobial regimen for treatment of a primary and a secondary IAIs.
7. Describe the patient-assessment process during the treatment of IAIs.

INTRODUCTION

Intra-abdominal infections (IAIs) are those contained within the peritoneal cavity or retroperitoneal space. The peritoneal cavity extends from the undersurface of the diaphragm to the floor of the pelvis and contains the stomach, small bowel, large bowel, liver, gallbladder, and spleen. The duodenum, pancreas, kidneys, adrenal glands, great vessels (aorta and vena cava), and most mesenteric vascular structures reside in the retroperitoneum. IAIs may be generalized or localized. They may be contained within visceral structures, such as the liver, gallbladder, spleen, pancreas, kidney, or female reproductive organs. Two general types of IAI are discussed throughout this chapter: peritonitis and abscess. (Peritonitis is defined as the acute inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign-body injury.)

An abscess is a purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells. Peritonitis and abscess differ considerably in presentation and approach to treatment.

EPIDEMIOLOGY AND ETIOLOGY

Peritonitis may be classified as primary, secondary, or tertiary. Primary peritonitis, also called spontaneous bacterial peritonitis, is an infection of the peritoneal cavity without an evident source of bacteria from the abdomen. In secondary peritonitis, a focal disease process is evident within the abdomen. Secondary peritonitis may involve perforation of the gastrointestinal (GI) tract (possibly because of ulceration, ischemia, or obstruction), postoperative peritonitis, or posttraumatic peritonitis (eg, blunt or penetrating trauma). Tertiary peritonitis occurs in critically ill patients, and it is an infection that persists or recurs at least 48 hours after apparently adequate management of primary or secondary peritonitis.

Most IAIs are secondary infections that are caused by a defect in the GI tract that must be treated by surgical drainage, resection, and/or repair. Primary peritonitis develops in 10% to 30% of hospitalized patients with alcoholic cirrhosis. Patients undergoing continuous ambulatory peritoneal dialysis (CAPD) average one episode of peritonitis every 2 years. Secondary peritonitis may be caused by perforation of a peptic ulcer; traumatic perforation of the stomach, small or large bowel, uterus, or urinary bladder; appendicitis; pancreatitis; diverticulitis; bowel infarction; inflammatory bowel disease; cholecystitis; operative contamination of the peritoneum; or diseases of the female genital tract such as septic abortion, postoperative uterine infection, endometritis, or salpingitis. Appendicitis is one of the most common causes of IAI. In 2010, approximately 305,000 appendectomies were performed in the United States for suspected appendicitis.

Primary peritonitis in adults occurs most commonly in association with alcoholic cirrhosis, especially in the end stage, or with ascites caused by postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, malignancy, systemic lupus erythematosus, and nephrotic syndrome. It also may result from the use of a peritoneal catheter for dialysis with renal failure or central nervous system ventriculoperitoneal shunting for hydrocephalus. Abscesses are the result of chronic inflammation and may occur without preceding generalized peritonitis. They may be located within the peritoneal cavity or in a visceral organ and may vary in size, taking a few weeks to years to form.

PATHOPHYSIOLOGY

IAI results from bacterial entry into the peritoneal or retroperitoneal spaces or from bacterial collections within intra-abdominal organs. In primary peritonitis, bacteria may enter the abdomen via the bloodstream or the lymphatic system by transmigration through the bowel wall, through an indwelling peritoneal dialysis (PD) catheter, or by a hepatic vein or direct lymphatic invasion.
A 32-year-old woman with a history of sickle cell disease presents to the surgery clinic with chief complaints of abdominal pain. She had an appendectomy 4 weeks ago and had an uneventful course. Her current medications are oxycodone 10 mg orally every 12 hours, zolpidem 5 mg orally at bedtime, and two herals (gingen and ginko biloba). On the previous hospital course, she was treated with a 2-day course of flucenozole.

PMH: Sickle cell disease and early onset ESRD for the last 7 years

Meds: Oxycodone 10 mg orally every 12 hours, zolpidem 5 mg orally every 12 hours, plus herbs

SOC: Single, no alcohol, smoking, or illicit drugs

PE: Tender, hard, distended abdomen, negative bowel sounds. Rest of the physical exam is noncontributory

The fluid and protein shift into the abdomen (called third spacing) may be so dramatic that circulating blood volume is decreased, which causes decreased cardiac output and hypovolemic shock. Accompanying fever, vomiting, or diarrhea may worsen the fluid imbalance. A reflex sympathetic response, manifested by sweating, tachycardia, and vasconstriction, may be evident. With an inflamed peritoneum, bacteria and endotoxins are absorbed easily into the bloodstream (translocation), and this may result in septic shock. Other foreign substances present in the peritoneal cavity potentiate peritonitis, notably feces, dead tissues, barium, mucus, bile, and blood.

Many of the manifestations of IAIs, particularly peritonitis, result from cytokine activity. Inflammatory cytokines are produced by macrophages and neutrophils in response to bacteria and bacterial products or to tissue injury, resulting from the production of synergistic organisms.
surgical incision. The outer membrane components of gram-negative and gram-positive organisms contribute to the release of proinflammatory cytokines, ultimately leading to end-organ dysfunction (lungs, heart, kidneys) and septic shock. Peritonitis may result in death because of the effects on major organ systems.

An abscess occurs if peritoneal contamination is localized but bacterial elimination is incomplete. The location of the abscess often is related to the site of primary disease. For example, abscesses resulting from appendicitis tend to appear in the right lower quadrant or the pelvis; those resulting from diverticulitis tend to appear in the left lower quadrant or pelvis. A mature abscess may have a fibrous capsule that isolates bacteria and the liquid core from antimicrobials and immunologic defenses.

**Microbiology of Intra-Abdominal Infection**

- **Key Concept**: Primary bacterial peritonitis is often caused by a single organism. In children, the pathogen is usually Streptococcus pneumoniae or a group A Streptococcus, Escherichia coli, S. pneumoniae, or Bacteroides species. When peritonitis occurs in association with cirrhotic ascites, E. coli and Klebsiella are isolated most frequently. Other potential pathogens are Haemophilus influenzae, klebsiella, Pseudomonas, anaerobes, and S. pneumoniae. Occasionally, primary peritonitis may be caused by Mycobacterium tuberculosis. Peritonitis in patients undergoing PD is caused most often by common skin organisms ranging from S. aureus to S. epidermidis, to Pseudomonas aeruginosa. Occasionally, aerobic gram-negative bacilli may cause infections, particularly in patients undergoing dialysis during hospitalization.

- **Key Concept**: Because of the diverse bacteria present in the GI tract, secondary IAIs are often polymicrobial.

**Bacterial Synergism and Other Factors**

A combination of aerobic and anaerobic organisms appears to increase the severity of infection (synergism). Facultative bacteria (eg, E. coli) may provide an environment conducive to the growth of anaerobic bacteria. Although many bacteria isolated in mixed infections are nonpathogenic by themselves, their presence may be essential for the pathogenicity of the bacterial mixture.

Complicating the clinical picture for treatment are polymicrobial IAIs with certain bacterial species being isolated such as enterococci or P. aeruginosa. Depending on the patients’ immune system (immunocompromised host), targeting these organisms may be necessary to avoid treatment failure or mortality.

**Clinical Presentation and Diagnosis**

IAIs have a wide spectrum of clinical features. Peritonitis usually is easily recognized, but intra-abdominal abscess often may continue unrecognized for long periods of time. Patients with primary and secondary peritonitis present quite differently.

**Treatment**

The primary goals of treatment are correction of the intra-abdominal disease processes or injuries that have caused infection and drainage of collections (source control) of purulent material (abscess). A secondary objective is to resolve the infection without major organ system complications (eg, pulmonary, hepatic, cardiovascular, or renal failure) or adverse drug effects. Ideally, the patient should be discharged from the hospital with full function for self-care and routine daily activities.

**General Approach to Treatment**

The treatment of IAI most often requires the coordinated use of three major modalities: (a) prompt drainage; (b) support of vital functions; and (c) appropriate antimicrobial therapy to treat infection not eradicated by surgery. Antimicrobials are an important adjunct to drainage procedures in the treatment of secondary IAIs; however, the use of antimicrobial agents without surgical intervention usually is inadequate. For most cases of primary peritonitis, drainage procedures may not be required, and antimicrobial agents become the mainstay of therapy.

**Key Concept**: In the early phase of serious IAIs, attention should be given to preserving major organ system function. With generalized peritonitis, large volumes of IV fluids are required to maintain intravascular volume, to improve cardiovascular function, and to ensure adequate tissue perfusion and oxygenation. Adequate urine output should be maintained to ensure appropriate fluid resuscitation and to preserve renal function. A common cause of early death is hypovolemic shock caused by inadequate intravascular volume expansion and tissue perfusion.

An additional important component of therapy is nutrition. IAIs often involve the GI tract directly or disrupt its function.
Clinical Presentation of Secondary Peritonitis

**General**
Patients may be in acute distress.

**Symptoms**
- Patients may complain of nausea, vomiting, and generalized abdominal pain.
- Patients may demonstrate abdominal guarding and a “boardlike abdomen.”

**Signs**
- Tachypnea and tachycardia are present.
- Temperature is normal initially, then may increase to 100°F to 102°F (37.8°C–38.9°C) within the first few hours, and may continue to rise for the next several hours.
- Hypotension and shock may develop if intravascular volume is not restored.
- Decreased urine output may develop owing to dehydration.
- Bowel sounds are faint initially and eventually cease.

**Laboratory Tests**
- The WBC is high (WBCs 15–20 × 10⁹/mm³ [15–20 × 10⁹/L]), with neutrophils predominating and an elevated percentage of immature neutrophils (bands).
- The hematocrit and blood urea nitrogen increase because of dehydration.
- Hyperventilation and vomiting result in early alkalosis, which changes to acidosis and lactic academia to reduced intravascular volume and diminished tissue perfusion.

**Other Diagnostic Tests**
Abdominal radiographs may be useful because free air in the abdomen (indicating intestinal perforation) or distension of the small or large bowel is often evident.

**Fluid Therapy**
In patients with peritonitis, hypovolemia is often accompanied by acidosis, and large volumes of an intravenous solution such as lactated Ringer may be required initially to restore intravascular volume. Maintenance fluids should be instituted (after intravascular volume is restored) with 0.9% sodium chloride and potassium chloride (20 mEq/L [20 mmol/L]) or 5% dextrose and 0.45% sodium chloride with potassium chloride (20 mEq/L [20 mmol/L]). The administration rate should be based on estimated daily fluid loss through urine and nasogastric suction, including 0.5 to 1.0 L for insensible fluid loss. Aggressive fluid therapy often must be continued in the postoperative period because fluid will continue to sequester in the peritoneal cavity, bowel wall, and lumen.

**Nonpharmacologic Therapy**

**Drainage Procedures**
Primary peritonitis is treated with antimicrobials and rarely requires drainage. Secondary peritonitis requires surgical removal of the inflamed or gangrenous tissue to prevent further bacterial contamination. If the surgical procedure is suboptimal, attempts are made to provide drainage of the infected or gangrenous structures.

The drainage of purulent material is the critical component of management of an intra-abdominal abscess. This may be performed surgically or with percutaneous image-guided techniques. Without adequate drainage of the abscess, antimicrobial therapy and fluid resuscitation can be expected to fail. The most valuable microbiologic information may be obtained at the time of percutaneous or operative abscess drainage.

**Pharmacologic Therapy**

**Antimicrobial Therapy**
The goals of antimicrobial therapy are as follows:
- To control bacteremia and prevent the establishment of metastatic foci of infection

Patient Encounter 1, Part 2: Physical Examination and Diagnostic Tests

**PE:**
The patient is becoming more encephalopathic and somnolent, and she is still having a lot of pain (7/10 pain scale) the attending physician decides to perform an invasive test.

Ascitic fluid analysis is reported as following: hazy yellow color with 2125 cu/mm³ (2.125 × 10⁹/L) WBC, (38% [0.38] neutrophils, 5% [0.05] lymphocytes, 57% [0.57] macrophages). Urinalysis is not significant because the patient is oliguric and almost anuric. Other physical exam findings are nonsignificant.

**VS:** As noted previously

**Labs:** As noted previously

**Serum:** As noted previously

**KUB:** Negative findings

**DPL (diagnostic peritoneal lavage):** 2125 cu/mm³ (2.125 × 10⁹/L)

Microbiological cultures: 2/2 bottles from the blood positive for gram-positive pairs in chains and gram-negative bacilli cultured the small amount of urine collected.

Discuss the most appropriate pharmacologic course of treatment, outlining medications, dosing, and monitoring parameters.

List the goals of treatment and follow-up plan that should be developed by the clinician to ensure positive patient outcomes.
To reduce suppurative complications after bacterial infection, antimicrobial treatment can be completed to prevent local spread of existing infection. For most patients, antimicrobial treatment can be completed with agents effective against aerobic gram-negative bacilli (eg, gentamicin or aztreonam).

For most IAIs, the antimicrobial regimen should be adjusted as soon as the presence of IAI is suspected and before identification of the infecting organisms is complete. Therapy should be initiated based on the likely pathogens, which vary depending on the site of IAI and the underlying disease process. Cultures of secondary IAI sites generally are not useful for directing antimicrobial therapy. Table 77–1 lists the likely pathogens against which antimicrobial agents should be directed.

**Antimicrobial Experience**

Important findings from the last 25 years of clinical trials regarding selection of antimicrobials for IAIs are as follows:

- **Antimicrobial regimens for secondary IAIs should cover a broad spectrum of aerobic and anaerobic bacteria from the GI tract.** Worrinome is the development of hospital-acquired IAIs with bacteria such as *P. aeruginosa*, *Acinetobacter* spp., *Proteus* spp., *B* lactamase producing bacteria, methicillin-resistant *S. aureus* (MRSA), *Enterobacteriaceae*, *Candida* spp., and Enterococci that make the clinical management of these patients challenging.

- **Single-agent regimens (such as antianaerobic cephalosporins, extended-spectrum penicillins with β-lactamase inhibitors, or carbapenems) are as effective as combinations of aminoglycosides or fluoroquinolones with antianaerobic agents.** This is also true for antimicrobial treatment of acute bacterial contamination from penetrating abdominal trauma.

- **Newer agents such as tigecycline and ertapenem may offer some theoretical advantages in the treatment of IAIs, but have some limitations.** Tigecycline has a broad spectrum of activity against both aerobic and anaerobic gram negative rods, but lacks sufficient anti-*Pseudomonal* activity. Ertapenem is an example of a carbapenem that has a favorable pharmacokinetic profile (once daily dosing) and, like the other agents, lacks MRSA activity.

- **Clindamycin and metronidazole appear to be equivalent in efficacy when combined with agents effective against aerobic gram-negative bacilli (eg, gentamicin or aztreonam).**

- **For most patients, antimicrobial treatment can be completed orally with moxifloxacin, ciprofloxacin and metronidazole, levofloxacin plus metronidazole, or amoxicillin–clavulanate or the combination of ciprofloxacin and metronidazole.**

- **Four to 7 days of antimicrobial treatment are sufficient for most IAIs of mild to moderate severity.** IAIs present in many different ways and with a wide spectrum of severity. The antibiotic regimen employed and duration of treatment depends on the specific clinical circumstances (ie, the nature of the underlying disease process and the condition of the patient).

**Recommendations**

For most IAIs, the antimicrobial regimen should be effective against both aerobic and anaerobic bacteria. Although it is impossible to provide antimicrobial activity against every possible pathogen, agents with activity against enteric gram-negative bacilli, such as *E. coli* and *Klebsiella*, and anaerobes, such as *B. fragilis* and *Clostridia* spp., should be administered. Table 77–2 presents the recommended agents for treatment of community-acquired and complicated IAIs from the Infectious Diseases Society of America and the Surgical Infection Society. These recommendations were formulated using an
enterococci; however, resistance is increasing, and this agent should be reserved for established infections when first-line therapies cannot be used.

Intraperitoneal (IP) administration of antibiotics is preferred over IV therapy in the treatment of peritonitis that occurs in patients undergoing CAPD. The International Society of Peritoneal Dialysis guidelines for the diagnosis and pharmacotherapy of PD-associated infections provide dosing recommendations for intermittent and continuous therapy based on the modality of dialysis (CAPD or automated PD [APD]) and the extent of the patient’s residual renal function.

<sup>a</sup>Empiric first- and second-generation cephalosporin use should be avoided unless local antibiograms show > 80% to 90% susceptibility of *E. coli* to these agents.

<sup>b</sup>Use of quinolones may be associated with treatment failure due to increasing resistance of enteric pathogens including *E. coli*. Empiric quinolone use should be avoided unless local antibiograms show > 80% to 90% susceptibility of *E. coli* to quinolones.

<sup>c</sup>Cephalosporins should be increased empirically by 25% in patients with residual renal function (greater than 100 mL/day urine output). Antimicrobial doses should be increased empirically by 25% in patients with residual renal function (greater than 100 mL/day urine output).

<sup>d</sup>Carbapenems should typically be reserved for settings where there is a high risk of resistance to other agents.

Data from Pharmacotherapy: A Pathophysiologic Approach, 9th edition Adapted from Solomkin et al.

Evidence-based approach. Most community-acquired infections are “mild to moderate,” whereas health care-associated infections tend to be more severe and difficult to treat. Table 77–3 presents guidelines for treatment and alternative regimens for specific situations. These are general guidelines; there are many factors that cannot be incorporated into such a table.

When used for IAI, aminoglycosides should be combined with agents that are effective against the majority of *B. fragilis*; however, their side-effect profile may prohibit use secondary to nephrotoxicity. Clindamycin or metronidazole is the agent of first choice, but others, such as antianaerobic cephalosporins (eg, cefoxitin, cefotetan, or ceftizoxime), piperacillin, mezlocillin, and combinations of extended-spectrum penicillins with β-lactamase inhibitors would be suitable alternative. Preemptive antifungal therapy should be considered in patients with residual renal function (greater than 100 mL/day urine output). Antimicrobial doses should be increased empirically by 25% in patients with residual renal function (greater than 100 mL/day urine output).

For appendicitis, the antimicrobial regimen used should depend on the appearance of the appendix at the time of operation, which may be normal, inflamed, gangrenous, or perforated. Because the condition of the appendix is unknown preoperatively, it is advisable to begin antimicrobial agents before the appendectomy is performed. Reasonable regimens would be antianaerobic cephalosporins or, if the patient is seriously ill, a carbapenem or β-lactam–β-lactamase-inhibitor combination. If, at operation, the appendix was normal or inflamed, postoperative antimicrobials would not be required. If the appendix is gangrenous or perforated, a treatment course of 5 to 7 days with the agents listed in Table 77–2 is appropriate.

**Key Concept** Acute intra-abdominal contamination, such as after a traumatic injury, may be treated with a short course (24 hours) of antimicrobials. For established infections (ie, peritonitis or intra-abdominal abscess), an antimicrobial course limited to 4 to 7 days is justified. Under certain conditions, therapy for longer than 7 days would be justified, for example, if the patient remains febrile or is in poor general condition, when relatively resistant bacteria are isolated, or when a focus of infection in the abdomen still may be present. For some abscesses, such as pyogenic liver abscess, antimicrobials may be required for a month or longer.
Table 77–3

Guidelines for Empiric Antimicrobial Agents for Intraabdominal Infections

<table>

<tr>
<th>Primary Agents</th>
<th>Alternatives</th>
</tr>
</thead>
</table>
| **Primary (Spontaneous) Bacterial Peritonitis** | 1. Piperacillin–tazobactam, carbapenems  
2. Aztreonam combined with an agent active against *Streptococcus* spp. (e.g., vancomycin) or quinolones with significant *Streptococcus* spp. activity (levofloxacin, moxifloxacin) |
| Cirrhosis | Ceftriaxone, cefotaxime |
| Peritoneal dialysis | Initial empiric regimens should be active against both gram-positive (including *S. aureus*) and gram-negative pathogens: Gram-positive agent (first-generation cephalosporin or vancomycin) plus a gram-negative agent (third-generation cephalosporin or aminoglycoside)  
1. *Staphylococcus* spp.:oxacillin/nafcillin or first-generation cephalosporin  
2. *Streptococcus* or *Enterococcus*: ampicillin |
| 1. Cefepime or carbapenems may be used alone  
2. Aztreonam or an aminoglycoside may be used in place of ceftazidime or cefepime as long as combined with a gram-positive agent  
3. Quinolones may be used in place of gram-negative agents if local susceptibilities allow  
1. Vancomycin should be used if concern for methicillin-resistant *Staphylococcus* spp.  
2. Add rifampin for 5–7 days with vancomycin for methicillin-resistant *Staphylococcus aureus* |
| 2. *Streptococcus or Enterococcus*: ampicillin |
| 3. Aerobic gram-negative bacilli: ceftazidime or cefepime  
4. *Pseudomonas aeruginosa*: two agents with differing mechanisms of action, such as an oral quinolone plus ceftazidime, cefepime, tobramycin, or piperacillin |
| Secondary Bacterial Peritonitis | 1. Ceftriaxone, cefotaxime, or antianaerobic cephalosporins |
| Perforated peptic ulcer | First-generation cephalosporins  
Third- or fourth-generation cephalosporin with metronidazole, piperacillin–tazobactam or ticarcillin–clavulanate, carbapenem |
| Other | As above  
Ceftriaxone or cefotaxime |
| Abscess | Third- or fourth-generation cephalosporin with metronidazole, piperacillin–tazobactam, or ticarcillin–clavulanate |
| General | 1. Imipenem–cilastatin, meropenem, doripenem, or ertapenem  
2. Ciprofloxacin or levofloxacin each with metronidazole or moxifloxacin alone  
3. Antianaerobic cephalosporins |
| Liver | Use metronidazole if amoebic liver abscess is suspected  
Moxifloxacin^b|levofloxacin^b |
| Spleen | Ceftriaxone or cefotaxime |
| Other Intraabdominal Infections | 1. Ceftriaxone or cefotaxime |
| Appendicitis | As above  
Same management as for community-acquired complicated intraabdominal infections as listed in Table 92-6^a |
| Community-Acquired Severe infection, piperacillin/tazobactam, antipseudomonal carbapenem, aztreonam with metronidazole  
Vancomycin with aztreonam with or without metronidazole |
| Acute Cholecystitis Antianaerobic cephalosporins or metronidazole | Ceftriaxone or cefotaxime each with or without metronidazole |
| Cholangitis Antianaerobic cephalosporins or metronidazole with either ceftriaxone or cefotaxime | 1. Piperacillin–tazobactam or a carbapenem  
2. Ciprofloxacin or levofloxacin each with metronidazole or moxifloxacin alone |
| Acute Contamination from Abdominal Trauma | Ceftriaxone or cefotaxime |

^aCefoxitin or ceftizoxime; these agents should be avoided empirically unless local antibiograms show > 80% to 90% susceptibility of *E. coli* to these agents.

^bUse of quinolones may be associated with treatment failure due to increasing resistance of enteric pathogens including *E. coli*. Empiric quinolone use should be avoided unless local antibiograms show > 80% to 90% susceptibility of *E. coli* to quinolones.

**OUTCOME EVALUATION**

- Whether diagnosed with primary or secondary peritonitis, monitor the patient for relief of symptoms. Once antimicrobials are initiated and the other important therapies described earlier are used, most patients should show improvement within 2 to 3 days.

Successful antimicrobial therapy with resolution of infection will result in decreased pain, manifested as resolution of abdominal guarding and decreased use of pain medications over time. The patient should not appear in distress, with the exception of recognized discomfort and pain from incisions, drains, and a nasogastric tube.
Monitor vital signs and WBC count with differential; each should normalize as the infection resolves. At 24 to 48 hours, aerobic bacterial culture results should be available. If a suspected pathogen is not sensitive to the antimicrobial agents being given, the regimen should be changed if the patient has not shown sufficient improvement. If the isolated pathogen is extremely sensitive to one antimicrobial and the patient is progressing well, concurrent antimicrobial therapy often may be discontinued.

With anaerobic culturing techniques and the slow growth of these organisms, anaerobes often are not identified until 4 to 7 days after culture, and sensitivity information is difficult to obtain. For this reason, anaerobic culture information generally is not helpful for selection of the antianaerobic component of the antimicrobial regimen.

Once the patient’s temperature is normal for 48 to 72 hours and the patient is eating, consider changing the IV antibiotic to an oral regimen for the duration of antibiotic treatment. Monitor the serum creatinine level to evaluate for renal complications as well as potential drug toxicity, especially if an aminoglycoside is a component of the antibiotic regimen. Bowel sounds should return to normal. Evaluate the patient daily for development of rash or other drug-related adverse effects.

For patients with primary peritonitis, if peritoneal dialysate cultures were positive initially, repeat cultures should be negative. For patients with secondary peritonitis, monitor the amount of fluid draining if a drain was placed. The volume of drainage should lessen as the infection resolves. Repeat abdominal radiographs should return to normal.

If symptoms do not improve, the patient should be evaluated for persistent infection. There are many reasons for poor patient outcome with IAI; improper antimicrobial selection is only one. The patient may be immunocompromised, which decreases the likelihood of successful outcome with any regimen. It is impossible for antimicrobials to compensate for a nonfunctioning immune system. There may be surgical reasons for poor patient outcome. Failure to identify all intra-abdominal foci of infection or leaks from a GI anastomosis may cause continued IAI. Even when IAI is controlled, accompanying organ system failure, most often renal or respiratory, may lead to patient demise.

**Key Concept** Health care–associated infections are becoming more common for IAIs secondary to acute care hospital admissions or admissions from chronic care settings. The major pathogens include more resistant gram-negative flora, Candida infections causing peritonitis, and Enterococcal species.

The outcome from IAI is not determined solely by what transpires in the abdomen. Unsatisfactory outcomes in patients with IAIs may result from complications that arise in other organ systems. Infectious complications commonly associated with mortality after IAI are urinary tract infections and pneumonia. Reasons for antimicrobial failure may not always be apparent. Even when antimicrobial susceptibility tests indicate that an organism is susceptible in vitro to the antimicrobial agent, therapeutic failures may occur. Possibly there is poor penetration of the antimicrobial agent into the focus of infection, or bacterial resistance may develop after initiation of antimicrobial therapy. Also, it is possible that an antimicrobial regimen may encourage the development of infection by organisms not susceptible to the regimen being used. Superinfection in patients being treated for IAI can be caused by Candida; however, Enterococci or opportunistic gram-negative bacilli such as *Pseudomonas* and *Serratia* may be involved.

Treatment regimens for IAI can be judged as successful if the patient recovers from the infection without recurrent peritonitis or intra-abdominal abscess and without the need for additional antimicrobials. A regimen can be considered unsuccessful if a significant adverse drug reaction occurs, reoperation or percutaneous drainage is necessary, or patient improvement is delayed beyond 1 or 2 weeks.

---

**Patient Care Process**

**Patient Assessment:**
- You should do a thorough patient medication history at the time of admission to document all recent medication use, including nonprescription medications and use of complementary or alternative medicines. You should also document any drug allergies or intolerances for your patient you are working up.

**Therapeutic Evaluation:**
- Be cognizant for the initial antimicrobial regimen conforming to standard guidelines (unless an appropriate justification for an alternative regimen is evident). See Table 77–3.

**Care Plan Development:**
- You need to review the dosages of all medications to be sure that they are appropriate for age, weight, and major organ function.
- You should also verify that the drugs selected are not contraindicated in the patient with allergies or other intolerances.
- You should select antimicrobials that are appropriate based on the susceptibility information, while reviewing the results of the obtained both preoperatively or during the surgical procedure.
- On the fifth day of antimicrobial treatment or when GI function returns, determine whether parenteral antimicrobial agents can be switched to oral agents to complete therapy.
- Assess nutritional needs and recommend appropriate supplementation. When the patient is tolerating an oral diet, determine whether any parenteral medications can be switched to the oral route.

**Follow-Up Evaluation:**
- You should monitor the patient for the development of potential complications of treatment such as delayed hypersensitivity reactions, antibiotic-induced diarrhea, pseudomembranous colitis, or fungal superinfections (manifested as oral thrush).
- You should also provide information to the patient concerning the medications administered in the hospital as well as any new medications prescribed for use at home.
- You should also advise the patient to contact his or her doctor or pharmacist if he or she experiences any adverse effects from medications.
Abbreviations Introduced in This Chapter

ANC  Absolute neutrophil count
APD  Automated peritoneal dialysis
CAPD  Continuous ambulatory peritoneal dialysis
DPL  Diagnostic peritoneal lavage
IAIs  Intra-abdominal infections
IP  Intraperitoneal
LD  Loading dose
MD  Maintenance dose
MRSA  Methicillin-resistant S. aureus
PD  Peritoneal dialysis

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify the primary reasons why some parasitic diseases may be more prevalent in the US population.
2. Describe the treatment algorithm for giardiasis and amebiasis.
3. List one effective therapy for nematodes and select the drugs of choice for strongyloidiasis and tapeworms.
4. List three major reasons why travelers are infected with malaria.
5. Describe the presenting signs and symptoms of malaria.
6. List some specific toxicities of mefloquine.
7. Identify the monitoring parameters for quinidine gluconate in severe malaria.
8. Define the major complications of falciparum malaria.
9. Discuss the cardiovascular complications of chronic South American trypanosomiasis.
10. Describe the steps to take to eradicate lice infestation and scabies.

INTRODUCTION

The increased desire of large segments of the US population to travel to Asia, Africa, and other parts of the world can expose them to parasitic infections that are endemic in those areas. The influx of refugees and new immigrant populations from Asia and other parts of the world have brought new parasitic infections to our shores. Migrant farm workers, the large and growing Central and South American immigrant population, and the presence of immunosuppressed populations (eg, those with the AIDS and transplant patients) represent significant sources of parasitic infections in the United States.1–5

Terms that are frequently used when discussing parasitic diseases are as follows.6 Symbiosis means “living together,” when two species are dependent on each other for food and protection. The term commensalism, implies a mutual association in which both organisms may benefit, or at least one benefits but does no harm to the other. In contrast, parasitism, although resembling symbiosis in that it is also an intimate relationship between two species does not represent a mutually beneficial association. One species (the host) does not benefit from the relationship, and in fact the relationship may be detrimental to its survival.

Parasites have made metabolic and other defensive adaptations over time to increase their ability to survive host defenses and have allowed them to utilize the host’s biochemical systems to synthesize necessary cellular components. Beef and pork tapeworms (cestodes) possess highly developed reproductive systems that allow them to transfer easily to new hosts. Because of the lack of digestive systems, cestodes are completely host-dependent for all nutrients. Cestodes (tapeworms) (Taenia saginata and Taenia solium) use specialized suckers that enable them to obtain blood and vital nutrients from their host. Entamoeba histolytica, once it has gained access to the human colon or large intestine is able to invade and utilize its specialized proteolytic enzyme to erode the GI mucosa. E. histolytica is also able to survive in adverse conditions by walling itself off and forming cysts; this protects the parasite from environmental conditions until it is ready to infect the next host.

Although acquired immunity to some parasitic diseases may lower the level of infection, absolute immunity as seen in bacterial and viral infections is seldom seen in parasitic diseases. Since parasitic infections produce a wide variety of antigens because of the many life cycle phases, it is more difficult to identify a constant antigenic protein against which specific antibodies are protective. However, malaria remains a likely candidate for a vaccine and there are ongoing studies to develop one.

For more detailed discussions of the world of parasites, clinicians and students are directed to some excellent resources on parasites and parasitic diseases.6,5 Discussion in this chapter includes parasitic diseases more likely seen in the United States and includes GI parasites (primarily giardiasis and amebiasis), protozoan infections (malaria and South American trypanosomiasis), some common helminthic diseases (specifically those caused by nematodes and cestodes), and ectoparasites (lice and scabies).

GIARDIASIS

Epidemiology and Etiology

Giardia lamblia (G. intestinalis or G. duodenalis), is the most common intestinal parasite responsible for diarrheal syndromes throughout the world and is the most frequently identified
intestinal parasites in the United States, with a prevalence rate of 5% to 15% in some areas. *G. lamblia* has been identified as the first enteric pathogen in children in developing countries, with prevalence rates between 15% and 30%.7,8

There are two stages in the life cycle of *G. lamblia*: the trophozoite and the cyst. *G. lamblia* is found in the small intestine, the gallbladder, and in biliary drainage.7,8 The distribution of giardiasis is worldwide, with children being more susceptible than adults.

**Pathophysiology**

Giardiasis is caused by ingestion of *G. lamblia* cysts in fecally contaminated water or food.7,8 The protozoan excysts in the low gastric pH to release the trophozoite. Colonization and multiplication of the trophozoite lead to mucosal invasion, localized edema, and flattening of the villi, resulting in malabsorption states in the host. Achlorhydria, hypogammaglobulinemia, or deficiency in secretory immunoglobulin A (IgA) predispose to giardiasis.7 Individuals with HIV infection and AIDS may have higher carriage rates than the general population. Some patients may develop lactose intolerance after chronic giardiasis.

**Pharmacologic Therapy**

*All symptomatic adults and children over the age of 8 years with giardiasis should be treated with metronidazole 250 mg three times daily for 7 days, or tinidazole 2 g as a single dose, or nitazoxanide (Alinia) 500 mg twice daily for 3 days.*3 The pediatric dose of metronidazole is 15 mg/kg/day three times daily for 7 days. Alternative drugs include furazolidone 100 mg four times daily or paromomycin 25 to 35 mg/kg/day in divided doses daily for 7 days. Paromomycin may be used in pregnancy instead of metronidazole. Pediatric patients can also be treated with suspensions of furazolidone 6 mg/kg/day in four divided doses for 7 days.

Quinacrine 100 mg three times in adults or 5 mg/kg/day in pediatric patients for 5 to 7 days, is available from a specialized pharmacy (eg, Panorama Compounding Pharmacy).8

**Outcome Evaluation**

Patients with symptomatic giardiasis and positive stool samples or positive enzyme-linked immunosorbent assay (ELISA) tests should be treated with metronidazole for 7 days. Patients who

---

**Patient Encounter 1: Giardiasis**

LA is a 29-year-old recently returned US resident who had traveled to Texcoco in Mexico to visit a friend he had met at a meeting in Mexico city. Although the majority of his meals were in his friend’s house, the night before returning home he had a meal at a local restaurant. Three days after his return from Texcoco he developed severe nausea, diarrhea, alternating with constipation. When he is seen at the travel clinic at a local hospital, he reports nausea and crampy, watery diarrhea with foul-smelling stools for four days. LA also reported that his stool was “light-colored.”

*Are his symptoms characteristic of parasitic-associated diarrhea?*

*How would you differentiate giardiasis from an Escherichia coli–induced diarrhea?*

---

**Clinical Presentation and Diagnosis of Giardiasis**

**Acute Onset**

- Diarrhea, cramp-like abdominal pain, bloating, and flatulence
- Malaise, anorexia, nausea, and belching

**Chronic Symptoms**

- Diarrhea: Foul-smelling, copious, light-colored, and greasy stools
- Weight loss, steatorrhea, and vitamin B12 and fat-soluble vitamin deficiencies
- Constipation alternating with diarrhea

**Diagnosis**

- Diagnosis is made by examination of fresh stool or a preserved specimen during acute diarrheal phase
- Fresh stool may show trophozoites, whereas preserved specimens yield cysts. (Note: stool for ova may show the presence of other parasites [eg, *Cryptosporidium parvum*, *E. histolytica*, or *E. hartmanni*]; multiple stool samples may be needed.)
- Stool examination for ova and parasites is the major means of diagnosis, and other diagnostic tests include enzyme-linked immunosorbent assay (ELISA), which is considered to be between 85% and 98% sensitive and almost 100% specific (ProSpec T, Giardia Microplate Assay, Remel, Lenexa, KS.)

**Patient Care Process: Giardiasis**

**Patient Assessment:**

- Evaluate patient medical history, recent travel, signs, and symptoms.
- Conduct a medication history, review laboratory findings and consider if stool for O/P and other tests may be necessary for diagnosis of giardiasis.

**Therapy Evaluation:**

- Based on symptoms and laboratory findings, consider the appropriate pharmacotherapy for the patient.
- Discuss expected side effects, any drug interactions and availability of the prescribed medication in the community or hospital.

**Care Plan Development:**

- Consider any dietary or other considerations for giardiasis—fluids and replacements for deficiencies if warranted.
- Address patient concerns about the infection and the therapy.

**Follow-Up Evaluation:**

- Decide when patient should come back for follow-up.
- Inform patient for repeat stool for O/P and the need for reevaluation at the end of therapy.
fail initial therapy with metronidazole should receive a second course of therapy. Pregnant patients can receive paromomycin 25 to 35 mg/kg/day in divided doses for 7 days. Giardiasis can be prevented by good hygiene and by using caution in food and drink consumption.

AMEBIASIS
Epidemiology and Etiology
Amebiasis remains one of the most important parasitic diseases because of its worldwide distribution and serious GI manifestations. The major causative agent in amebiasis is *E. histolytica*, which invades the colon and must be differentiated from *Entamoeba dispar*, which is associated with an asymptomatic carrier state and is considered nonpathogenic. Invasive amebiasis is almost exclusively the result of ingesting *E. histolytica* cysts found in fecally contaminated food or water. Approximately 50 million cases of invasive disease result each year worldwide, leading to an excess of 100,000 deaths. In the general population, the highest incidence is found in institutionalized mentally retarded patients, sexually active homosexuals, AIDS patients, the Native American population, and new immigrants from endemic areas (eg, Mexico, South and Southeast Asia, West and South Africa, and portions of Central and South America).

Pathophysiology
*E. histolytica* invades mucosal cells of colonic epithelium, producing the classic flask-shaped ulcer in the submucosa. The trophozoite toxin has a cytocidal effect on cells. If the trophozoite gets into the portal circulation, it will be carried to the liver, where it produces abscess and periportal fibrosis. Liver abscesses are more common in men than women and are rarely seen in children. Amebic ulcerations can affect the perineum and genitalia, and abscesses may occur in the lung and brain. Erosion of liver abscesses can result in peritonitis. Liver abscesses that are located in the right lobe can spread to the lungs and pleura. Pericardial infection, although rare, may be associated with extension of the amebic abscesses from the liver.

Patient Encounter 2: Amebiasis
DR is a 32-year-old computer programmer who, on returning from visiting Angkor Wat in Siem Reap, Cambodia, is seen in the emergency department at Detroit Receiving Hospital with complaints of a 3-day history of severe diarrhea, cramps, and postprandial abdominal pain. The abdominal pain is over the right lower quadrant and associated with nausea and flatulence. DR indicates that he had some diarrhea the night after he had visited a local restaurant in Siem Reap. The diarrhea subsided after treatment from a local physician. However, 5 days later after his return to the States, his symptoms came back.

What specific findings in this patient suggest that he may have giardiasis, amebiasis or an E. coli-associated diarrhea? What specific laboratory or diagnostic test will confirm a diagnosis of amebiasis? Describe some of the complications associated with amebiasis.

Clinical Presentation and Diagnosis of Amebiasis
Review of the patient’s history should include the following: recent travel, type of foods ingested (eg, salads or unpeeled fruit), the nature of water and fluid consumed, and description of any symptoms of friends or relatives who ate the same food.

Intestinal Disease
- Vague abdominal discomfort
- Symptoms may range from malaise to severe abdominal cramps, flatulence, and nonbloody or bloody diarrhea (heme-positive in 100% of cases) with mucus
- May have low-grade fever, but this may be absent in many patients
- Eosinophilia is usually absent, although mild leukocytosis is not unusual

Note: Fecal screening may show other intestinal parasites, including Cryptosporidium spp., *Balantidium coli*, *Dientamoeba fragilis*, *Isospora belli*, *G. lamblia*, or *Blastocystis hominis*.

Amebic Liver Abscesses
- May present with high fever with significant leukocytosis with *left shift*, anemia, elevated alanine aminotransferase, and dull abdominal pain on palpation
- Physical findings: Right upper quadrant pain, hepatomegaly, and liver tenderness, with referred pain to the left or right shoulder (Note: Erosion of liver abscesses may present as peritonitis.)

**KEY CONCEPT** Diagnosis
- Intestinal amebiasis is diagnosed by demonstrating *E. histolytica* cysts or trophozoites (may contain ingested erythrocytes) in fresh stool or from a specimen obtained by sigmoidoscopy
- Microscopy may not differentiate between the pathogenic *E. histolytica* and the nonpathogenic (commensal) *E. dispar* or *E. moshkovskii* in stools
- Sensitive techniques are available to detect *E. histolytica* in stool: antigen detection, antibody test (ELISA) and polymerase chain reaction (PCR)
- Endoscopy with scrapings or biopsy and stained slides (iron hematoxylin or trichrome) may provide more definitive diagnosis of amebiasis
- Diagnosis for liver abscess includes serology and liver scans (using isotopes by ultrasound or computed tomography [CT]) or MRI; however, none of these are specific for liver abscess. In rare instances, needle aspiration of hepatic abscess may be attempted using ultrasound guidance

Pharmacologic Therapy
Metronidazole (Flagyl), dehydroemetine, and chloroquine (Aralen) are tissue-acting agents, and iodoquinol (Yodoxin), diloxanide furoate (Furamide), and paromomycin (Humatin) are well absorbed that the amounts of the drug remaining in the bowel may be insufficient to have luminal or local effects. A agent active in the GI lumen, on the other hand, may not attain effective enough
levels in the tissue to be efficacious. Asymptomatic cyst passers (identified by stool examinations, and who may develop invasive disease) and patients with mild intestinal amebiasis should receive a luminal agent: paromomycin 25 to 35 mg/kg/day three times daily for 7 days, or iodoquinol 650 mg three times daily for 20 days. These regimens have cure rates of between 84% and 96%. The pediatric dose of paromomycin is the same as that used in adults, whereas the pediatric dose of iodoquinol is 30 to 40 mg/kg (maximum: 2 g) per day in three doses for 20 days, and the pediatric dose of diloxanide furoate is 20 mg/kg/day in three doses for 10 days. Paromomycin is the preferred agent in pregnant patients.9,11

Patients with severe intestinal disease or liver abscess should receive metronidazole 750 mg three times daily for 10 days, followed by the luminal agents indicated previously. The pediatric dose of metronidazole is 50 mg/kg/day in divided doses, which should be followed by a luminal agent.11–14 An alternative regimen of metronidazole is 2.4 g/day for 2 days in combination with the luminal agent.9,11,12 Tinidazole administered in a dose of 2 g daily for 3 days (pediatric dose: 50 mg/kg for 3 days; can be crushed and added to cherry syrup) is an alternative to metronidazole.9 If there is no prompt response to metronidazole or aspiration of the abscess, an antibiotic regimen should be added. Patients who cannot tolerate oral doses of metronidazole should receive an IV dose of metronidazole.9,11

Outcome Evaluation

Follow-up in patients with amebiasis should include repeat stool examinations, serology, colonoscopy (in colitis), or CT scan a month after the end of therapy. Serial liver scans have demonstrated healing of liver abscesses over 4 to 8 months after adequate therapy.12,14

Patient Care Process: Amebiasis

**Patient Assessment:**
- Based on physical exam, review of systems and travel history, determine if these findings are consistent with giardiasis or amebiasis.
- Address what specific diagnostic tests would be required to make a definitive diagnosis for amebiasis.
- Conduct a medication history and check for allergies.

**Therapy Evaluation:**
- Determine, based on the results of the diagnostic tests, whether this is amebic colitis or colitis with liver abscess.
- Verify whether the drug or drugs you intend to use is on the hospital formulary or readily available at a local pharmacy.

**Care Plan Development:**
- Select pharmacotherapy and appropriate regimen and check for any potential drug interactions.
- Address any patient concerns and discuss the need for medication adherence and dietary restrictions.

**Follow-Up Evaluation:**
- Follow-up in 10 days and repeat tests to evaluate therapy.
- Monitor for efficacy and toxicity.

**HELMINTHIC DISEASES**

Helminthic infections include three groups of organisms: roundworms or nematodes, flukes (trematodes), and tapeworms (cestodes). Brief descriptions of some of the helminthic infections most commonly seen in North America and their treatments are provided here. Although helminthic infections may not produce clinical manifestations, they can cause significant pathology. One factor that determines the pathogenicity of helminthic infections is their population density; a high-density population (“worm burden”) results in predictable disease presentation. In the United States, these infections are reported most frequently in recent immigrants from Southeast Asia, the Caribbean, Mexico, and Central America.15–17 Populations at risk include institutionalized patients (both young and elderly), preschool children in daycare centers, residents of Native American reservations, and homosexuals.16,18 Certain conditions and drugs (anesthesia and corticosteroids) can cause atypical localization of worms. Immunocompromised hosts can be overwhelmed by some helminthic infections, such as Strongyloides stercoralis.

**Nematodes**

➤ **Hookworm Disease**

Hookworm infection is caused by Ancylostoma duodenale or Necator americanus. N. americanus is found in the southeastern United States.15–17 Infective larvae enter the host in contaminated food or water or penetrate the skin and migrate to the small intestine. The adult worm attaches to GI mucosa and causes injury by lytic destruction of the tissue. Over a period of time, the adult worm can cause anemia and hypoproteinemia in the host.16–20

➤ **Treatment**

**KEY CONCEPT** The drug of choice is mebendazole (Vermox), which is also active against ascariasis, enterobiasis, trichuriasis, and hookworm.9,21 The adult and pediatric (age greater than 2 years) oral dose of mebendazole for hookworm is 100 mg twice daily for 3 days. An alternative agent that can be used in both pediatric and adult patients is albendazole (Zentel), 400 mg as a single oral dose. Diagnosis is by detection of eggs or larvae in stool. Stool examination for eggs and the larvae should be repeated in 2 weeks and the patient retreated if necessary.

**Ascariasis**

The causative agent in ascariasis is the giant roundworm Ascaris lumbricoides, which is found worldwide and is responsible for about 4 million infections in the United States (it primarily affects residents of the Appalachian mountain range and the Gulf Coast states).15–17 Migration of the worm into the lungs usually produces pneumonitis, fever, cough, eosinophilia, and pulmonary infiltrates. Ascaris infection can also cause abdominal discomfort, intestinal obstruction, and appendicitis. Diagnosis is made by detection of the characteristic eggs in the stool or passed worms.

➤ **Treatment**

In both adults and pediatric patients older than 2 years of age, mebendazole 100 mg orally twice daily for 3 days is the treatment to use. An alternative agent is pyrantel pamoate (Antiminth).9 The stool should be checked within 2 weeks and the patient retreated when warranted.

**Ascariasis**

The causative agent in ascariasis is the giant roundworm Ascaris lumbricoides, which is found worldwide and is responsible for about 4 million infections in the United States (it primarily affects residents of the Appalachian mountain range and the Gulf Coast states).15–17 Migration of the worm into the lungs usually produces pneumonitis, fever, cough, eosinophilia, and pulmonary infiltrates. Ascaris infection can also cause abdominal discomfort, intestinal obstruction, and appendicitis. Diagnosis is made by detection of the characteristic eggs in the stool or passed worms.

➤ **Treatment**

In both adults and pediatric patients older than 2 years of age, mebendazole 100 mg orally twice daily for 3 days is the treatment to use. An alternative agent is pyrantel pamoate (Antiminth).9 The stool should be checked within 2 weeks and the patient retreated when warranted.
Enterobiasis

Enterobiasis, or pinworm infection, is caused by *Enterobius vermicularis*. It is the most widely distributed helminthic infection in the world.\(^{15-17}\) There are approximately 42 million cases in the United States, primarily affecting children. The most common manifestation of the infection is cutaneous irritation in the perianal region, resulting from the migrating female or the presence of eggs. The intense pruritus may lead to dermatitis and secondary bacterial infections. Diagnosis is made by the use of a perianal swab and cellophane tape sampling, which will aid in egg identification.

### Treatment

The three agents that are administered for enterobiasis include pyrantel pamoate, mebendazole, and albendazole.\(^{9}\) The oral dose of pyrantel pamoate is 11 mg/kg (maximum: 1 g) as a single dose that can be repeated in 2 weeks. The oral dose of mebendazole for both adults and children older than 2 years of age is 100 mg as a single dose. This may be repeated in 2 weeks.\(^{9}\) Following treatment, to eradicate the eggs, all bedding and underclothing should be sterilized by steaming or washing in the hot cycle of the washing machine.

Strongyloidiasis

Strongyloidiasis is caused by *Strongyloides stercoralis*, which has a worldwide distribution and is predominantly prevalent in South America (Brazil and Columbia) and in Southeast Asia.\(^{35-38}\) Strongyloidiasis is primarily seen among institutionalized populations (those in mental hospitals and children’s hospitals) and immunocompromised individuals (those with HIV infection, AIDS, and patients with hematologic malignancies).\(^{22-24}\) The worm is usually found in the upper intestine, where the eggs are deposited and hatch to form the rhabditiform larvae. The rhabditiform larva (male and female) migrate to the bowel where they may be excreted in the feces. If excreted in the feces, the larva can evolve into either one of two forms after copulation: a free-living noninfectious rhabditiform larva, or an infectious filariform larva. The filariform larva can penetrate host skin and migrate to the lungs and produce progeny, a process called autoinfection. This can result in hyperinfection (ie, an increased number of larva in the intestine, lungs, and other internal organs), especially in an immunocompromised host.

Patients with acute infection may develop a localized pruritic rash, but heavy infestations can produce eosinophilia (10%–15% eosinophils [0.10–0.15]), diarrhea, abdominal pain, and intestinal obstruction. Administration of corticosteroids or other immunosuppressive drugs to an infected individual can result in hyperinfections and disseminated strongyloidiasis.\(^{22,24}\) Diagnosis of strongyloidiasis is made by identification of the rhabditiform larva in stool, sputum, or duodenal fluid, or from small bowel biopsy specimens. Even though antigen testing (ELISA essay) remains the most sensitive method, stool examinations and other body fluids should also be utilized in the diagnosis.\(^{22,24}\)

### Treatment

The drug of choice for strongyloidiasis is oral ivermectin 200 mcg/kg/day for 2 days, whereas albendazole 400 mg twice daily is given for 7 days as an alternative.\(^{9}\) With hyperinfection or disseminated strongyloidiasis, immunosuppressive drugs should be discontinued and treatment should be initiated with ivermectin 200 mcg/kg/day until all symptoms are resolved. Patients should be tested periodically to ensure the elimination of the larva.

Cestodiasis

Cestodiasis (tapeworm infection) is caused by species of the phylum Platyhelminthes (flatworms) and include, among others, the pork tapeworm (*Taenia solium*) and the beef tapeworm (*T. saginata*).\(^{6,25}\) The tapeworm attaches itself to the mucosal wall of the upper jejunum by the scolex (mouth parts) and by two to four cup-shaped suckers and a structure called a rostellum, which may have hooks in some species. Since the parasite lacks a digestive system, it obtains all nutrients directly from the host. The scolex, proglottids (segments), and eggs are specific for each species and used for identification of tapeworms. Tapeworm infections are caused by ingestion of poorly cooked meat that contains the larva or cysticerci. Cysticerci, when released from the contaminated meat by host digestive juices, mature in the host jejunum. Cysticercosis is a systemic disease caused by the larva of *T. solium* (oncosphere or hexacanth) and is usually acquired by ingestion of eggs in contaminated food or by autoinfection.\(^{6,25}\) The larvae can penetrate the bowel and migrate through the bloodstream to infect different organs, including the central nervous system (CNS) (neurocysticercosis). Diagnosis of both *T. saginata* and *T. solium* is accomplished by recovery of the gravid proglottids and the scolex in the stool. Newer diagnostic tools for neurocysticercosis include serum and cerebrospinal antigen and antibody testing.\(^{25}\)

### Treatment

*Tapeworm infections (T. saginata and T. solium) are treated with praziquantel 5 to 10 mg/kg as a single dose (use the same dose for adults and pediatric patients).*\(^{9}\) The treatment for cystercerosis and neurocysticercosis may include surgery, anticonvulsants (neurocysticercosis can cause seizures), and anthelmintic therapy. The anthelmintic therapy of choice is albendazole 400 mg twice daily for 5 to 30 days.\(^{25-29}\) The pediatric dose of albendazole is 15 mg/kg (maximum: 800 mg) in two divided doses for 8 to 30 days. The doses for both adults and pediatric subjects can be repeated if necessary. Praziquantel is an alternative therapy.\(^{9}\)

Outcome Evaluation

Morbidity and disease due to helminthic infections is related to the intensity of infection. The major adverse effects of helminthic infections are malnutrition, fatigue, and diminished work capacity. Unlike other helminthic infections, strongyloidiasis can cause autoinfection, and in the presence of immunosuppression, it can cause CNS and disseminated infections, which have high mortality.\(^{22,24}\)

The most serious complication of cysticercosis is neurocysticercosis that can cause strokes and seizures.\(^{26,27}\) Treatment of neurocysticercosis with antihelmintic treatment remains controversial.

MALARIA

Malaria is one of the most devastating parasitic diseases, affecting a population in excess of 500 million and causing in excess of 660,000 deaths a year worldwide.\(^{2,3}\) In the year 2000, approximately 27 million US travelers visited countries where malaria is endemic. In 2011, the Centers for Disease Control and Prevention indicated that there were 1925 cases of malaria, an increase of 14% over 2010 and the highest number reported since 1971.\(^{3}\) There were five fatalities, three due to *Plasmodium falciparum*...
Patient Encounter 3, Part 1: Malaria

AR is a 52-year-old West African man who had recently returned from Cameroon. He was well since returning from Cameroon until 2 days ago, when he developed a temperature as high as 39.0°C (102.2°F), with anorexia, headache, chills, sweats, myalgias, and abdominal pain. AR comes to the emergency department with high fever (greater than 39.8°C [greater than 103.6°F]), headache, abdominal pain, nausea, stiffness of the neck, and back pain. AR indicates that he took some antimalarials but missed some days and is not able to name the exact medication or doses taken.

What are the symptoms in this patient that are consistent with malaria?

Why is this patient at risk for malaria?

Are there any additional information you like to have, to be able to develop a pharmacotherapy plan for this patient?

and one due P. vivax (the malaria species in one case was not reported).3 KEY CONCEPT The primary reasons for morbidity and death in malaria are failure to take recommended chemoprophy- laxis, inappropriate chemoprophylaxis, delay in seeking medical care or in initiating therapy promptly, and misdiagnosis.8 Evaluation of a patient should include specific travel history, details of chemoprophylaxis, and physical findings (eg, splenomegaly).

Malaria is transmitted by the bites of the Anopheles mosquitoes, which introduce into the bloodstream one of five species of sporozoites of the plasmodia (Plasmodium falciparum, P. ovale, P. vivax, P. malariae, and P. knowlesi).9–33 Initial symptoms of malaria are nonspecific and may resemble influenza and include chills, headache, fatigue, muscle pain, rigors, and nausea. The onset of the symptoms is between 1 and 3 weeks following exposure. Fever may appear 2 to 3 days after initial symptoms and may follow a pattern and occur every 2 or 3 days (P. vivax, P. ovale, and P. malariae). Fever with P. falciparum can be erratic and may not follow specific patterns. It is not unusual for patients to have concomitant infections with P. vivax and P. falciparum. Falciparum malaria (or P. knowlesi) must always be regarded as a life-threatening medical emergency.

Epidemiology and Etiology

The distribution of the various species of malaria is not well defined, but P. vivax is reported to be prevalent in the Indian subcontinent, Central America, North Africa, and the Middle East, whereas P. falciparum is predominantly in Africa (including sub-Saharan Africa), both East and West Africa, Haiti, the Dominican Republic, the Amazon region of South America, Southeast Asia, and New Guinea.9,30,33 Most P. ovale infections occur in Africa, whereas the distribution of P. malariae is worldwide.9,30 Most infections in the United States are reported in American travelers, recent immigrants, or immigrants who have visited friends and family in an endemic area.3,30 Placental transmission and blood transfusions are also sources of malaria.

Pathophysiology

Within minutes after the bite of the Anopheles mosquito, the sporozoites invade hepatocytes and begin an asexual phase called schizonts (exoerythrocytic stage or schizogony). The patient may be asymptomatic during this period. After a lapse of between 5 and 15 days (depending on the species), schizonts rupture to release daughter cells (merozoites) into the blood, which then invade erythrocytes. In erythrocytes, the merozoites undergo a number of sequential forms: a ring form, trophozoite, schizont, and merozoite, which then invade new erythrocytes. This asexual phase is about 48 hours for P. falciparum, P. vivax, and P. ovale, and 72 hours for P. malariae. Subsequently, the merozoites develop into gametocytes and undergo a sexual phase (sporogony) in the Anopheles mosquito. In the mosquito, the gametocytes undergo a number of stages: zygote, ookinete, and oocyst, and finally transform into sporozoites in the salivary glands, where it is again able to infect the next host. Unlike P. falciparum and P. malariae, which only remain in the liver for about 3 weeks before invading erythrocytes, P. ovale and P. vivax can remain in the liver for extended periods in a latent stage (as hypnozoites); this can result in the recurrence of the infection after weeks or months. Primaquine therapy is necessary to eradicate this stage of the infection.9

Clinical Presentation and Diagnosis

The clinical presentation of malaria can be quite variable. Normally, the appearance of a prodrome with headache, abdominal pain, fatigue, fever, and chills, which coincides with the erythrocytic phase of malaria, occurs frequently between 10 and 21 days after being exposed.9,30,31 This phase causes extensive hemolysis, which results in anemia and splenomegaly. The most serious complications are caused by P. falciparum infections. Infants and children younger than 5 years and nonimmune pregnant women are at high risk for severe complications with falciparum infections.9,30,31,34 The complications associated with falciparum malaria are related to two unique features of P. falciparum: (a) its ability to produce high parasitism (up to 80%) of red cells of all ages; and (b) the propensity to be sequestered in post-capillary venules of critical organs such as brain, liver, heart, lungs, and kidneys.30,34 It has been postulated that tissue hypoxia from anemia, together with P. falciparum–parasitized red blood cell adherence to endothelial cells in capillaries, contributes to severe ischemia and metabolic derangements.34 P. malariae is implicated in immune-mediated glomerulonephritis and nephrotic syndrome.15

Clinical Presentation and Diagnosis

Innovations for detecting malaria include DNA or RNA probes by PCR and monoclonal antibody testing.3,30 These, however, are not widely available for clinical use. A P. falciparum–specific monoclonal antibody test, histidine-rich protein 2 (HRP-2), is fairly sensitive for P. falciparum and is recommended by the World Health Organization as an alternative for microscopic test (the “gold standard”). However, the rapid malaria diagnostic tests (MDRTDs) are restricted from wide use by cost, regulatory standards, operative expertise, and availability.9,30

Treatment

The primary goal in the management of malaria is the rapid identification of the Plasmodium species by blood smears (both thick and thin smears repeated every 12 hours for 3 days). Anti-malarial therapy should be initiated promptly to eradicate the infection within 48 to 72 hours and avoid complications such as hypoglycemia, pulmonary edema, and renal failure.9,31,34,36

Pharmacologic Therapy

In an uncomplicated attack of malaria (for all plasmodia except chloroquine-resistant P. falciparum and P. vivax), the
Initial Presentation
Include a careful travel history of patient and physical findings (eg, splenomegaly) and details of antimalarial chemoprophylaxis, when obtainable

Erythrocytic Phase
1. Prodrome: Headache, anorexia, malaise, fatigue, and myalgia
2. Nonspecific complaints include abdominal pain, diarrhea, chest pain, and arthralgia
3. Paroxysm: High fever, chills, and rigor
4. Cold phase: Severe pallor, cyanosis of the lips and nail beds
5. Hot phase: Fever between 40.5°C (104.9°F) and 41.0°C (105.8°F) (seen more frequently with *P. falciparum*)
6. Sweating phase: Follows the hot phase by 2 to 6 hours
7. When fever resolves, it is followed by marked fatigue and drowsiness, warm dry skin, tachycardia, cough, headache,

HEENT: Slightly dry oral mucosa
ABD: Splenomegaly
Rest of the systems were WNL

Labs: Sodium 148 mEq/L (148 mmol/L), hemoglobin 10.2 g/dL (102 g/L or 6.33 mmol/L), potassium 4.1 mEq/L (4.1 mmol/L), hematocrit 31% (0.31), chloride 96 mEq/L (96 mmol/L), WBC 14.8 x 10^9/mm^3 (14.8 x 10^9/L), BUN 28 mg/dL (10.0 mmol/L), total bilirubin 1.8 mg/dL (30.8 µmol/L), Scr 1.4 mg/dL (124 µmol/L), platelets 110 x 10^9/mm^3 (110 x 10^9/L), glucose 77 mg/dL (4.3 mmol/L), aspartate aminotransferase 87 U/L (1.45 µkat/L), albumin 3.2 g/dL (32 g/L), alanine aminotransferase 94 U/L (1.57 µkat/L), blood smear (Giemsa stain): *P. falciparum*.

As a result of above findings, what is your approach in the management of TW?
Describe the specific steps one need to take to ensure a good outcome and minimize the associated complications with *P. falciparum* infection.

**Recommended oral regimen is chloroquine 600 mg (base) initially, followed by 300 mg (base) 6 hours later, and then 300 mg (base) daily for 2 days.** In severe illness or *falciparum* malaria, patients should be admitted to an acute care unit, and quinidine gluconate 10 mg salt/kg as a loading dose (maximum 600 mg) in 250 mL normal saline should be administered IV slowly over 1 to 2 hours. This should be followed by continuous infusion of 0.02 mg/kg/min of quinidine for at least 24 hours until oral therapy can be started. In patients who have received either quinine or mefloquine, the loading dose of quinidine should be omitted. Oral quinine salt (650 mg every 8 hours) plus doxycycline 100 mg twice daily should follow the IV dose of quinidine to complete 7 days of therapy. The pediatric dose of IV quinidine gluconate is the same as the dose for adults. The pediatric dose of oral quinine is 25 mg/kg/day in three divided doses, whereas the dose of doxycycline (children greater than 8 years) is 4 mg/kg in two divided doses for 7 days. An alternative to doxycycline is clindamycin 900 mg (20 mg/kg/day) three times daily for 3 days. The pediatric dose of clindamycin is the same as in adults. (In patients who cannot tolerate quinidine or if quinidine is not readily available, IV artesunate 2.4 mg/kg/dose for 3 days, at 0, 12, 24, 48, and 72 hours may be used, followed by oral therapy. Artesunate is available from the Centers for Disease Control and Prevention [CDC] under an investigational new drug application. The pediatric dose of artesunate is same as in adults. Oral therapy may include atovaquone/proguanil, doxycycline, mefloquine or clindamycin.)

**Clinical Presentation and Diagnosis of Malaria**

**Initial Presentation**
Include a careful travel history of patient and physical findings (eg, splenomegaly) and details of antimalarial chemoprophylaxis, when obtainable

**Erythrocytic Phase**
1. Prodrome: Headache, anorexia, malaise, fatigue, and myalgia
2. Nonspecific complaints include abdominal pain, diarrhea, chest pain, and arthralgia
3. Paroxysm: High fever, chills, and rigor
4. Cold phase: Severe pallor, cyanosis of the lips and nail beds
5. Hot phase: Fever between 40.5°C (104.9°F) and 41.0°C (105.8°F) (seen more frequently with *P. falciparum*)
6. Sweating phase: Follows the hot phase by 2 to 6 hours
7. When fever resolves, it is followed by marked fatigue and drowsiness, warm dry skin, tachycardia, cough, headache,

**Diagnostic Procedures for Malaria**
1. To ensure a positive diagnosis, blood smears (both thick and thin films) should be obtained every 12 to 24 hours for 3 consecutive days
2. The presence of parasites in the blood 3 to 5 days after initiation of therapy suggests resistance to the drug regimen
In *P. falciparum*, *P. vivax*, *P. ovale*, or *P. malariae* (chloroquine-resistant) infections, a dose of 750 mg of mefloquine followed by 500 mg 12 hours later is recommended. The pediatric dose of mefloquine is 15 mg/kg (less than 45 kg) followed by 10 mg/kg 8 to 12 hours later. Mefloquine is associated with sinus bradycardia, confusion, hallucinations, and psychosis and should be avoided in patients with a history of epilepsy, cardiovascular problems or depression. IV quinidine gluconate followed by quinine plus doxycycline or clindamycin should be administered for severe illness as indicated previously. The IV quinidine regimen requires close monitoring of the ECG (QT-segment) and other vital signs (hypotension and hypoglycemia). An alternative oral treatment for *P. falciparum* infections in adults, especially those with a history of seizures, psychiatric disorders, or cardiovascular problems, is the combination of atovaquone 250 mg and proguanil 100 mg (Malarone) (two tablets twice daily for 3 days).

The pediatric dose of Malarone is as follows: it is not indicated for children less than 5 kg; 9 to 10 kg: three pediatric tablets per day for 3 days; 11 to 20 kg: one adult tablet per day for 3 days; 21 to 30 kg: two adult tablets per day for 3 days; 31 to 40 kg: three adult tablets per day for 3 days; greater than 40 kg: two adult tablets twice daily for 3 days.

**Outcome Evaluation**

Acute *P. falciparum* malaria resistant to chloroquine should be treated with IV quinidine and the loading dose of quinidine should be omitted in patients who have received quinine or mefloquine. Hypoglycemia, that is associated with both *P. falciparum* and quinidine administration, should be checked every 6 hours and when necessary, corrected with dextrose (5%–10%) infusions. Quinidine infusions should be slowed or stopped if the QT interval is greater than 0.6 second, the increase in the QRS complex is greater than 25%, or hypotension unresponsive to fluid challenge results. Quinidine levels should be maintained at 3 to 7 mg/dL (9.2–21.6 μmol/L). If quinidine is not readily available, artesunate (investigational protocol) should be obtained from the Centers for Disease Control and Prevention (www.cdc.gov/malaria/features/artesunate_now_available.htm).

When advising potential travelers on prophylaxis for malaria, be aware of the incidence of chloroquine-resistant *P. falciparum* malaria and the countries where it is prevalent. In patients who have *P. vivax* or *P. ovale* malaria (note that some patients can have *P. falciparum* and one of these species), following the treatment of the acute phase of malaria and screening for glucose-6-phosphate dehydrogenase deficiency, patients should receive a regimen of primaquine for 14 days to ensure eradication of the hypnozoite stage of *P. vivax* or *P. ovale*. For detailed recommendations for prevention of malaria, go to www.cdc.gov/travel/. Vaccines for malaria are under investigation.

**AMERICAN TRYPANOSOMIASIS**

**Etiology**

Two distinct forms of the genus *Trypanosoma* occur in humans. One is associated with African trypanosomiasis (sleeping sickness) and the other with American trypanosomiasis (Chagas disease). *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense* are the causative organisms for the East African and West African trypanosomiasis, respectively. *T. brucei rhodesiense* causes the acute disease and is the more virulent of the two species. Both East and West African trypanosomiasis are transmitted by various species of tsetse fly belonging to the genus *Glossina*. Further discussion of this subject will focus on American trypanosomiasis.

*Trypanosoma cruzi* is the agent that causes American trypanosomiasis. American trypanosomiasis is transmitted by a number of species of reduviid bugs (*Triatoma infestans* and *Rhodium prolixus*) that live in wall cracks of houses in rural areas of North, Central, and South America. The reduviid bug is infected by sucking blood from animals (eg, opossums, dogs, and cats) or humans infected with circulating trypomastigotes. American trypanosomiasis is endemic in all Latin American countries and can be transmitted congenitally, by blood transfusion, and by organ transplantation.

**Pharmacologic Therapy**

The drugs used for *T. cruzi* include nifurtimox (Lampit) and benznidazole (Rochagan). Oral nifurtimox is available from

---

**Patient Care Process: Malaria**

**Patient Assessment:**
- Based on the physical exam and review of systems, determine whether patient has acute malaria.
- Review all laboratory tests and take note of blood work that identifies the species of plasmodia reported.
- Conduct a medication history and identify any allergies.

**Therapy Evaluation:**
- Determine, based on patient presentation and previous therapy, if acute malaria is chloroquine sensitive or chloroquine-resistant.
- Assess the efficacy of present therapy and patient adherence.
- Recheck blood smears and parasite load.

**Care Plan Development:**
- Determine what modification in therapy is warranted.
- Review new regimen, consider whether a combination therapy is needed and check for any drug interactions.
- Check the CDC Malaria Website for recommended therapy.

**Follow-Up Evaluation:**
- Monitor patient for efficacy and toxicity.
- Review physical exam findings, lab tests, and diagnostic tests.
Clinical Presentation and Diagnosis of Trypanosomiasis

**Acute**
- Unilateral orbital edema (Romana sign)
- Granuloma (chagoma)
- Fever, hepatosplenomegaly, and lymphadenopathy

**KEY CONCEPT Chronic**
- Cardiac: cardiomyopathy and heart failure
- ECG: first-degree heart block, right bundle-branch block, and arrhythmias
- GI: enlargement of the esophagus and colon (“mega” syndrome
- CNS: meningoencephalitis, strokes, seizures, and focal paralysis

**Diagnosis**
Positive history of exposure and use of serology: indirect hemagglutination test, ELISA (Chagas EIA, Abbott Labs, Abbott Park, IL), and complement fixation (CF) test. (Note: CF may produce false-positive reactions in those exposed to leishmaniasis, syphilis, and malaria. PCR may be more definitive for diagnosis.)

**Outcome Evaluation**
Treatment of the acute phase of the disease (ie, fever, malaise, edema of the face, and hepatosplenomegaly) is nifurtimox. The congestive heart failure associated with cardiomyopathy of Chagas disease is treated the same way as cardiomyopathy from other causes.

ECTOPARASITES

A parasite that lives outside the body of the host is called an ectoparasite. Approximately 6 to 12 million subjects become infested with pediculosis (lice infestation) yearly in the United States. Pediculosis is usually associated with poor hygiene, and infections are passed from person to person through social and sexual contact.

**Lice**
The two species that belong to this group include *Pediculus humanus capitis* (head louse) and *Pediculus humanus corporis* (body louse). The eggs (or nits) remain firmly attached to the hair, and in about 10 days the lice hatch to form nymphs, which mature in 2 weeks. The lice become attached to the base of the hair follicle and feed on the blood of the host. Public or crab lice is found on the hairs around the genitals but may occur in other parts of the body (eg, eyelashes or axillae). Hypersensitivity to the secretions from lice can produce macular swellings and lead to secondary bacterial infections.

**Treatment**
The agent of choice for all three infections (body, head, and crab lice) is 1% permethrin (Nix). Benzyl alcohol 5% (Ulesfia) is a recently available lice therapy; it is pediculicidal and ovicidal activity against *P. humanus capitis*. The cure rate is reported to be between 90% and 97%. A cream rinse of permethrin 1% (Nix-Crème Rinse) is also available. Individuals with a history of hypersensitivity to ragweed or chrysanthemum may react to permethrin and should avoid this preparation. An alternative agent is oral ivermectin 100 mcg/kg for 3 days (days 1, 2, and 10). Permethrin can cause itching, burning, stinging, and tingling with application. Permethrin 1% should be applied to the dry scalp after shampooing and be left on the scalp for 10 minutes. The application may need to be repeated. Because of the reports of resistance to permethrin, an alternative agent is 0.5% malathion (Ovide), which has to be left on the scalp for 90 minutes and has also been found to be effective. Two applications of malathion, 7 days apart, may be necessary to eradicate the infection. An alternative for head lice is Spinosad 0.9% Crème which became available for patients who may not tolerate permethrin. Benzyl alcohol 5% (Ulesfia) is a recently available lice therapy for subjects over 6 months. For the relief of pruritus, calamine lotion with 0.1% menthol or an equivalent agent may be used. All individuals, including immediate family members and sexual partners, should be treated for lice infestation.

**Patient Care Process: Trypanosomiasis (Chagas Disease)**

**Patient Assessment:**
- Review medical history and laboratory tests including serology to establish the diagnosis for *T. cruzi*.
- Identify common complications associated with *T. cruzi*.

**Therapy Evaluation:**
- Determine if patient needs to be treated for primary disease and any secondary complications.
- Assess efficacy, safety, and potential drug interactions.

**Care Plan Development:**
- Determine the doses and regimen for pharmacotherapy.
- Address patient concerns and discuss the importance of adherence.

**Follow-Up Evaluation:**
- Review medical history, physical exam findings, and lab tests monthly.
- Determine, after assessing efficacy and toxicities of pharmacotherapy, if changes in regimen are necessary.
partners of the primary host, should be treated. All bedding and clothes should be sterilized as previously indicated for enterobiasis.

SCABIES

**KEY CONCEPT** Scabies is caused by the itch mite *Sarcoptes scabiei hominis*, which affects both humans and animals. Infection usually affects the interdigital and popliteal folds, axillary folds, the umbilicus, and the scrotum. Diagnosis is made by identifying the mite from skin scrapings on a wet mount.

**Treatment**

The agent of choice for scabies is permethrin 5% (Elimite) cream. Alternative agents in subjects who cannot use permethrin are crotamiton 10% (Eurax) and oral ivermectin (Stromectol) 200 mcg/kg as a single dose. To initiate the treatment with permethrin, the skin should be scrubbed in a warm soapy bath to remove the scabs. The permethrin lotion should then be applied to the whole body, avoiding the face, mucous membranes, and eyes, and left on for 8 to 14 hours. A single application eradicates 97% of scabies. However, in subjects with poor response, permethrin application can be combined with oral ivermectin therapy. All close contacts should be treated appropriately. The pruritus associated with scabies may persist for 2 to 4 weeks because of the remnants of mite parts in the skin.

**Outcome Evaluation**

Infections due to arthropods can be controlled by preventing their access to the host. Improving living conditions and avoiding sharing common personal items like hats and hair brushes may minimize these infections due to arthropods. Permethrin (1%–5%) is an effective agent for all these infections.

INTRODUCTION
Urinary tract infections (UTIs) are comprised of a diverse array of syndromes depending on the location of the infection within the urinary tract. 1–3 UTIs are one of the most common infectious diseases accounting for approximately 10.5 million annual ambulatory patient visits. 4 In hospitalized patients, UTIs are also common and are reported in 3.7% of catheterized and 0.9% of non-catheterized patients. 5 A UTI is defined by microorganism(s) in the urinary tract, which does not represent contamination.

Epidemiology and Etiology
The prevalence and type of UTIs generally vary by age and gender. 7,8 Premature infants have a higher rate than full-term infants, and neonatal boys are five to eight times more likely to have UTIs than neonatal girls. In young children 1 to 5 years of age, significant bacteriuria occurs more in girls than boys, 4.5% compared with 0.5%, respectively. 9 Once adulthood is reached, bacteriuria increases in young, nonpregnant women (range, 1%–3%), yet remains low in men (up to 0.1%). 10 Symptomatic UTI affects 30% of women between 20 and 40 years of age, which represents a prevalence that is 30 times greater than that of men in the same age group. The lifetime risk of UTIs in women is as high as 50% based on symptomatic reporting. 11

The etiology of UTIs has remained relatively unchanged over the past several decades. Key Concept: UTIs are either uncomplicated or complicated. There is a lack of consensus regarding the definition of what makes a UTI complicated (specifically in postmenopausal women or patients with diabetes mellitus), but in general, a complicated UTI refers to a structural or functional abnormality of the urinary tract. 1 Patients with complicated UTIs are typically given longer treatment durations than those patients with uncomplicated infections. Those with complicated UTIs by definition are also prone to more frequent infections. It is important to note that an upper UTI does not necessarily imply complicated UTI, nor does lower UTI imply uncomplicated UTI.

Pathophysiology
There are three potential ways for bacteria to enter into the urinary tract and cause infection: the ascending, hematogenous, and lymphatic pathways.

Ascending Pathway
The ascending pathway is involved when bacteria colonizing the urethra subsequently travel upwards, or ascend, the urethra to the bladder and cause cystitis (Figure 79–1). Women have a shorter urethra than men, and colonization of the female urethra is likely due to its proximity to the perirectal area. 12–14 Once in the bladder, bacteria are not limited to causing cystitis. These bacteria may continue to ascend the urinary tract via the ureters and cause more complicated infections, such as pyelonephritis.

Hematogenous Pathway
The hematogenous route is involved when bacteria colonizing the urethra subsequently travel upwards, or ascend, the urethra to the bladder and cause cystitis (Figure 79–1). Women have a shorter urethra than men, and colonization of the female urethra is likely due to its proximity to the perirectal area. 12–14 Once in the bladder, bacteria are not limited to causing cystitis. These bacteria may continue to ascend the urinary tract via the ureters and cause more complicated infections, such as pyelonephritis.
Host Defense Mechanisms

Urine possesses characteristics that are not ideal for bacterial metabolism and growth such as low pH, high urea concentration, and high osmolality. Bacteria in the bladder can stimulate an urge to urinate and increase bacterial voiding. In men, prostatic fluid secretions can inhibit bacterial growth, whereas normal vaginal flora in women such as *Lactobacillus* spp. can secrete lactic acid that further lowers the pH of the environment.\(^\text{17–19}\)

Innate host response and adaptive immunity are a primary defense against bacterial infections including UTIs.\(^\text{20}\) Several other secreted host factors specifically inhibit bacterial virulence factors. Virulence factors are mechanisms that bacteria utilize to cause infection and/or ensure their survival. Glycosaminoglycan is compound produced by the bladder that coats the epithelial cells. This separates the bladder from the urine by forming a protective layer against bacterial adhesion.\(^\text{21}\) Tamm-Horsfall protein is also secreted into the urine and prevents *E. coli* from binding to receptors present on the surface of the bladder.

Risk Factors

There are several risk factors for development of UTIs.\(^\text{30}\) Common risk factors for UTIs in women include sexual intercourse, use of a cervical diaphragm, use of spermicidal jellies, diabetes, and pregnancy.\(^\text{22–24}\) In men, the risks are increased in uncircumcised males and older age men with prostatic hyperplasia. Common risk factors for both men and women include urologic instrumentation, urethral catheterization, renal transplantation, neurogenic bladder, and urinary tract obstruction.\(^\text{25,26}\)

### CLINICAL PRESENTATION AND DIAGNOSIS

Bacteriuria, or bacteria in the urine, does not always represent infection. For this reason, quantitative diagnostic criteria have been created (Table 79–1) to identify the amount of bacteria in

#### General
- Most women present with hematuria; however, this is not a presentation restricted only to UTIs.
- Elderly patients frequently will not present with common signs and symptoms of UTI, but may present with altered mental status.
- More than 95% of uncomplicated UTIs are caused by a single organism.
- Patients may present with urosepsis.

**KEY CONCEPT** Signs and Symptoms of Lower UTI
- Dysuria, gross hematuria, suprapubic heaviness, nocturia, increased urinary frequency and urgency

**KEY CONCEPT** Signs and Symptoms of Upper UTI
- Fever, nausea, vomiting, malaise, and often severe flank pain

#### Laboratory Tests

Urinalysis should show:
- **Pyuria** typically greater than 10 white blood cells/mm\(^3\) urine (10 x 10^9/L)
- Bacteriuria, usually greater than \(10^5\) CFU organisms/mL (10^8 CFU/L)
- Nitrites present
- Leukocyte esterase present

#### Other Diagnostic Tests
- Bacterial urine culture
- Presence of costovertebral tenderness (upper UTI only)
AC is a 30-year-old woman who presents to an acute care clinic with complaints of a 3-day history of dysuria and urgency. She has had three prior UTI episodes in the last 6 months each treated with oral trimethoprim/sulfamethoxazole 800/160 mg daily for 3 days. Her last antibiotic course finished 6 days ago. She denies vomiting, fever, nausea, or flank pain. Urine culture information is not available from previous UTI episodes.

What signs and symptoms are suggestive of a lower urinary tract infection (UTI)?

Would you classify this patient as noncomplicated or complicated UTI?

How does this change your treatment approach?

What additional patient information is required before creating an appropriate treatment plan for this patient?

The goals of treatment are to eradicate the causative pathogen, minimize unnecessary exposure to noncausative organisms, and prevent, if possible, recurrence of infection. Therapy is directed at microbiologic eradication of the offending organism through antibiotics with a defined duration of treatment based on the UTI classification.

Antimicrobial therapy is the cornerstone of treatment in symptomatic UTIs. The selected antimicrobial should ideally be well tolerated, lend itself to patient compliance (low total number of doses), have adequate concentrations at the site of the infection in the urinary tract, have good oral bioavailability, and be narrow in antimicrobial spectrum to limit collateral damage and resistance development in human flora not affiliated with the infection.\(^1\)

Nonpharmacologic Therapy

Several nonpharmacologic therapies have been proposed for prevention of UTIs. The intake of large volumes of cranberry juice has been associated with a decrease in the number of UTIs over a year period in patients with recurrent UTIs in small randomized controlled trials. The efficacy is uncertain in the general population and with smaller intake volumes.\(^17,19\) Probiotics such as *Lactobacillus* spp. lower urinary pH and may reduce the growth of pathogenic bacteria\(^18,19\), and the agents have demonstrated promise in preventing recurrent UTIs in women.\(^19\) Topical estrogen replacement therapy significantly decreases the incidence of UTIs in postmenopausal women as compared with placebo.\(^21\) Methenamine hippurate and methenamine mandelate are hydrolyzed in acidic urine to the antimicrobial formaldehyde and are effective in preventing UTIs in patient without renal tract abnormalities.\(^32\) Patient education of common risk factors is important.

Pharmacologic Therapy

Table 79–2 reviews oral and IV antibiotics frequently used to treat UTIs with comments on their use, and Table 79–3 reviews frequency, duration, and doses of oral antibiotics used commonly for outpatient treatment of UTIs.

Uncomplicated UTIs

Cystitis Uncomplicated cystitis is frequently managed in the outpatient setting and occurs mostly in women of childbearing age.\(^1\)

E. coli represent the vast majority of causal organisms in this setting, but Staphylococcus saprophyticus, Klebsiella pneumoniae, Proteus mirabilis, Enterococcus spp. are also known pathogens. Treatment in the outpatient setting is frequently relegated to a urinalysis and empiric therapy without a urine culture. Patients are subsequently monitored for resolution of signs and symptoms.

Uncomplicated UTIs may be managed with a short-course antimicrobial therapy with one-dose, 3-day, or 5-day regimens depending on the clinical factors involved.

<th>Commonly Used Antimicrobial Agents for the Treatment of UTIs (Continued)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Agent</strong></td>
</tr>
</tbody>
</table>
| **Tetracyclines**  
Doxycycline  
Minocycline  
Tetracycline | These agents have been effective for initial episodes of UTI; however, resistance can develop rapidly. Avoid during pregnancy. |
| **Fluoroquinolones**  
Ciprofloxacin  
Levofoxacin  
Norfloxacin  
Ofloxacin | The newer quinolones have a greater spectrum of activity; rates of resistance are increasing. Concern for use as a first-line agent for uncomplicated UTI therapy exists due to potential selection of multidrug resistant organisms (collateral damage). These agents are often effective for pyelonephritis. Avoid in pregnancy and children. Moxifloxacin is not listed due to limited urinary excretion. |
| **Trimethoprim-sulfamethoxazole** | This combination is highly effective against most aerobic enteric bacteria except *P. aeruginosa*. High urinary tract tissue levels and urine levels are achieved, which may be important in complicated UTI treatment. Also effective as prophylaxis for recurrent infections. Generally well tolerated and low cost but increasing resistance rates above 20% in certain regions has limited empiric use. Its use may be precluded in patients with sulfa allergies. |
| **Nitrofurantoin** | This agent is effective in treatment and prophylaxis in patients with uncomplicated or recurrent lower tract UTIs. Should not be used in patients with low estimated CrCl (< 40–60 mL/min [0.67–1.00 mL/s]) due to limited urine concentrations and potential increased risk of neuropathy. |
| **Azithromycin**  
Fosfomycin | Commonly used for sexually transmitted diseases (ie, chlamydia infections) rather than for UTIs. Single-dose therapy for uncomplicated cystitis. Has been recommended for empiric therapy since resistance rates are low but may have inferior efficacy when compared with short courses of other oral antibiotic agents. |
| **Parenteral Therapy** | |
| **Aminoglycosides**  
Amikacin  
Gentamicin  
Tobramycin | Gentamicin and tobramycin are generally equally effective, whereas tobramycin has slightly better coverage of certain *Pseudomonas* spp. Amikacin generally is reserved for multidrug-resistant bacteria. Typically used as a short course of therapy followed by a switch to an oral agent. Concern for neurotoxicity and ototoxicity generally limit use, especially in patients with impaired renal function. |
| **Penicillins**  
Amoxicillin  
Amoxicillin-sulbactam  
Piperacillin  
Piperacillin-tazobactam  
Cephalosporins**First-, second-, third-, and fourth-generation** | These agents are generally effective for susceptible bacteria. The extended-spectrum penicillins are active against certain strains of *Pseudomonas* spp. They are very useful in renally impaired patients since urine concentration can remain adequate or when an aminoglycoside is avoided. Empiric use of ampicillin with an aminoglycoside is recommended only in patients with suspected infection due to *Enterococcus* spp. |
| **Carbapenems**  
Doripenem  
Ertaopenem  
Imipenem-clastatin  
Meropenem | These agents have broad-spectrum activity, including gram-positive, gram-negative, and anaerobic bacteria. Ertaopenem is not active against *Pseudomonas* spp. All may be associated with *Candida* spp. superinfections. Rarely used for UTIs. |
| **Fluoroquinolones**  
Ciprofloxacin  
Levofoxacin | These agents have broad-spectrum activity against both gram-negative and gram-positive bacteria. They provide high urine and tissue concentrations and are actively secreted in reduced renal function. Switch to oral therapy when possible due to excellent bioavailability. |
| **Monobactam**  
Aztreonam | Only active against gram-negative bacteria, including some strains of *P. aeruginosa*. Generally useful for nosocomial infections when aminoglycosides are to be avoided and in patients with type 1/immediate hypersensitivity to penicillins. |
| **Glycopeptide**  
Vancomycin | May be considered in combination for empiric therapy based on patient risk factors for multidrug-resistant organisms and gram-positive cocci shown in urinalysis. |

<sup>a</sup> Majority of listed antimicrobial agents require dosage adjustment in patients with significant renal dysfunction.

<sup>b</sup> DS, double strength (160 mg trimethoprim/800 mg sulfamethoxazole).

<sup>c</sup> Not approved for use by the US FDA as of November 2011.

<sup>d</sup> SS, single strength (80 mg trimethoprim/400 mg sulfamethoxazole).

<sup>e</sup> Doses listed for acute pyelonephritis are for oral regimens.

For acute uncomplicated UTIs, it is reasonable to pursue oral empiric therapy with one dose (3000 mg) of fosfomycin, a 3-day course of trimethoprim-sulfamethoxazole (one double-strength tablet twice daily), or a 5-day course of nitrofurantoin (100 mg twice daily) depending on the patient’s characteristics and risk factors. For treatment of multidrug resistant organisms, multiple doses of fosfomycin (given every other day) have been used. The antibiotic selection for empiric therapy partly depends on known resistance rates in the geographic region, particularly *E. coli* resistance to trimethoprim-sulfamethoxazole. Empiric therapy with trimethoprim-sulfamethoxazole should be considered only if the local resistance rates in *E. coli* is less than 20%, due to poor UTI treatment responses with trimethoprim-sulfamethoxazole when resistance rates are above this threshold. Although fluoroquinolone antibiotics and certain β-lactam agents can be highly active and efficacious against *E. coli*, these agents should be considered alternative agents in uncomplicated UTIs due to their broad-spectrum activity and risk of resistance development in bacteria unaffiliated with the infection.

**Complicated UTIs**

Complicated UTIs including acute pyelonephritis should be treated for at least 7 days and sometimes 2 weeks or longer.

**Acute Pyelonephritis**

Patients who present with pyelonephritis usually have high-grade fever (greater than 38.3°C [100.9°F]) and severe flank pain. Select patients with pyelonephritis may be treated in the outpatient setting; however, patients with infection-related vomiting, decreased food intake, and dehydration may need to be treated in the hospital. These patients will often receive IV antibiotics initially before being switched to oral therapy depending on susceptibility testing.

Patients with pyelonephritis are traditionally given 14 days of therapy. Shorter course fluoroquinolone therapy for 7 days has been successful in women with acute pyelonephritis, but further studies are needed for validation. Gram stain and culture are important in ensuring that appropriate antimicrobial coverage is selected. Women who present with mild cases of pyelonephritis...
In both of the above UTIs in Men and pregnant women, treatment options. Tetracyclines and fluoroquinolones should be considered due to their relatively narrow spectrum of activity directed against gram-negative organisms.

### Special Populations

#### Pregnant Women

Changes to the urinary tract in pregnant women predispose them to an increased incidence of bacteriuria and subsequent UTIs that may follow. These changes include alterations in amino acid and nutrient concentrations in the urine along with physiologic changes such as reduced bladder tone and dilation of the renal pelvis and ureters.

An association exists between maternal UTI during pregnancy and fetal death, labor complications, mental retardation, and developmental delay. Therefore, screening for UTI during pregnancy is necessary. In pregnant patients with significant bacteriuria, whether symptomatic or asymptomatic, treatment is recommended to avoid these complications. In the majority of patients, a sulfonamide (with the exception of use during the third trimester due to concerns for kernicterus), amoxicillin-clavulanic acid, cephalixin, or nitrofurantoin are effective treatment options. Tetracyclines and fluoroquinolones should be avoided due to risk of teratogenicity and ability to inhibit cartilage and bone development, respectively. Follow-up usually consists of a urine culture 1 to 2 weeks after completion of therapy and then subsequent monthly urine cultures until birth.

#### Catheterized Patients

An indwelling catheter is commonly used in various health care settings and is associated with UTIs. Bacteria may be introduced into the bladder via the catheter by colonization and direct introduction during catheterization. UTIs as a result of an indwelling catheter are common and occur at a rate of 3% to 8% per day of catheter presence.

The approach to management of a patient with bacteriuria and an indwelling urinary catheter follows two paths. The first, in asymptomatic patients with catheterization, is to hold antibiotics and remove the catheter if possible. The second, in symptomatic patients with catheterization, is to initiate antibiotic therapy and remove the catheter if possible. In both of the above situations, if discontinuation of the catheter is not possible, the patient should be recatheterized with a new urinary catheter if the previous catheter is greater than 2 weeks old.

#### UTIs in Men

Although UTIs in men are not always complicated by definition, due to the relative infrequency of UTIs in men compared

---

### Patient Encounter, Part 2 of Patient AC: Medical History, Physical Exam, and Diagnostic Tests

**PMH:** Obesity (body mass index 32); history of UTI with three episodes in last 6 months  
**FH:** Mother living with hypertension; father living with chronic obstructive pulmonary disease, hypertension, and dyslipidemia  
**SH:** Unmarried, sexually active with two partners in last 6 months, occupation: store clerk  
**Allergies:** None  
**Meds:** Norethindrone 0.5 mg/ethinyl estradiol daily  
**ROS:** (+) dysuria, urinary frequency; (-) fever, nausea, vomiting, flank pain  
**VS:** BP 125/77 mm Hg, P 70 beats/min, RR 16 breaths/min, T 37.0°C  
**CV:** RRR, normal S1, S2; normal findings  
**Abd:** Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly, heme (-) stool  

**Lab:** Within normal limits including blood glucose; (-) pregnancy test  
**Urinalysis:** Greater than 200 white blood cells/mm\(^3\) (200 × 10\(^9\)/L); urine nitrates positive; leukocyte esterase positive  
**Urine Gram Stain:** Gram-negative rods, more than 10\(^5\) CFU/mL (10\(^9\) CFU/L)

Given this additional information, what is your assessment of the patient’s condition?  
Identify your treatment goals for the patient.  
What nonpharmacologic and pharmacologic alternatives are available for the patient?  
What duration of antibiotic therapy is appropriate for this patient?

---

### Patient Encounter, Part 3: Creating a Care Plan for AC

Based on the information presented, create a care plan for this patient’s UTI. Your plan should include:  
(a) A statement of the drug-related needs and/or problems  
(b) A patient-specific detailed therapeutic plan  
(c) Monitoring parameters to assess efficacy and safety
**Table 79–4**

**Monitoring Parameters for Select Antibiotics Used in the Treatment of UTIs**

<table>
<thead>
<tr>
<th>Drug Class or Drug</th>
<th>What to Monitor</th>
<th>Frequency</th>
<th>Endpoint</th>
</tr>
</thead>
<tbody>
<tr>

<td>Decreases in glomerular filtrate rate can significantly decrease the urine concentration of these agents</td>
</tr>
</tbody>
</table>

*Streptomycin concentrations are different than those listed here; because streptomycin is not used to treat UTIs, monitoring for this agent is not included.

With women, an abnormality (structural or functional) should be suspected and therefore treated as a probable complicated infection until proven otherwise." For this reason, men should not be treated with a single dose or short course of therapy if diagnosed with a UTI. Typically, these patients will receive 2 weeks of therapy and in situations of failure may be treated up to 6 weeks, particularly if a prostatic source of infection is suspected.

**Outcome Evaluation**

- Monitor the patient for resolution of symptoms with the goal of 48 to 72 hours to resolution after start of antimicrobial therapy
- If possible, follow-up on susceptibilities of the infecting organism detected by the urine culture
- Repeat urine culture is necessary only if symptoms do not acutely abate or reinfection or recurrence occurs. Resistance rates to *E. coli* are increasing to antibiotics commonly prescribed for UTI, and certain isolates are multidrug resistant.
- Depending on the chosen antibiotic therapy, evaluate the patient based on drug therapy monitoring parameters including those presented in Table 79–4 to optimize therapy and decrease incidence of adverse events.

**Patient Care Process**

**Patient Assessment:**
- Based on physical exam, review of systems, and urinalysis, determine whether the patient is experiencing signs and symptoms of UTI.
- Assess patient medication history and risk factors for drug potential of an antibiotic resistant infection.
- Assess patient renal function and other laboratory tests for antibiotic dosing and systemic complications.
- Identify potential sources of infection such as urinary catheters.

**Therapy Evaluation:**
- Based on urinalysis and Gram stain (if available), determine whether the empiric antibiotic selection is appropriate.
- Based on culture and susceptibility data (if available), determine whether any changes should be made from your initial empiric antimicrobial selection (ie, resistance to the regimen initially selected).
- Evaluate the patient’s symptoms to determine response to the antimicrobial regimen you have chosen.
- Evaluate the patient for the presence of adverse drug reactions, drug allergies, and potential drug interactions.

**Care Plan Development:**
- Determine the optimal antibiotic dose and duration of therapy based on the patient and infection type (complicated vs uncomplicated).
- Determine whether the patient may benefit from prophylactic therapy (ie, recurrent UTIs secondary to chronic urinary catheterization due to paraplegia).
- Recommend lifestyle modifications as needed to minimize UTI recurrence.
- Discuss the importance of medication adherence throughout the entire recommended treatment duration.

**Follow-Up Evaluation:**
- Stress the importance of complying with the prescribed antimicrobial regimen and to follow up with the health care provider if signs and symptoms recur.
This Chapter

Abbreviations Introduced in

CFU  Colony-forming units
CrCl  Creatinine clearance
IV   Intravenous
SCr  Serum creatinine
UTI  Urinary tract infection

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Analyze the behavioral considerations and assess the importance of contraception with regard to the contributing factors of sexually transmitted infections (STIs).
2. Apply the "expedited partner treatment" method when recommending treatment for STIs.
3. Identify the patient populations that are typically affected by specific STIs.
4. Identify causative organisms for STIs.
5. Devise a list of the clinical signs and symptoms corresponding to each type of STI and classify patients based on recommended criteria.
6. Select appropriate diagnostic procedures for STIs.
7. Identify STI treatment regimens and recommend therapy when appropriate.
8. Design a patient care plan based on the monitoring parameters.

INTRODUCTION

Though we have made progress in medicine, age-old problems of infectious disease continue to plague us. Even with the discovery of newly improved antibiotics, sexually transmitted infections (STIs) have not been eradicated. Many have reemerged secondary to modern social trends of sexual activity, and some as a result of the HIV epidemic, socioeconomic concerns, and the global lack of preventive education. Optimal detection and treatment of sexually transmitted diseases depends on counseling by a patient-friendly and knowledgeable clinician who can establish open communication with the patient.

The correlation between risky sexual behavior and STIs is well documented. Inconsistent and incorrect condom use increases the incidence of new STIs. However, counseling patients on the consistent use of condoms, spermicides, or diaphragms is an important component in reducing the overall incidence of STIs. Health care providers who manage persons at risk for STIs should counsel women concerning the option for emergency contraception, if indicated, and provide it in a timely fashion if desired by the woman or the couple. Plan B (two 750 mcg levonorgestrol) is approved in the United States for the prevention of unintended pregnancy.

In addition to the increasing number of adolescents engaging in unsafe sexual practices is a high incidence of men who have sex with men (MSM) and women who have sex with women (WSW). Many MSM do not disclose their HIV status. This “don’t ask, don’t tell” practice has been linked to an upsurge in newly diagnosed HIV infections and STIs among previously noninfected people. Although limited data are available with regard to STIs in WSW, risk of transmission probably varies by the specific STI and sexual techniques. Sharing penetrative items or employing practices involving digital vaginal or digital anal contact most likely represent common modes of transmission. This possibility is supported by reports of metronidazole-resistant trichomoniasis and genotype-specific HIV transmitted sexually between women who reported such behaviors and an increased prevalence of bacterial vaginosis (BV) among monogamous WSW.

Sexual abuse in adolescents and children is becoming prevalent in the United States. Any child or adolescent with a STI should be evaluated for sexual abuse. In cases of abusive contact, commonly found infections include Neisseria gonorrhoeae or Chlamydia trachomatis. Abusive cases should be reported to Child Protective Services.

Defined as a person who engages in the exchanging of spouses for sexual activities, the emergence of “swingers” as a new category of at-risk patients has been seen in STI clinics throughout the world. In fact, in one Canadian clinic, swingers composed 40.8% of patients that rarely accessed STI health services. To this end, although little data exists, swingers now represent a group with risky behaviors that must be identified and treated, when necessary.

Optimally, both sex partners should be treated simultaneously for a STI; however, this is difficult to accomplish. Clinics and health departments often proactively attempt dual treatment by providing a prescription for the partner to the index patient (the patient who is evaluated by a clinician), a practice commonly known as patient-delivered partner therapy. Medications or prescriptions should be accompanied by treatment instructions and appropriate warnings. Counseling regarding the appropriate use of condoms, cervical diaphragms, spermicides, and emergency contraception is also important to mitigate the occurrence of reinfection.
Clinical Presentation of Gonorrhea

**General**
- Purulent discharge

**Signs**
- Painful or swollen testicles
- Tubal scarring

**Symptoms**

Men:
- May be asymptomatic, though acute urethritis is the predominant manifestation
- Urethral discharge and dysuria, usually without urinary frequency or urgency
- When compared with nongonococcal urethritis, the discharge in gonococcal urethritis is generally more profuse and purulent
- Pain during urination

Women:
- Cervicitis, urethritis, increased vaginal discharge, dysuria, and intermenstrual bleeding
- Pain during urination
- Abdominal pain

GONORRHEA

Gonorrhea is a curable STI caused by the gram-negative diplococcus *Neisseria gonorrhoeae*. Gonorrhea may be the second most commonly reported bacterial STI. Proper therapeutic management with antimicrobial agents is essential to eradicate this infection and prevent the development of associated sequelae such as a urethritis, cervicitis, or dysuria.

In the United States, the highest rate of gonococcal infection is seen within the 15- to 24-year-old age groups for both sexes; although more cases are reported in men. Approximately 700,000 new cases occur annually in the United States. Factors associated with an increased risk of infection include ethnicity, low socioeconomic status, illicit drug use, and age. Targeted screening of young women, less than 25 years of age, who are at an increased risk has been correlated to gonorrhea control in the United States. In fact, the risk of a cervical infection after a single episode of vaginal intercourse is approximately 50% and increases with multiple exposures. Furthermore, rates of reinfection are significantly higher among ethnic minorities.

PATHOPHYSIOLOGY

Attachment to mucosal epithelium, mediated in part by pili and opa (outer membrane opacity proteins), is followed by penetration of *N. gonorrhoeae* through epithelial cells to the submucosal tissue within 24 to 48 hours. A vigorous response by neutrophils begins with sloughing of the epithelium, development of submucosal microabscesses, and exudation of pus. Stained smears usually reveal large numbers of gonococci within a few neutrophils, whereas most cells contain no organisms.

DIAGNOSIS

Several laboratory tests are available to aid in the diagnosis of gonorrhea and include Gram-stained smears, endocervical or vaginal specimens, culture, or the DNA hybridization probe.

- A Gram stain of a male urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular gram-negative

**Patient Encounter 1, Part 1**

BJ is a 52-year-old man who visits a clinic complaining of profuse urethral discharge and swollen testicles for the past several days. The patient admits to having sexual intercourse with his wife and with another woman without barrier contraception (condoms). He also admits to having sexual intercourse with the other woman for more than 6 months.

*What information is suggestive of gonorrhea?*

*What potential risk factors for STIs are present?*

*What other diagnostic tests should be ordered?*

**Patient Encounter 1, Part 2**

PMH: Hypertension, diabetes, hyperlipidemia; no prior history of STIs; no drug allergies noted

Meds: Amlodipine 10 mg by mouth daily; furosemide 40 mg by mouth daily; metformin 500 mg by mouth three times daily; glipizide XL 5 mg by mouth daily; simvastatin 40 mg by mouth at bedtime

FH: Mother has diabetes and hypertension. Father is deceased

SH: Admits to having unprotected sex with wife and another woman. Does not smoke; drinks alcohol occasionally

ROS: C/o urethral discharge and swollen testicles

PE:
- VS: BP 145/88 mm Hg, post prandial glucose 132 mg/dL (7.3 mmol/L), total cholesterol 188 mg/dL (4.86 mmol/L), P 70 beats/min, T 37.0°C (98.6°F)
- Lab: Urethral discharge swab revealed *N. gonorrhoeae*; rapid plasma reagin (RPR) test was positive

*Given this additional information, what is your assessment of the patient’s condition?*

*What consideration should be given to other STIs?*

*Identify your treatment goals for this patient.*

*What pharmacologic alternatives are available for this patient?*
Doxycycline and fluoroquinolones are contraindicated. Recommendations During Pregnancy

Pregnant women should be treated with a recommended or

Though transmission of if it deters the acquisition of gonococcal infections in women. Antimicrobial management programs, expanding surveillance To mitigate the prevalence of cephalosporin resistance, strong

The recommended first-line treatment for gonorrhea in most countries is third generation cephalosporins, and in some cases, spectinomycin, doxycycline, and azithromycin. The mechanism of resistance appears to be associated with a mosaic penicillin-binding protein in addition to other chromosomal mutations previously found to confer resistance to β-lactam antimicrobials. To mitigate the prevalence of cephalosporin resistance, strong antimicrobial management programs, expanding surveillance networks and procedures, and STI control and prevention is warranted.

Oral hormonal contraception has been evaluated to determine if it deters the acquisition of gonococcal infections in women. Though transmission of N. gonorrhoea is poorly understood, one study suggested that oral hormonal contraception may lessen the probability of infection. More studies are required to support this theory as a viable option for prevention.

Treatment of gonorrhea may vary according to clinical presentation and is indicated as follows:

**Uncomplicated Gonococcal Infection of the Cervix, Urethra, and Rectum**: Ceftriaxone 250 mg intramuscularly or cefixime 400 mg orally plus azithromycin 1 g orally or doxycycline 100 mg orally twice daily for 7 days. Several alternative agents possess notable activity; however, they should not be used if pharyngeal infection is suspected. Alternatives include cefpodoxime 400 mg orally or cefuroxime axetil 1 g orally or azithromycin 2 g. Though unavailable in the United States, spectinomycin has also been prescribed.

**MSM or Heterosexuals with a History of Recent Travel** Ceftriaxone 250 mg intramuscularly or cefixime 400 mg orally plus treatment for chlamydial infection if it has not been ruled out.

**Uncomplicated Gonococcal Infection of the Pharynx, Cervix, Urethra, or Rectum** Ceftriaxone 250 mg intramuscularly plus azithromycin 1 g orally or doxycycline 100 mg orally twice daily for 7 days.

**Coverage for Coinfection with C. trachomatis** Azithromycin 1 g orally as a single dose or doxycycline 100 mg orally twice daily for 7 days. Since most gonococcal infections in the United States are susceptible to azithromycin and doxycycline, routine cotreatment might hinder the development of resistance.

**Treatment of Gonorrhea in Special Situations** Uncomplicated infections of the cervix, urethra, and rectum can be treated with one of the following regimens in adults:

- **Recommendations During Pregnancy**
  - Pregnant women should be treated with a recommended or alternative cephalosporin. For women who cannot tolerate a cephalosporin, azithromycin 2 g orally may be prescribed. For treatment of presumptive or diagnosed C. trachomatis, azithromycin or amoxicillin is recommended.
  - Doxycycline and fluoroquinolones are contraindicated.

**Recommendations for Disseminated Gonococcal Infection (Regimens Should Be Continued for 24 to 48 Hours)** Ceftriaxone 1 g intramuscularly or IV every 24 hours or cefotaxime 1 g IV every 8 hours or cefixime 1 g IV every 8 hours. Continue regimens for 24 to 48 hours after improvement is noted. Once improvement begins, therapy should be converted to Cefixime 400 mg orally twice daily for at least one week.

**Uncomplicated Infections of the Cervix, Urethra, and Rectum in Children Less Than 45 kg** Ceftriaxone 250 mg intramuscularly as a single dose or spectinomycin 40 mg/kg intramuscularly as a single dose (not to exceed 2 g).

**Gonococcal Conjunctivitis** Ceftriaxone 1 g intramuscularly once for adults has demonstrated excellent response rates. Lavage of the infected eye(s) once with saline solution should also be considered. Patients treated for gonococcal conjunctivitis should also be treated prophylactically for C. trachomatis infection.

---

*Regimens are given for one dose only.
**Ophthalmic Neonatorum or Prophylactic Treatment for Infants Whose Mothers Have Gonococcal Infection** Ceftriaxone 25 to 50 mg/kg IV or intramuscularly in a single dose, not to exceed 125 mg.

**Gonococcal Scalp Access in Newborns** Ceftriaxone 25 to 50 mg/kg/day IV or intramuscularly in a single daily dose for 7 days or cefotaxime 25 mg/kg IV or intramuscularly every 12 hours for 7 days may be used. If meningitis is noted, treatment duration of both medications should be extended for a total of 10 to 14 days.

**Ophthalmic Neonatorum Prophylaxis** Erythromycin (0.5%) ophthalmic ointment in a single application to the eyes or ceftriaxone 25 to 50 mg/kg IV or intramuscularly, not to exceed 125 mg in a single dose.

**Outcome Evaluation**
- Order diagnostic test for gonorrhea. If positive, recommend antibiotics that cover gonorrhea and chlamydia.
- Subsequent to treatment, expect the eradication of organisms responsible for gonorrhea and chlamydia.
- Monitoring is generally not required.

**Epidemiology**
Infection with *C. trachomatis* has increased dramatically in recent years. This bacterium is the most common cause of non-gonococcal urethritis, accounting for as many as 40% of cases. Worldwide, this intracellular, gram-negative bacterium produces around 92 million new genital infections. The prevalence is highest in individuals less than or equal to 25 years. Associated sequelae include pelvic inflammatory disease (PID), ectopic pregnancy, and infertility.

**PATHOPHYSIOLOGY**
*C. trachomatis* possesses characteristics resembling both bacteria and viruses. Its major membrane is comparable to that of gram-negative bacteria, although it lacks a peptidoglycan cell wall and requires cellular components from the host for replication. Chlamydia transmission risk is thought to be less than that of gonorrhea.

**CLINICAL PRESENTATION AND DIAGNOSIS**
- Common tests used to diagnose *C. trachomatis* include culture, enzyme immunoassay, DNA hybridization probe, or the direct fluorescent monoclonal antibody test. Diagnosis has been confirmed in women through urine or swab specimen collected from the endocervix and in men using a urethral swab or urine specimen. Most women are asymptomatic; therefore, an annual screening or physical is necessary, as early detection may reduce rates of transmission.

**TREATMENT**

**Uncomplicated Urethral, Endocervical, or Rectal Infection in Adults**
The recommended adult regimen is azithromycin 1 g orally in a single dose or doxycycline 100 mg orally twice daily for 7 days. An alternate regimen is erythromycin ethylsuccinate 800 mg orally four times daily for 7 days or erythromycin base 500 mg orally four times daily for 7 days or levofloxacin 500 mg orally once daily for 7 days or ofloxacin 300 mg orally twice daily for 7 days.

The recommended regimen for pregnant patients is azithromycin 1 g orally in a single dose or amoxicillin 1 g orally in a single dose or amoxicillin 500 mg orally three times daily for 7 days.

Alternate regimens include erythromycin base 500 mg orally four times daily for 7 days or 250 mg orally four times daily for 14 days or erythromycin ethylsuccinate 800 mg orally four times daily for 7 days or 400 mg orally four times daily for 14 days.

**C. trachomatis Infection in Infants**
Treatment of ophthalmia neonatorum or infant pneumonia should be with erythromycin base or ethylsuccinate 50 mg/kg/day orally divided into four doses daily for 14 days. An association between oral erythromycin and infantile hypertrophic pyloric stenosis (IHPS) has been reported in infants aged less than 6 weeks.

---

**Patient Care Process**

**Patient Assessment:**
- Review the patient’s medical history and determine whether the patient’s symptoms are consistent with gonorrhea.
- Order a culture to identify whether *N. gonorrhoea* is present.

**Therapy Evaluation:**
- Recommend therapy consistent with the treatment of gonorrhea and chlamydia.
- Ensure that the patient and partner receive adequate treatment for both organisms.

**Care Plan Development:**
- Counsel the patient on effective methods of contraception and on the possibility of side effects or of an allergy to the drug.

**Clinical Presentation of Chlamydia**

**General**
- Asymptomatic

**Signs**
- Beefy red cervix that bleeds easily (women)

**Symptoms**
- When present, the urethral discharge is watery and less purulent than that seen with acute gonococcal urethritis. Complications resulting from lack of treatment or inadequate treatment include: epididymitis (in males), and PID including associated complications in women.

**Other Diagnostic Tests**
- Culture is usually positive for both chlamydia and gonorrhea.
Review the patient’s medical history and determine whether the patient’s symptoms are consistent with chlamydia. Order a culture to identify whether C. trachomatis is present.

Therapy Evaluation:
- Recommend therapy consistent with the treatment of gonorrhea and chlamydia.
- Ensure that the patient and partner receive adequate treatment for both organisms.

Care Plan Development:
- Counsel the patient on effective methods of contraception and on the possibility of side effects or of an allergy to the drug.

who were treated with this drug. Infants treated with erythromycin should be monitored for signs and symptoms of IHPS.

► Infant Pneumonia Caused by C. Trachomatis
Erythromycin base or ethylsuccinate 50 mg/kg/day orally divided into four doses daily for 14 days.

Outcome Evaluation
- Order diagnostic test for chlamydia. If positive, recommend antibiotics that cover gonorrhea and chlamydia.
- Subsequent to treatment, expect the eradication of organisms responsible for gonorrhea and chlamydia.
- Monitoring is generally not required.

SYPHILIS
- Syphilis, attributed to the spirochete Treponema pallidum, can have numerous and complex manifestations. Clinician familiarity, stage-specific diagnosis, and effective treatment are vital. Missed or inappropriately treated syphilis may result in cardiovascular complications, neurologic disease, or congenital syphilis.

EPIDEMIOLOGY AND ETIOLOGY
Since the 1940s, the incidence of syphilis declined drastically following the introduction of penicillin, but rose when HIV arrived from obscurity in the 1980s. In 2009, rates of primary and secondary syphilis increased for the tenth consecutive year, reaching the highest rate reported since 1995. Although increases have occurred mostly among men, in 2013, the rate of reported primary and secondary syphilis in the United States was 5.3 cases per 100,000 population. Additionally, from 2005 to 2013, the number of primary and secondary cases nearly doubled. The primary and secondary syphilis rate among black men was 5.2 times that among white men; the rate among black women was 13.3 times that among white women, emphasizing the need for enhanced preventive measures among blacks and MSM. The disparity among men and women has been observed across racial and ethnic groups and is highest in the South and among non-Hispanic blacks.19

PATHOPHYSIOLOGY
T. pallidum rapidly penetrates intact mucous membranes or microscopic dermal abrasions, and within a few hours, enters the lymphatics and blood to produce systemic illness. During the secondary stage, examinations commonly demonstrate abnormal findings in the cerebrospinal fluid (CSF). As the infection progresses, the parenchyma of the brain and spinal cord may subsequently be damaged.

Diagnosis and Clinical Presentation
► Stages of Syphilis

Primary Syphilis Usually manifests as a solitary, painless chancre. Primary syphilis develops at the site of infection approximately 3 weeks after exposure to T. pallidum; the chancre is highly infectious.20

Secondary Syphilis Without appropriate treatment, primary syphilis will advance to secondary syphilis, a stage usually apparent from its clinical symptomatology. Symptoms include fatigue, diffuse rash, fever, lymphadenopathy, and genital or perineal condyloma latum. Additionally, the skin is most often affected and a rash may present as macular, macropapular, or pustular lesions or may involve skin surfaces including the palms of the hands and soles of the feet.

Latent Syphilis
- Early Latent Usually occurs during the first year after infection and may be established in patients who have seroconverted, who had symptoms of primary or secondary syphilis, or who had sex with a partner with primary, secondary, or latent syphilis.

Late Latent Patients should be considered to have late latent syphilis if the aforementioned criteria (early latent) are not met. In both stages, patients are usually asymptomatic and the lesions noted in the primary and secondary phase usually resolve; however, individuals are still seropositive for T. pallidum.

Tertiary Syphilis Develops years after the initial infection and may involve any organ in the body.

Congenital Syphilis
Congenital syphilis is a condition in which the fetus is infected with T. pallidum as a result of the hematogenous spread from an infected mother, although transmission may also occur from direct contact with the infectious genitalia of the mother. Since the primary stage of syphilis is characterized by spirochetemia, infectious rates of the fetus are nearly 100% if the mother has primary syphilis.20,21

Diagnostic procedures include dark-field microscopy, nontreponemal exams (ie, the Venereal Disease Laboratory [VDRL] and the rapid plasma reagin [RPR] test), and treponemal exams (ie, enzyme immunoassay, the T. pallidum hemagglutination test, the fluorescent treponemal antibody test, and the enzyme-linked immunosorbent assay).

TREATMENT
After confirming the diagnosis of syphilis, the desired outcome is a fourfold decrease in quantitative nontreponemal titers over a 6-month period and within 12 to 24 months after treatment of
Patient Encounter 2

RM is a HIV-positive male who complains of first observing the appearance of a “sore” on his penis. He admits to disregarding the lesion; however, he is now experiencing fatigue, diffuse rash, fever, and perineal condyloma latum. He reports having unprotected sexual intercourse with two male partners. He denies pain or itching at the original site of the lesion, dysuria, or frequent urination. Additionally, there appears to be no vesicles in the genital area.

What information is suggestive of syphilis?

What stage of syphilis is present?

What potential risk factors for STIs are present?

How should the diagnosis of syphilis be confirmed in this patient?

If the diagnosis of syphilis is confirmed, what therapeutic options exist for this patient?
CHAPTER 80  | SEXUALLY TRANSMITTED INFECTIONS

Positive syphilis screening exam

Perform treponemal-specific test

Positive treponemal-specific test

Establish stage of infection; obtain quantitative nontreponemal test titers

No clinical signs or symptoms (latent syphilis)

Early latent syphilis

Benzathine penicillin G, 2.4 million units IM (single dose)\(^a\)

Late latent syphilis

Benzathine penicillin G, 2.4 million units IM once weekly for 3 weeks (three doses)

Signs or symptoms of primary or secondary syphilis

Signs or symptoms of tertiary (late) syphilis, HIV-positive patient, or otherwise immunocompromised

Obtain quantitative nontreponemal test titers

Benzathine penicillin G, 2.4 million units IM (single dose)\(^a\)

Lumbar puncture

Signs, symptoms, or CSF findings consistent with neurosyphilis

Refer to appropriate subspecialist. Benzathine penicillin G, 2.4 million units IM once weekly for 3 weeks (three doses)\(^b\)

No clinical signs or symptoms (latent syphilis)

No penicillin allergy

Aqueous crystalline penicillin G, 3–4 million units IV every 4 hours for 10–14 days or procaine penicillin G, 2.4 million units IM daily, plus 500 mg of probenecid orally four times daily for 10–14 days

Penicillin allergy

Densensitization

Positive treponemal-specific test

Primary syphilis suspected

False positive test result suspected

Consider other causes

Obtain quantitative nontreponemal test titers

Negative treponemal-specific test

No penicillin allergy

Penicillin allergy

Densensitization

FIGURE 80–1. Treatment of syphilis. (CSF, cerebrospinal fluid; IM, intramuscularly.) (From Brown D, Frank J. Diagnosis and management of syphilis. Am Fam Physician. 2003;68(2):283–290.) \(^a\)Alternative treatments for nonpregnant penicillin-allergic patients: doxycycline 100 mg orally twice daily for 2 weeks, or tetracycline 500 mg four times daily for 2 weeks; limited data support ceftriaxone 1 g once daily IM or IV for 8 to 10 days; or azithromycin, 2 g orally (single dose). \(^b\)Alternative treatments for nonpregnant penicillin-allergic patients: doxycycline, 100 mg orally twice daily for 4 weeks, or tetracycline 500 mg orally four times daily for 4 weeks.
The regimens of choice are aqueous penicillin G 3 to 4 million units administered IV every 4 hours or continuous infusion for 10 to 14 days or procaine penicillin G 2.4 million units administered intramuscularly once daily, plus probenecid 500 mg orally four times daily, both for 10 to 14 days.

**Table 80–1**

CNS, central nervous system; IM, intramuscular.

The regimens of choice are aqueous penicillin G 3 to 4 million units administered IV every 4 hours or continuous infusion for 10 to 14 days or procaine penicillin G 2.4 million units administered intramuscularly once daily, plus probenecid 500 mg orally four times daily, both for 10 to 14 days.

**Congenital Syphilis**

The decision to treat an infant should be based on a diagnosis of syphilis in the mother and confirmation of adequacy of maternal treatment. Clinical, laboratory, or radiographic evidence of syphilis in the infant should be documented. Maternal nontreponemal titers (at delivery) should be compared with the infant’s nontreponemal titers. Since diagnosis based on neonatal serologic testing is complicated by the transplacental transfer of maternal IgG antibodies, which can cause a positive test in the absence of infection, neonatal titers are assessed. A titer greater than four times the maternal titer would not generally result from passive transfer and diagnosis is considered confirmed or highly probable.

The following regimens are recommended for treatment of maternal syphilis: benzathine penicillin G 2.4 million units or 7.2 million units intramuscularly over 3 weeks if the duration of syphilis has been at least a year. An alternative regimen is procaine penicillin 0.6 to 0.9 million units intramuscularly for 10 to 14 days, or ceftriaxone 1 g daily intramuscularly or IV for 8 to 10 days.

In women who experience uterine cramping, pelvic pain, or fever, administer acetaminophen to combat these symptoms. Additionally, the patient should be well hydrated and rested.

Treatment of asymptomatic neonates is with 50,000 units/kg of benzathine penicillin G in a single intramuscular dose. Symptomatic neonates should receive 50,000 units/kg of aqueous crystalline penicillin G every 12 hours intramuscularly for the first 7 days of life, then every 8 hours for 3 days or procaine penicillin G 50,000 IU/kg intramuscularly as a single dose daily for 10 days.

**Outcome Evaluation**

The CDC has provided patient care monitoring guidelines for syphilis (Figure 80–2). 9,11,20

**Primary and Secondary Syphilis**

- After 6, 12, and 24 months of treatment, reexamine the patient and recommend a follow-up quantitative nontreponemal titer. More frequent assessment might be sensible if follow-up is uncertain. If the patient is asymptomatic, yet has a fourfold increase in nontreponemal titer or persistent or recurrent symptoms are observed, order an HIV test and a lumbar puncture; if the patient is HIV-positive, suggest an infectious disease consult.

- In patients who are both negative for HIV and the lumbar puncture, administer benzathine penicillin G 2.4 million units intramuscularly once weekly for three additional weeks. Perform a patient follow-up in 6 months including a clinical examination and another nontreponemal titer. In HIV-negative patients with lumbar puncture findings compatible with neurosyphilis, treat the patient accordingly for neurosyphilis.

- Six months after the original diagnosis, institute a standard clinical follow-up exam in patients who show no symptomatology and a fourfold decrease in nontreponemal titers. By testing and observing the patient for signs of remission, you may be able to initiate proper treatment or recommend a consult in a timely fashion, thereby decreasing the propensity of the patient’s condition to advance to a higher stage.
• If serologic titers do not decline despite a negative CSF examination and a repeated course of therapy, it is unclear whether additional therapy or CSF examinations are needed; additional testing or repeated therapy is not generally recommended.

**Early and Late Latent Syphilis**

- Order nontreponemal titers 6, 12, and 24 months after instituting treatment for early or late latent syphilis. Neurosyphilis should be strongly considered in patients who show a fourfold increase in titers, patients who have an initially high titer (1:32 or greater) that fails to decline at least fourfold within 12 to 24 months of therapy, HIV-infected patients, and patients who develop signs or symptoms associated with neurosyphilis.

**Neurosyphilis**

- Follow-up is dependent on the CSF findings. If pleocytosis is present, reexamine the CSF every 6 months until the WBC count normalizes. Consider recommending a second course of treatment if the CSF white count does not decline after 6 months or completely normalize after 2 years. Failure to normalize may require retreatment; most treatment failures occur in immunocompromised patients.

**Congenital Syphilis**

- Observe the patient for changes in clinical features; hepatomegaly, jaundice, and bone changes will usually resolve in 3 months.
- Monitor elevated serologic markers (nontreponemal tests) for reduction in titer levels. Given effective treatment, clinical
Patient Assessment:  
- Review the patient’s medical history. Evaluate patient for HIV infection.  
- Order darkfield examinations to detect *T. pallidum* in lesion exudate or tissue.  
- If positive, a positive treponemal test is observed, order nontreponemal titers as they correlate closely with disease activity. Titers generally decline subsequent to treatment initiation.  
- If a negative treponemal test is observed, perform a different treponemal test to confirm initial results. If second treponemal test is positive, do not recommend further management unless a likelihood of reexposure is suspected.  
- Offer treatment to those without prior exposure to *T. pallidum*.  

Therapy Evaluation:  
- Recognize that treatment failure may occur with any regimen.  
- Evaluate response to treatment by reviewing the nontreponemal titers. Failed treatment or reexposure is consistent with persistent or recurrent signs and symptoms or a sustained fourfold increase in nontreponemal titers over a 6- to 12-month period.

If treatment failure is observed, analyze CSF for neurosyphilis and test patient for HIV infection. Additional serologic tests may be required.

Care Plan Development:  
- Test patient for possible HIV infection.  
- Test patient for an allergy to penicillin. If allergic, recommend desensitization.  
- Recommend treatment for the appropriate stage of syphilis.  
- Perform clinical and serologic evaluation at 6 and 12 months after treatment to assess for treatment success or failure.  
- Evaluate treatment success or failure and the necessity of retreatment based on serologic and clinical exams.

Follow-Up Evaluation:  
- Order quantitative nontreponemal and CSF tests to determine patient response to therapy. Adjust doses and treatment accordingly.  
- Evaluate patient for signs of advancement in stages of syphilis and treat appropriately.  
- When neurosyphilis is present, order CSF exams and leukocyte count to evaluate effectiveness of treatment.

Pharmacologic Therapy  
The 5-nitroimidazoles (metronidazole and tinidazole) have been the standard therapy for trichomoniasis for over 45 years. When using these agents advise patients to avoid the consumption of alcohol.

Clinical Presentation of Trichomoniasis

**General**  
- Asymptomatic

**Signs**  
- Strawberry cervix (women)  
- Colpitis macularis (women)  
- Prostatitis or epididymitis (men)

**Symptoms**  
- Vaginal/vulvar erythema  
- Excessive yellow-green discharge  
- Vulvar itching  
- Vaginal odor  
- Urethral discharge or irritation  
- Dysuria  
- Vaginal pH greater than 4.5

- **KEY CONCEPT**  
  The 5-nitroimidazoles (metronidazole and tinidazole) have been the standard therapy for trichomoniasis for over 45 years. When using these agents advise patients to avoid the consumption of alcohol.
Patients with HPV do not develop symptoms. Most people with HPV do not develop symptoms. At least half of sexually active persons will become infected at least once in their lifetime. In 90% of the cases, the body immune system clears HPV naturally within 2 years. Routine testing for HPV infection is not recommended. HPV types 16 and 18 cause 99.7% of all cervical cancer while HPV types 6 and 11 are responsible for about 90% of genital warts.

**PATHOPHYSIOLOGY**

HPV replicates in terminally differentiated squamous cells in the intermediate layers of the genital mucosa. Hence, these effects of the viral early region genes on DNA synthesis are critical for viral survival. Genital warts are the clinical manifestation of active viral replication and virion production at the infection site.

**Clinical Presentation and Diagnosis**

- **Pathology:** A definitive diagnosis of HPV is based on DNA or RNA or capsid protein detection.

- **Diagnosis:** Diagnosis is generally made from the clinical presentation and may be classified into several categories: classic condyloma acuminata, which are pointed or cauliflower; keratotic warts with a thick, horny surface resembling common skin warts; and flat warts, frequently observed on the surface.

- **Tissue biopsy or viral typing is only indicated if the diagnosis is uncertain and is not recommended for patients with routine or typical lesions.**

- **Since HPV is highly associated with cervical cancer and has more than 20 different cancer-associated HPV types, patients who are diagnosed with HPV should be tested for cervical cancer.**

**GENITAL WARTS**

Genital warts, caused by the human papillomavirus (HPV), usually appear in the genital area as very contagious, small bumps. Responsible for various visible, keratotic, and nonkeratotic manifestations, HPV has more than 120 noted strains, some of which have been linked to squamous cell carcinoma. More than 40 strains have been linked to the genital area.

**EPIDEMIOLOGY AND ETIOLOGY**

Genital warts are caused by several strains of HPV and are spread by skin-to-skin contact during sexual activity. Afflicting over 20 million Americans, HPV is the most common newly diagnosed STI in the United States, with prevalence just about 15.2%. Approximately 6.2 million new HPV infections occur every year in the United States. Condoms offer incomplete (grade B, level II [fair research-based evidence to support the recommendation]) protection against HPV.

The frequency of cervicovaginal HPV infection among sexually active women has been observed at 43%, with the greatest incidence noticed in men with three or more sex partners and women whose most recent regular sexual partner had two or more lifetime partners. Most people with HPV do not develop symptoms. At least half of sexually active persons will become infected at least once in their lifetime. In 90% of the cases, the body immune system clears HPV naturally within 2 years. Routine testing for HPV infection is not recommended. HPV types 16 and 18 cause 99.7% of all cervical cancer while HPV types 6 and 11 are responsible for about 90% of genital warts.

**Clinical Presentation of Genital Warts**

- **General:** Appear as rough, thick, cauliflower-like lesions

- **Signs:**
  - Black dots within warts
  - Disrupted surface

- **Symptoms:**
  - Anogenital pruritus
  - Burning
  - Vaginal discharge or bleeding
  - Although rare, dyspareunia may occur with vulvovaginal condyloma

---

**Metronidazole** Metronidazole may be administered orally as a single 2 g dose or 500 mg twice daily for 7 days. Pregnant women should be prescribed the single dose of metronidazole. Cure rates are greater than 90% when metronidazole is administered as either a single 2 g dose or a 7-day regimen. Possible adverse effects include an unpleasant metallic taste, reversible neutropenia, urticaria, rash, flushing, dry mouth, darkened urine, and a disulfiram-like reaction.

**Tinidazole** Tinidazole, a second-generation nitroimidazole with protozoal and anaerobic activity, as a single 2 g dose, has an efficacy equivalent to a 2 g dose of metronidazole. Tinidazole also has a longer half-life than metronidazole, 14 and 7 hours, respectively, and penetrates into male reproductive tissue better than metronidazole.

Tinidazole is effective for metronidazole-resistant trichomoni- asis. Possible side effects include an unpleasant metallic taste, dizziness, loss of coordination, seizures, severe diarrhea, darkened urine, nausea, vomiting, and a swollen or discolored tongue.

**Outcome Evaluation**

- Order diagnostic test for trichomoniasis. If positive, recommend antibiotics that cover *T. vaginalis.*

- Subsequent to treatment, expect the eradication of the protozoa.

- Monitoring is generally not required.
### Treatment

Approximately 40% to 60% of untreated warts will spontaneously resolve in 9 to 12 months if left untreated.\(^9\) Treatment of benign, symptomatic genital warts is aimed at alleviation of physical symptoms and cosmetic improvement. Removal of visible warts and reduction of infectivity are the goals of treatment.

A comparison of adverse effects related to treatment options may be found in Table 80–2.\(^{32}\)

> **Patient-Applied Treatment**

**Podofilox** Available as a 0.5% gel or solution containing purified extract of the most active compound of podophyllin, podofilox arrests the mitotic spindle, prevents cell division, and may also induce damage in blood vessels within the warts. The surface area treated must not exceed 10 cm\(^2\), and a maximum of 0.5 mL should be used on a daily basis.

Apply podofilox twice daily for 3 consecutive days without treatment. This cycle may be repeated until there are no visible warts or for a maximum of 4 weeks. Side effects are generally local and may include erythema, swelling, and erosions. Podofilox is not recommended for use in the vagina, anus, or during pregnancy.

**Imiquimod** Imiquimod is a cell-mediated immune-response modifier, available as a topical 5% cream in single-dose application packets. There are two recommended dosage regimens:

a. Apply at bedtime, three times a week for up to 16 weeks.

b. Apply every other day for three applications.

The treatment area should be washed with soap and water 6 to 10 hours after application. Mild to moderate erythema has been noted with imiquimod use; however, this generally suggests that the drug is reaching a therapeutic range and may be clearing the lesion.\(^{33,34}\)

**Sinecatechins** A green tea extract with an active product (catechins), is available as a 15% ointment. Apply a thin layer (0.5 cm) using a finger to each wart, three times a day until complete clearance of warts. Do not wash off after use and all sexual contact should be avoided while ointment is on the skin. This product should not be continued for longer than 16 weeks.\(^9\)

> **Physician-Applied Treatments**

**Podophyllin Resin** A 10% to 25% solution of podophyllin resin has been the standard in-office treatment for genital warts. Because podophyllin is neurotoxic and easily systemically absorbed, only a small amount (no more than 0.5 mL) should be applied, avoiding normal tissue. Application should be limited to less than 0.5 mL of podophyllin on an area of less than 10 cm\(^2\) of warts per session and no open lesions or wounds should exist in the area to which treatment is administered. The affected area will likely become erythematous and painful within 48 hours of application.\(^{34}\)

Topical podophyllin is applied once weekly and the area should be allowed to dry. Immediately following treatment, the dried drug should be removed using alcohol or soap and water. It is contraindicated in pregnant patients.

**Bichloroacetic (BCA) and Trichloroacetic (TCA) Acids** These products are available in 80% to 90% concentrations and are not systemically absorbed. The products are effective when used to treat a few, small, moist lesions. Apply once a week until wart is resolved. They may be applied to both keratinized epithelial and mucosal surfaces and may be used in pregnancy. A noted reaction to these medications is transient burning; contact with surrounding epithelium may prove to be painful, producing significant local erythema and swelling. To avoid these effects, place petroleum jelly around the external lesion, including unaffected skin, and carefully apply the agent with a small applicator. If an excess amount of acid is used, t alc or sodium bicarbonate (baking soda) may be administered to neutralize unreacted acid.

**Other Treatments** Other treatments may include fluorouracil/epinephrine/bovine collagen gel, an intralesional injection that has been proven effective in clinical trials for refractory patients or an intralesional injection of interferon.\(^{31}\)

> **Ablative Therapy**

Several ablative options have been employed in the treatment of genital warts and include cryotherapy, surgical removal, and vaporization.

> **Special Therapeutic Issues** \(^{32–35}\)

**Large Warts** Treat warts greater than 10 mm in diameter with surgical excision. Use imiquimod for three to four treatment cycles to reduce the number of warts and improve surgical outcomes. Fifty percent reduction in wart size after four treatment cycles warrants continued use of imiquimod until warts clear or eight cycles have been completed; less than 50% reduction warrants surgical excision or other ablative therapy.

**Subclinical Warts** Subclinical warts may be identified through colonoscopy, biopsy, acetic acid application, or laboratory serology. However, early treatment has not been linked to a favorable effect during the course of therapy in the index patient or the partner with regard to reduction of the transmission rate.

**Pregnancy** Agents contraindicated in pregnancy include podofilox, sinecatechins, fluorouracil, and podophyllin. Imiquimod is not approved for use in pregnancy, although it has been
Patient Care Process

Patient Assessment:
- Physical examination should be done.
- Order a pregnancy test.
- Review symptoms.
- Verify sexual history.
- Determine if lesions are a first episode or reoccurrence.
- Review all medical conditions and medications.

Therapy Evaluation:
- Discuss the treatment options with the patient including observation without active treatment.
- Determine the choice of therapy based on the size, site, and morphology of the lesion.
- Include patient preference, treatment cost, adverse effects, and convenience before making a decision.

Care Plan Development:
- Emphasize to the patient that sexually active people can lower the chance of getting HPV by limiting the number of partners.
- Order oral contraception for fertile women.
- Start patient treatment and continue for the recommended duration.
- Switch to an alternate therapy if there has been no response after two to three treatment cycles.

Follow-up Evaluation:
- Follow-up every 2 to 3 months for a reduction in lesions or disease remission.
- Monitor patient compliance, disease remission, and benign or cancerous tumors.

Outcomes Evaluation
- Monitor the patient for any visible warts and relief of symptoms.
- Apply powder with talc, baking soda, or liquid soap to remove unreacted trichloracetic or bichloroacetic acid.
- Dry area before contact with normal mucosa after application of podophyllin.
- Repeat TCA, BCA, podophyllin treatment weekly if necessary.
- Administer a different agent if warts persist after one type of therapy.
- Refer all recalcitrant patients to local STI clinic, gynecologists, dermatologists, or urologists.

Vaccinations
Several HPV genotypes have been linked to the development of cervical cancer. Gardasil, developed to protect against HPV genotypes 6, 11, 16, and 18, was the first vaccine employed to prevent cervical cancer, precancerous genital lesions, and genital warts due to HPV. Cervarix vaccine prevents cervical cancer and precancers caused by HPV types 16 and 18. The CDC recommends the HPV vaccine for all 11- and 12-year-old females and males. Vaccination is also recommended for females aged 13 through 26 years and males 13 to 21 years old who have not been previously vaccinated or who have not completed the full series of shots. The quadrivalent vaccine Gardasil is FDA-approved for females and males 9 to 26 years old.

Both inactivated vaccines are given in a series of three injections over a 6-month period. The second and third doses should be given at 2 and 6 months (respectively) after the first dose. HPV vaccine may be given at the same time as other vaccines. Vaccines are efficacious in preventing genital warts; however, they will not clear those that are already present.

Genital Herpes
Genital herpes (GH) is caused by herpes simplex virus (HSV) types 1 and 2. HSV is a chronic lifetime viral infection, for which there is no cure. Once latency is established, neither competent host immunity nor therapeutic agents can eradicate the virus. Currently, there is no vaccine available for HSV, and it seems that the development of one is unlikely in the near future.

Epidemiology and Etiology
Approximately 50 million Americans have GH. HSV-2 is the most common cause of recurrent genital herpes. Roughly 1 in 6 people in the United States (16.2%) aged 14–49 is infected with HSV-2. Prevalence of HSV-2 infection has grown by approximately slightly since the late 1970s (16.4%–17.2%), and currently over 500,000 new cases of HSV-2 occur annually.

Pathophysiology
Nearly all HSV-2 infections are sexually acquired. Since HSV is only found in humans, infection may only be transmitted from infectious secretions onto mucosal surfaces (ie, cervix or urethra) or direct contact with an active lesion (abraded skin). The virus may survive for a limited amount of time on environmental surfaces. Most sexual transmission occurs while the source case is asymptomatic. Most patients with asymptomatic or unrecognized genital HSV infections will still shed virus intermittently in the genital tract. Patients will have small, painful blisters that are filled with fluid. The first outbreak takes 2 to 4 weeks to heal, with later attacks being less severe. Because there is no cure for this illness, treatment will only help reduce the signs, symptoms, and number of attacks.

Clinical Presentation and Diagnosis
Ulcerative or multiple vesicular lesions are absent in many infected persons. Laboratory confirmation is vital to effective treatment of HSV, especially in individuals in whom a clinical diagnosis cannot be obtained. There are several methods by which a definitive diagnosis may be acquired, and these include virologic typing, serologic diagnosis, rapid point-of-care antigen detection, enzyme-linked immunosorbent assay (ELISA), immunoblot, and DNA polymerase chain reaction. Glycoprotein G-based assays may also be used to aid in the diagnosis of HSV.

Treatment
The desired outcome is to curtail the number of episodic proddromes and to minimize any side effects experienced due to the
Clinical Presentation of Genital Herpes

**General**
- Asymptomatic

**Classic Sign**
- A cluster of painful vesicles on an erythematous base

**Symptoms**
- Itching
- Burning
- Tingling
- Groin lump
- Dysuria
- Dyspareunia
- Increased urinary frequency

**Other Symptoms**
- Ulcerative lesions, fissures, cervicitis

antivirals. Counseling of infected persons and their partners is vital to the management of HSV.

**First Episode**

The first episode is a systemic illness associated with the vesicular lesions, may last up to 21 days, usually has an uncomplicated course of infection, and in severe cases may require hospitalization. Several agents are effective during this period (Table 80–3). At the cited dosages, these agents have had excellent outcomes with regard to lesion healing time, viral shedding, and loss of pain. Common adverse effects are nausea, headache, and diarrhea. It is important to note that the first episode does not necessarily indicate recent infection and the genital symptoms may develop several years after the infection was acquired. Condom use in new or uninfected partners particularly in the 12 months after the first attack is recommended.

**Episodic Therapy**

In a patient with a previous diagnosis of genital herpes, the appearance of new vesicular lesions is synonymous with HSV reactivation. For most patients, genital herpes recurrence is self-limiting and short-lived, lasting approximately 6 to 7 days.

**Suppressive Therapy**

Suppressive therapy is effective for controlling all symptoms related to the disease and may impact troublesome complications of infection. Before beginning suppressive therapy, discuss patient expectations. Encourage patients to record any breakthrough episodes, as this may require treatment reevaluation and adjustment.

**Preventive Therapy**

Valacyclovir 500 mg orally once daily has been used to prevent the sexual transmission of HSV to an uninfected partner. In addition to pharmacologic therapy, counsel patients regarding safe sex practices.

**Drug Resistance**

All acyclovir resistant strains are resistant to valacyclovir and the majority are resistant to famciclovir. Foscarnet, cidofovir, and trifuridine have been administered in acyclovir-resistant patients. These agents are usually reserved for use after other medications have failed because of their associated toxicities.

**Pregnancy**

- Women who are pregnant may transmit the virus to the neonate during delivery. There are two management strategies: caesarean section and antiviral therapy. Acyclovir 200 to 400 mg every 8 hours has been administered from 38 weeks’ gestation until delivery. Acyclovir, famciclovir, and valacyclovir are all classified as category B (no evidence of risk in humans) for use during pregnancy. Suppressive treatment includes the use of acyclovir or valacyclovir from week 36 until delivery. The goal of therapy is to reduce the number of lesions and asymptomatic shedding at delivery.

**Neonates**

The risk for transmission from an infected mother to a neonate is high among women who acquired GH near time of delivery. HSV infections should be considered in all neonates who present with nonspecific symptoms such as fever, poor feeding, lethargy, or seizures in the first month of life. Infants suspected to have or who are diagnosed with an HSV infection should be treated parenterally. Acyclovir 20 mg/kg/day in three divided doses IV for 21 days for disseminated and CNS disease or 14 days for disease limited to skin, eyes, and mucous membranes.

**Outcome Evaluation**

- Monitor for systemic symptom improvement and a decrease in viral shedding in initial HSV treatment.
- Take lukewarm baths three to four times a day to ease itching and pain. Pat dry infected areas.
- Wear loose-fitting underwear to help the sore dry.
- Avoid sexual contact until treatment is finished.
- Consider stopping suppressive therapy after 1 year to assess recurrence rate.
- Compound topical 1% cidofovir gel in acyclovir-resistant strains where IV foscarnet is not preferred.

**PELVIC INFLAMMATORY DISEASE**

Pelvic inflammatory disease (PID) usually affects young, sexually active, reproductive-age women. PID includes a spectrum of inflammatory disorders of the upper female genital tract. In the majority of cases, the pathogens responsible are C. trachomatis and N. gonorrhoeae; although anaerobes, enteric gram-negative rods, and cytomegalovirus have also been implicated in the pathogenesis. PID has been correlated with ectopic pregnancy, infertility, tubo-ovarian abscess, and chronic pelvic pain.

**Epidemiology and Etiology**

PID is most common in women younger than 25 years of age, who have more than one sex partner. More than 750,000 women are affected by PID each year in the United States. The highest rates of PID occur in teenagers and first time mothers. Up to 10% to 15% of these women may become infertile as a result of PID. The CDC estimates that more than 1 million women experience...
Patient Encounter 3

LS is a 27-year-old female model who decides to visit her gynecologist because of a 1-month history of vaginal burning, vaginal bleeding, and rough thick lesions around her perianal area. Currently, LS is not in a monogamous relationship. Upon questioning, LS stated she was treated twice before for STIs in the past decade. Her last sexual encounter was 2 weeks ago and stated they did not utilize protection.

What information is suggestive of genital herpes?
What potential risk factors for STIs are present?
What additional information is required to initiate a treatment plan? What is your opinion about the use of the Gardasil vaccine in this patient?

Patient Encounter 4

BC is the father of patient 1 (LS) only child. BC is a 33-year-old former NBA player that was forced to retire 4 years ago due to a long history of substance abuse. BC has three other children from two different women. BC became mentally and emotionally stress after hearing of LS’s diagnosis. BC has experienced symptoms of painful urination, enlarged lymph nodes, and small blisters in his genital area 3 days ago. BC was initially informed of his HSV-2 status during his rookie year in the NBA.

Given this information, what is your assessment of the patient?
Identify the treatment goals for this patient?
BC subsequently states that acyclovir did not work during his last episode. What are his options?
Based on physical exam, ask a series of questions: Do you have sores in the genital area or anywhere else on your body? Do the sores come and go? Do you have frequent urination or burning/stinging with urination? If discharge is present, does it smell or have color? Do you use condoms or birth control? Have you or your partner ever been treated for a STI in the past? Is this your first outbreak?

Review all medical conditions and medications including dosing.

Review available laboratory test if available of definitive diagnosis.

Therapy Evaluation:

Base treatment on likelihood of patient compliance, whether it is first or a recurrent episode, host immunity, and pregnancy.

Remind patient that response has been linked to the time it takes to initiate treatment with acyclovir, or its analogues, after symptom onset.

Care Plan Development:

Immediately initiate therapy (within one day of onset) in episodic treatment of systematic recurrent lesions for patient to experience benefit from agent.

Emphasize that sexually active people can lower their chances of spreading HSV by using condoms.

Evaluate and educate all sex partners of infected persons.

Follow-up Evaluation:

Reevaluate the patient’s psychosocial and psychosexual status.

Order tests to detect malignant changes of the female genital tract.

Order yearly testing for HIV status.

Review side effects of drugs with the patient.

Frequently reassess all recurrent episodes and therapy adjustments.

OUTCOME EVALUATION

- Reevaluate any patient who does not respond significantly within 72 hours of parenteral/oral treatment.
- Initiate parenteral therapy (inpatient or outpatient) for patients that do not respond to oral treatment.
- Continue parenteral therapy for 14 days; however, it may be stopped 24 hours after clinical improvement and doxycycline continued to complete 14 days of therapy.
- Hospitalization and reassessment of the antimicrobial regimen and diagnostics are recommended in women without clinical improvement.
- Repeat testing of all women who have been diagnosed with chlamydia or gonorrhea is recommended 3 to 6 months after treatment, regardless of whether their sex partners were treated.
- Inform the patient that an alteration in sexual behavior should be the first concern, as promiscuous sexual activity augments the probability of infection.

PATHOPHYSIOLOGY

PID is an infection that occurs when bacteria move upward from a woman’s vagina into her reproductive organs. Normally, the cervix prevents bacteria from entering the vagina and spreading to the reproductive organs. However, when the cervix is exposed to STI’s such as chlamydia and gonorrhea, the bacteria is disseminated to the female internal organs. Chlamydia may produce a heat-shock protein that causes tissue damage through a delayed hypersensitivity reaction. *C. trachomatis* may also possess DNA evidence of toxin-like genes that code for high-molecular-weight proteins with structures similar to *Clostridium difficile* cytotoxins, enabling inhibition of immune activation. This may explain the observation of a chronic *C. trachomatis* infection in subclinical PID.

Clinical Presentation and Diagnosis

Because many women with PID have subtle or mild symptoms, delays in diagnosis and treatment probably led to inflammatory sequelae in the upper reproductive tract. To be diagnosed with PID, patients must have uterine tenderness, cervical motion tenderness, painful urination, lower abdominal pain, painful intercourse, and adnexal tenderness with no other cause of these signs. Additional criteria include:

- Oral temperature greater than 38.3°C (101°F)
- Abnormal cervical or vaginal discharge or that has an unusual color (green or yellow)
- WBC presence on saline microscopy of vaginal secretions
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein
- Laboratory documentation of cervical infection with *N. gonorrhoeae or C. trachomatis*

Treatment

The removal of causative bacteria and reduction of any related sequelae are the desired goals of treatment. Resolution of infection (ie, *N. gonorrhoeae, C. trachomatis, Streptococcus* spp., and gram-negative facultative bacteria) and mitigation of sequelae should be the main goal of pharmacologic therapy. Treatment regimens for PID must provide empiric, broad-spectrum coverage of likely pathogens. CDC-approved treatment regimens are shown in Table 80–4.

Though outpatient management remains contentious, many feel that outpatient management should be limited to individuals who: remain afebrile, have a WBC counts less than $11 \times 10^9$/mm$^3$ (11 $\times$ 10$^9$/L), have minimal evidence of peritonitis, have active bowel sounds, and can tolerate oral nourishment. Nonetheless, outpatient therapy with a parenteral cephalosporin followed by doxycycline and metronidazole is recommended.

### Clinical Presentation of Pelvic Inflammatory Disease

**General**
- Signs and symptoms may vary from mild to severe

**Signs**
- Vague

**Symptoms**
- Lower abdominal or pelvic pain
- Malodorous vaginal discharge
- Abnormal uterine bleeding
- Dyspareunia
- Dysuria
- Nausea and/or vomiting
- Fever

Abstinence is the best course of action, especially in patients with herpes during lesional episodes. However, compliance in some may be minimal, in which case, appropriate condom use should always be recommended. To alleviate any possible misconceptions about condom application, either demonstrate how to apply a condom or ask the patient to demonstrate. During

### Patient Care Process

**Patient Assessment:**
- Based on a physical exam that includes a pelvic exam, determine if the patient is experiencing pain in the lower belly or back, vagina discharge with or without color, painful sex, fever, or burning during urination.
- Test for pregnancy, complete blood count, gonorrhea, chlamydia, and bacterial vaginosis.

**Therapy Evaluation:**
- Optimal management of PID should be individualized based on clinical setting and patient characteristics.
- For some patients, hospitalizations, IV antibiotics, and surgical treatment of complications may be needed.

**Care Plan Development:**
- If no clinical improvement has occurred within 3 days after parenteral or outpatient oral therapy, perform further assessment.
- Educate the patient about the goals of monitoring patients with PID are related to reducing long-term complications.
- Examine the male sex partners of women with PID if the patient’s onset of symptoms occurred within the previous 60 days. Remind women that numerous sex partners increase the risk of developing PID.

**Follow-up Evaluation:**
- Advise a combination of prevention efforts.
- The primary approach should be prevention and education of at-risk women.
- Secondary prevention includes screening by conducting a pelvic exam during a routine check-up.
- Verify substantial clinical improvement within 72 hours after initiation of therapy.

### Patient Encounter 5

**PMH:** History of chlamydia 2 years ago. Allergy to clindamycin

**FH:** Noncontributory

**SH:** 18-year-old college freshman and current girlfriend of BC. Admits that she has a secretive sexual relationship with the starting football quarterback

**ROS:** Unpleasant vaginal odor, painful sex, and pain in her lower abdomen

**PE:**
- **VS:** BP 135/85, Ht 5’4” (163 cm), Wt 117 lb (53.2 kg) T 97.8°F (36.6°C)
  - In the past, the patient utilized condoms frequently; but states they cause her to have yeast infections and has since discontinued their use.

**What consideration should be given to other STIs?**

**What oral treatment options are available for this patient?**

**What non-pharmacologic therapy should be recommended for this patient?**

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List common risk factors for osteomyelitis.
2. Discuss the pathophysiology of osteomyelitis.
3. Compare and contrast the classic signs and symptoms of acute and chronic osteomyelitis.
4. Evaluate microbiology culture data and other laboratory tests and imaging studies utilized for diagnosis of osteomyelitis.
5. List the most common pathogens isolated in acute and chronic osteomyelitis.
6. Develop a treatment plan for osteomyelitis.
7. Recommend parameters to monitor antimicrobial therapy for effectiveness and toxicity.
8. Educate patients regarding disease state and drug therapy.

INTRODUCTION

Osteomyelitis is an infection of the bone that can be an acute or chronic process. The inflammatory response associated with acute osteomyelitis can lead to bone necrosis and subsequently chronic infections. Bacterial pathogens, particularly Staphylococcus aureus, are the most common microorganisms implicated in these infections. Diagnosis and treatment are often difficult due to the heterogeneous nature of osteomyelitis. Medical management is the mainstay of treatment for acute infections; however, surgical intervention is necessary for chronic infections that involve bone necrosis. Outcomes may vary based on patient-specific risk factors, duration of disease, and site of infection.

Osteomyelitis is most often classified by duration of disease and route of infection. Historically, osteomyelitis has been classified as acute or chronic based on duration of disease. However, there are no established definitions for acute and chronic infections. Acute infection has been defined as first episode or recent onset of symptoms (within 2 weeks). Chronic osteomyelitis is generally defined as relapse of the disease or symptoms persisting beyond 2 months. Because there is no abrupt demarcation, but rather a gradual shift from acute to chronic infection, others describe chronic osteomyelitis as the presence of necrotic bone.

In the Waldvogel classification scheme, the route of infection is categorized as either hematogenous or contiguous. Osteomyelitis secondary to a contiguous focus is further subdivided into infections with or without vascular insufficiency. Typical bone involvement in osteomyelitis depends on the route of infection.

- Hematogenous: long bones (femur, tibia) in children and vertebra in the elderly
- Contiguous with vascular insufficiency: lower extremities
- Contiguous without vascular insufficiency: bones affected by trauma, surgery, or adjacent to soft-tissue infection

A single pathogen is most often isolated in hematogenous osteomyelitis, whereas multiple organisms are often isolated in contiguous osteomyelitis.

EPIDEMIOLOGY AND ETIOLOGY

Hematogenous osteomyelitis is the most common type of osteomyelitis in children while osteomyelitis due to contiguous spread is most common in adults. Hematogenous osteomyelitis is reported in older adults and IV drug users, with the spine (vertebral osteomyelitis) being the most common site of infection. S. aureus is the predominant pathogen seen in all types of osteomyelitis, with methicillin-resistant S. aureus (MRSA) being increasingly reported. However, the spectrum of potential causative pathogens varies with patient-specific risk factors including the following:

- Patients with uncontrolled diabetes and/or peripheral vascular disease have poor wound healing and often present with nonhealing skin ulcers. These wounds are typically colonized with a mixture of aerobic and anaerobic microorganisms, which can lead to polymicrobial osteomyelitis. Common aerobic pathogens in this setting may include MRSA, Enterobacteriaceae, and Pseudomonas aeruginosa. Therefore, if a wound is deep or extensive, these patients should be evaluated for underlying osteomyelitis.
- Sickle cell patients (Salmonella spp)
• Individuals with prosthetic implants (coagulase-negative staphylococci)
• Neonates (E. coli or group B streptococci)
• Patients with pressure sores (polymicrobial)

PATHOPHYSIOLOGY
Both microbial and host factors are important determinants in the development of osteomyelitis. Healthy bone tissue is normally resistant to infection but may become susceptible under certain conditions. Bone can become infected: (a) via the presence of bacteria in the bloodstream, (b) by direct inoculation from trauma or surgery, and (c) by spread from an adjacent site (eg, soft-tissue infection). The latter is particularly problematic in patients with foreign body implants (eg, hip replacement) and chronic skin ulcers.

Staphylococcus species possess bacterial adhesins, which promote their attachment to tissues and foreign devices. Microbial adherence to bone elicits an inflammatory response. The subsequent release of leukocytes and cytokines leads to edema and ischemia. In some cases, these processes can lead to bone necrosis. Pieces of dead bone may become separated, forming sequestra. These areas typically cannot be penetrated by antimicrobials and phagocytic cells and thus require surgical intervention to eradicate the bacterial nidus.

CLINICAL PRESENTATION AND DIAGNOSIS
General
The clinical presentations of osteomyelitis may vary depending on route and duration of infection, as well as patient-specific factors such as infection site, age, and comorbidities. The gold standard for diagnosis of osteomyelitis is a bone biopsy with isolation of microorganism(s) from culture and the presence of inflammatory cells and osteonecrosis on histologic exam. Due to the invasive nature of the bone biopsy, the diagnosis of osteomyelitis is often based on clinical findings, laboratory tests, and imaging studies rather than bone biopsy.

Typical signs and symptoms of osteomyelitis include local pain and tenderness over the affected bone, as well as inflammation, erythema, edema, and decreased range of motion. Patients with acute hematogenous osteomyelitis may also present with fever, chills, and malaise. A cardinal sign of chronic osteomyelitis is the formation of sinus tracts (a channel from the infected site to the skin) with purulent drainage.

Laboratory Tests
No single noninvasive laboratory test is currently available for the diagnosis of osteomyelitis. Despite low specificity, several tests are commonly used to aid in the diagnosis and to monitor response to therapy.

Nonspecific inflammatory markers for infection include:
- White blood cell count (WBC)
- Erythrocyte sedimentation rate (ESR)
- C-reactive protein (CRP)
- Procalcitonin

WBC, ESR, and CRP are often elevated, but may also be within normal limits. An elevated WBC is mostly seen in patients with acute osteomyelitis. CRP rises faster than ESR during early stages of infection and also returns to normal levels more quickly than ESR. This makes CRP a more useful tool for both diagnosis and monitoring of therapeutic response. Similar to CRP, procalcitonin may be useful for both diagnosis and monitoring of therapeutic response; however, it is often more expensive and may not be as readily available.

Microbiologic Evaluation
Isolation of causative pathogen from bone biopsy samples is essential for targeted antimicrobial therapy. Bone biopsy is not done, quality specimens (eg, two consecutive samples with bone contact [deep samples] in patients with contiguous osteomyelitis or blood cultures in patients with acute hematogenous osteomyelitis) may assist in pathogen identification. Superficial swabs often represent colonization rather than infecting organism(s).

Imaging Studies
- Imaging tests are used to assist in the diagnosis of osteomyelitis.
- Plain film radiographs (x-rays) are the initial imaging study.
- Imaging studies are useful in the identification of sequestra, and it is less expensive than MRI when they are readily repeatable.
- Magnetic resonance imaging (MRI) is considered the best overall imaging modality for the diagnosis of osteomyelitis. Advantages include early detection (ie, 3–5 days after onset of infection), no radiation exposure, and high resolution. Disadvantages include expense, inconvenience to patients (long examination time), and the limitations to scanning patients with pacemakers and other implantable metal devices.
- Computed tomography (CT) scans have high resolution and reproducibility. CT scans have reduced sensitivity compared to MRI and should not be routinely used to diagnose osteomyelitis. Advantages are that it is useful for the identification of sequestra, and it is less expensive than MRI. Disadvantages are the exposure of the patient to radiation and inability to use contrast medium to enhance images in patients with impaired renal function or previous allergic reactions.
- Radionuclide imaging is also used for the early diagnosis of bone infections. The most widely used nuclear medicine test is the three-phase bone scan. An advantage is early detection within 24 to 48 hours after onset of symptoms. Disadvantages include low specificity (increased risk of false positives) in patients with recent trauma, surgery, orthopedic prosthesis, diabetes, and ischemia, and high radiation dose required. Using a labeled WBC scan in combination with the three-phase bone scan can increase sensitivity and specificity.

TREATMENT
The treatment goals for osteomyelitis are to eradicate the infection and prevent recurrence. In comparison to acute hematogenous osteomyelitis, chronic osteomyelitis is associated with higher failure rates, largely due to the presence of necrotic bone. These patients typically require surgical intervention to remove the necrotic bone and tissue, and if applicable,
Patient Encounter, Part 1

A 42-year-old man limps into the emergency department complaining of pain and swelling in his left lower leg. He states that he also has a fever and feels tired. After questioning him, you discover that he was recently discharged from the hospital following surgery for an open fracture of his left tibia. He had undergone debridement and irrigation, followed by internal fixation and treatment with IV cefazolin. He was discharged home on oral cephalexin. On physical examination, the area above the fracture is red and swollen (erythematous and inflamed).

What information is suggestive of osteomyelitis?
What risk factors, if any, does he have for osteomyelitis?

replace infected hardware. Comorbidities such as vascular insufficiency can further contribute to the poor outcomes seen with chronic osteomyelitis. Due to the high failure rates, treatment in this patient population may require prolonged therapy, with the primary goal of preventing amputation of infected areas.

General Approach to Treatment

Antimicrobial therapy alone is the mainstay of treatment for acute osteomyelitis. In comparison, treatment for chronic osteomyelitis typically requires a combination of antimicrobial therapy and surgical intervention. If the patient is not a candidate for surgical intervention, prolonged antimicrobial therapy is generally necessary.

Nonpharmacologic Therapy

In addition to medical and surgical management, nonpharmacologic interventions for health promotion such as smoking cessation, weight-control and good nutrition should be communicated to the patient. Additionally, a diabetic patient should be counseled regarding the necessity of controlled blood glucose, routine care and self-examination of lower extremities, and aggressive wound care. Patients with chronic immobility should be counseled on skin care and techniques to prevent the development of pressure ulcers.

Pharmacologic Therapy

Empiric antimicrobial therapy should target likely causative pathogen(s) based on patient-specific risk factors and route of infection. Empiric antimicrobial coverage against S. aureus should be considered for all classifications of osteomyelitis. With MRSA increasingly being reported in the hospital and community settings, the use of anti-MRSA antimicrobials (eg, vancomycin) should be considered as first-line therapy for empiric coverage of suspected staphylococcal osteomyelitis. In addition to anti-MRSA coverage, patients with contiguous osteomyelitis with vascular insufficiency (eg, diabetic) should also receive empiric antimicrobial therapy to cover Enterobacteriaceae, P. aeruginosa, and anaerobes. Specific recommendations may vary based on factors such as patient allergies, potential for harboring a resistant organism, institution formulary, and cost considerations.

Antimicrobial therapy should be modified based on culture and sensitivity data of appropriately collected specimens. If MRSA is isolated, vancomycin is considered first-line therapy unless the minimum inhibitory concentration is greater than 2 mcg/mL. Other anti-MRSA agents (tigecycline, telavancin, ceftaroline, dalbavancin, tedizolid, oritavancin) lack clinical data to support their routine use in osteomyelitis. Clindamycin is commonly used in pediatric patients. Microbiology laboratories must screen with a disk diffusion test (D-test) for inducible resistance via the macrolide-lincosamide-streptogramin gene, as clindamycin failures have been associated with infections caused by isolates that are D-test positive. Clindamycin commonly used as oral therapy for osteomyelitis include fluoroquinolones, clindamycin, linezolid, and trimethoprim-sulfamethoxazole in combination with oral rifampin. Other anti-MRSA agents (tigecycline, telavancin, ceftaroline, dalbavancin, tedizolid, oritavancin) lack clinical data to support their routine use in osteomyelitis. Clindamycin is commonly used in pediatric patients. Microbiology laboratories must screen with a disk diffusion test (D-test) for inducible resistance via the macrolide-lincosamide-streptogramin gene, as clindamycin failures have been associated with infections caused by isolates that are D-test positive. Clindamycin commonly used as oral therapy for osteomyelitis include fluoroquinolones, clindamycin, linezolid, and trimethoprim-sulfamethoxazole in combination with oral rifampin. Additionally, oral rifampin may be used in combination with another antibiotic in patients with foreign devices or MRSA osteomyelitis. For chronic osteomyelitis, some clinicians recommend placement of antibiotic impregnated beads or cement. This enables antibiotics such as aminoglycosides and vancomycin to be delivered in high concentrations at the site of infection.

The duration of treatment is typically 4 to 6 weeks for acute and chronic osteomyelitis. Shorter regimens (weeks) are often recommended for uncomplicated acute hematogenous infections due to S. aureus in children greater than 3 months of age. Infectious Diseases Society of America (IDSA) MRSA guidelines recommend a minimum of 8 weeks for treatment of MRSA osteomyelitis in adults. Prolonged therapy (greater than 3 months) may be necessary for certain populations such as patients with vascular insufficiency or patients with recalcitrant infections that do not respond to 4 to 6 weeks of therapy.

OUTCOME EVALUATION

Therapeutic success is measured by the extent to which the care plan (a) resolves signs and symptoms, (b) eradicates the microorganism(s), (c) prevents relapses, and (d) prevents complications such as amputation. Patients should be evaluated for resolution of clinical signs and symptoms and normalization of laboratory tests (WBC, CRP, ESR, procalcitonin, and cultures). Improvement in clinical manifestations may be

seen within 2 to 4 days of initiation of IV antimicrobial therapy in patients acute osteomyelitis. A reduction in CRP should be seen within 1 week of therapy and should be monitored weekly throughout therapy for a continued downward trend. ESR can also be monitored weekly, although normalization will be slower than for CRP. Patients should also be monitored for antimicrobial tolerability and toxicity (Table 81–2). If poor response is noted, the following should be evaluated: (a) patient adherence, (b) significant drug–drug or drug–food interactions, (c) appropriate dosage to achieve therapeutic concentrations, (d) development of antimicrobial resistance necessitating a change in the treatment regimen, (e) need for additional imaging studies, and (f) diagnostic reevaluation. Treatment is considered successful if all clinical signs and symptoms are resolved and all laboratory tests have returned to normal.

<tbody>
<tr>
<td>Daptomycin</td>
<td>Muscle pain or weakness particularly of the distal extremities; monitor CPK weekly with more frequent monitoring in patients with renal insufficiency or receiving (or recent discontinuation) of HMG-CoA reductase inhibitors; consider temporarily discontinuing HMG-CoA reductase inhibitors while patient receiving daptomycin. Peripheral neuropathy: Monitor for neuropathy. Decreased efficacy was observed in patients with moderate baseline renal impairment. Myelosuppression: Monitor CBC once weekly.</td>
</tr>
<tr>
<td>Linezolid</td>
<td>Peripheral neuropathy: Monitor for neuropathy. Decreased efficacy was observed in patients with moderate baseline renal impairment. Myelosuppression: Monitor CBC once weekly. Linezolid should not be used concomitantly or within 2 weeks of medications that inhibit monoamine oxidases A or B. Serotonin syndrome: Evaluate for potential drug–drug and drug–food interactions. Patients taking serotonergic antidepressants should receive linezolid only if no other therapies are available. Discontinue serotonergic antidepressants and monitor patients for signs and symptoms of both serotonin syndrome and antidepressant discontinuation.</td>
</tr>
<tr>
<td>Vancomycin</td>
<td>Peripheral and/or optic neuropathy has been reported with long-term therapy; perform routine neurologic and ophthalmic evaluations in these patients. Elevation of blood pressure in certain patients (eg, uncontrolled hypertension): Monitor blood pressure. Hypoglycemia in patients with diabetes mellitus receiving insulin or oral hypoglycemic agents: Monitor glucose. Targeted steady state trough is 15–20 mcg/mL (15–20 μg/L; 10–14 μmol/L) for serious infections such as osteomyelitis. Renal dysfunction: Monitor weekly renal function (BUN/Scr) and troughs in stable patients; more often in nonstable patients. Potential for additive renal toxicity if being coadministered with a nephrotoxic agent (eg, aminoglycoside).</td>

### Patient Encounter, Part 3: The Medical History, Physical Exam, and Diagnostic Tests

**PMH:** Type 2 diabetes mellitus, dyslipidemia, depression

**SH:** Tobacco smoker (one pack per day for 10 years), two to three cans of beer daily. Employed as mechanic

**Allergies:** NKDA

**Meds:** Cephalexin 500 mg orally four times a day; rosvuastatin 20 mg orally at bedtime; metformin 500 mg orally twice daily; fluoxetine 20 mg orally daily

**PE:**

**Gen:** Moderate distress with pain and tenderness in lower left leg; limps

**Skin:** Erythema and inflammation

**VS:** BP 120/70 mm Hg, P 85 beats/min, RR 20 breaths/min, T 38.4°C (101.2°F), Ht 5’ 7” (170 cm), Wt 73 kg (161 lb)

**Labs:** WBC 16.4 x 10³/mm³ (16.4 x 10⁹/L), hemoglobin 13.0 g/dL (130 g/L; 8.07 mmol/L), hematocrit 37.0% (0.37), platelets 220 x 10³/μL (220 x 10⁹/L), BUN 23 mg/dL (8.2 mmol/L), serum creatinine (Scr) 1.3 mg/dL (11.5 μmol/L), total bilirubin 1.1 mg/dL (18.8 μmol/L), alkaline phosphatase 82 U/L (1.37 μkat/L), AST 28 U/L (0.47 μkat/L), ALT 13 U/L (0.22 μkat/L), albumin 3.7 g/dL (37 g/L), fasting blood glucose 180 mg/dL (10.0 mmol/L), ESR 110 mm/h, CRP 14 mg/dL (140 mg/L)

**Microbiology:** Culture from bone aspirate grew *S. aureus* (sensitive to daptomycin, linezolid, rifampin, trimethoprim-sulfamethoxazole, and vancomycin but resistant to clindamycin, erythromycin, and oxacillin).

*Based on the information presented, create a care plan for this patient’s osteomyelitis. Your plan should include:
(a) Goals of therapy
(b) Patient-specific detailed therapeutic plan
(c) Nonpharmacologic interventions
(d) Follow-up plan to determine whether outcomes have been achieved*

### Patient Encounter, Part 4

The patient received 2 weeks of IV antimicrobial therapy following debridement. The patient has shown clinical and laboratory improvement. The multidisciplinary medical team plans to complete therapy with an oral antibiotic.

**What oral antimicrobial therapy would you recommend for this patient?**

**Evaluate the patient’s medication profile for drug–drug interactions.**

**Counsel the patient regarding this drug therapy.**
**Patient Assessment:**
- Review the medical history to assess risk factors for osteomyelitis.
- Based on physical exam and review of systems, determine whether the patient is experiencing signs or symptoms of osteomyelitis.
- Review available imaging studies and laboratory tests, especially WBC, ESR, and CRP.
- Obtain a thorough history of prescription, nonprescription, and natural drug product use.

**Therapy Evaluation:**
- Determine the appropriateness of current antibiotic therapy based upon patient-specific factors and microbiology data (if available).

**Care Plan Development:**
- Determine whether the antibiotic dosage regimen is optimal based upon patient-specific factors and site of infection.
- Provide patient education with regard to disease state and drug therapy. Stress the importance of adherence to the therapeutic regimen.

**Follow-Up Evaluation:**
- Patients should be monitored for clinical and laboratory response, development of adverse drug reactions, and potential drug–drug interactions. Patients should also be closely monitored for adherence in the outpatient setting.

following 4 to 8 weeks of appropriate treatment. Due to high rates of relapse, patients should have medical follow-up for at least 1 year following resolution of symptoms. Patients should be evaluated at predefined follow-up intervals (3- to 6- to 12-months) for any clinical manifestations of recurring infection and continued normalization of laboratory tests. Follow-up imaging studies at 1 to 2 years may be useful in some patients to confirm therapeutic success.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Compare and contrast the definitions of syndromes related to sepsis.
2. Identify the pathogens associated with sepsis.
3. Discuss the pathophysiology of sepsis as it relates to pro- and anti-inflammatory mediators.
4. Identify patient symptoms as early or late sepsis and evaluate diagnostic and laboratory tests for patient treatment and monitoring.
5. Assess complications of sepsis and discuss their impact on patient outcomes.
6. Design desired treatment outcomes for septic patients.
7. Formulate a treatment and monitoring plan (pharmacologic and nonpharmacologic) for septic patients.
8. Evaluate patient response and devise alternative treatment regimens for nonresponding septic patients.

INTRODUCTION

Sepsis occurs across a continuum of physiologic stages in response to infection which manifests as systemic inflammation, coagulation, and tissue hypoperfusion, potentially leading to organ dysfunction known as severe sepsis. The American College of Chest Physicians and the Society of Critical Care Medicine have defined the nomenclature to standardize sepsis terminology. Physiologic parameters categorize patients as having systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, or septic shock.

EPIDEMIOLOGY AND ETIOLOGY

Sepsis is the leading cause of morbidity and mortality for critically ill patients and the tenth leading cause of death overall. Mortality rates remain high for patients with severe sepsis and septic shock with septic shock and multiorgan failure as the most common causes of death. There are approximately 750,000 cases of sepsis diagnosed every year in the United States which continues to increase.

Risk factors for sepsis include increased age, cancer, immunodeficiency, chronic organ failure, genetic factors (male gender and nonwhite ethnic origin in North America), and bacteremia. Pulmonary infections cause approximately half of all cases, followed by intra-abdominal and genitourinary infections. In approximately one-third of cases of sepsis a pathogen is not identified making de-escalation from broad spectrum to a more narrowed antimicrobial regimen difficult.

Gram-positive and gram-negative bacteria, fungal species, and viruses may cause sepsis (Table 82–2). Gram-positive infections account for 30% to 50% of sepsis and septic shock cases. The percentages of gram-negative, polymicrobial, and viral sepsis cases are 25%, 25%, and 4%, respectively. A multinational study of 14,000 critically ill patients showed an increase in gram-negative bacterial causes of sepsis compared to gram-positive bacterial and fungal causes. Multidrug-resistant (MDR) bacteria are responsible for approximately 25% of sepsis cases, are difficult to treat, and increase mortality. The rate of fungal infections has significantly increased with Candida albicans as the most common fungal species identified; however, non-albicans species (C. glabrata, C. krusei, and C. tropicalis) have increased from 24% to 46%. Other fungi identified as causes of sepsis include species of Cryptococcus, Coccidioides, Fusarium, and Aspergillus.

PATHOPHYSIOLOGY

The development of sepsis is complex and multifactorial. The normal host response to infection is designed to localize and control bacterial invasion and initiate repair of injured tissue through phagocytic cells and inflammatory mediators. Sepsis results when the interplay between the host’s immune, inflammatory, and coagulant responses becomes exaggerated extending to normal tissue distant from the initial tissue site.

Pro- and Anti-inflammatory Mediators

The key factor in the development of sepsis is inflammation, which is intended to be a local and contained response to infection or injury. Infection or injury is controlled through proinflammatory and anti-inflammatory mediators. Proinflammatory mediators facilitate clearance of the injuring stimulus, promote resolution of injury, and are involved in processing of damaged tissue. To control the intensity and duration of the inflammatory response, anti-inflammatory mediators are released that act to regulate proinflammatory mediators. The balance between pro- and anti-inflammatory mediators localizes...
The clinical presentation of sepsis varies, and the rate of development of clinical manifestations may differ from patient to patient.

Data from Refs. 5, 6, 12, and 13.

A physical examination should be performed rapidly and efficiently when sepsis is suspected, with efforts directed toward uncovering the most likely cause of sepsis. The patient may not provide any medical history; therefore, historical data may be obtained from medical records and/or family. The patient’s medical condition, recent illnesses, infections, or activities may provide valuable information about the cause of sepsis.

**Diagnostic and Laboratory Tests**

Microbiologic cultures should be obtained before antimicrobial therapy is initiated as long as this does not significantly delay diagnosis.

**Physical Examination Results in Sepsis**

**HEENT:** Scleral icterus, dry mucous membranes, pinpoint pupils, dilated and fixed pupils, nystagmus

**Neck:** Jugular venous distention, carotid bruits

**Lungs:** Crackles (rales), consolidation, egophony, absent breath sounds

**CV:** Irregular rhythm, S₃ gallop, murmurs

**Abd:** Tense, distended, tender, rebound, guarding, hepatosplenomegalgy

**Rectal:** Decreased tone, bright red blood

**Ext:** Swollen calf, disparity of blood pressure between upper extremities

**Neurologic:** Agitation, confusion, delirium, obtundation, coma

**Skin:** Cold, clammy, or warm; hyperemic skin; rashes
Clinical Presentation and Diagnosis of Sepsis

The signs and symptoms of septic patients are referred to as early and late sepsis.

**Signs and Symptoms**
The initial clinical signs and symptoms represent early sepsis, and they include fever, chills, and change in mental status. Other signs and symptoms include:
- Tachycardia
- Tachypnea
- Nausea and vomiting
- Hyperglycemia
- Myalgias
- Lethargy and malaise
- Proteinuria
- Leukocytosis
- Hypoxia
- Hyperbilirubinemia

Septic patients may have an elevated, low, or normal temperature. The absence of fever is common in neonates and elderly patients. Hypothermia is associated with a poor prognosis. Hyperventilation may occur before fever and chills and may lead to respiratory alkalosis. Disorientation and confusion may develop early in septic patients, particularly in the elderly and patients with preexisting neurologic impairment. Disorientation and confusion may be related to the infection or due to sepsis signs and symptoms (eg, hypoxia).

Late sepsis represents a slow process that develops over several hours of hypoperfusion. Signs and symptoms of late sepsis include:
- Lactic acidosis
- Oliguria
- Leukopenia
- Thrombocytopenia
- Myocardial depression
- Pulmonary edema
- Hypotension
- Hypoglycemia
- Gastrointestinal hemorrhage

Oliguria often follows hypotension because of decreased renal perfusion. Metabolic acidosis ensues because of diminished clearance of lactate by the kidneys and liver.

**Patient Encounter, Part 1**

A 35-year-old woman with history of asthma presents to the emergency department with complaints of several days of high fevers, chills, cough, and increased purulent sputum production. The patient appears to be in severe respiratory distress and is becoming increasingly lethargic.

**What information is suggestive of infection and/or sepsis?**

**What information do we need in order to confirm or diagnose sepsis in this patient?**

the start of therapy. However, cultures take 6 to 48 hours for results to be completed and often are negative (no growth of bacterial organisms). Negative cultures do not rule out the presence of infection. Administering antimicrobials before obtaining cultures may lead to a false-negative culture. Rapid diagnostics of blood cultures allows for identification of specific pathogens within as little as 20 minutes to 3 hours after initial growth is identified. However not all health care systems have this technology available.

At least two sets of blood cultures should be obtained to rule out contamination with at least one set drawn percutaneously and one set drawn through each vascular access device present for greater than 48 hours.

Cultures of urine (with urinalysis), respiratory secretions, cerebrospinal fluid, and wounds should be obtained if the clinical presentation suggests infection of these specific fluids, tissues, or organs. Laboratory tests should be performed to evaluate infection or complications of sepsis, including complete blood count (CBC) with differential, coagulation parameters, comprehensive metabolic panel (CMP), serum lactate concentration, arterial blood gas (ABG), and appropriate diagnostic radiographic imaging studies.

The use of biomarkers of sepsis has been controversial. Measurement of endotoxin, procalcitonin, or other markers in blood or serum is not routinely recommended if the clinical presentation suggests infection of these specific fluids, tissues, or organs. Laboratory tests should be performed to evaluate infection or complications of sepsis, including complete blood count (CBC) with differential, coagulation parameters, comprehensive metabolic panel (CMP), serum lactate concentration, arterial blood gas (ABG), and appropriate diagnostic radiographic imaging studies.

The use of biomarkers of sepsis has been controversial. Laboratory tests should be performed to evaluate infection or complications of sepsis, including complete blood count (CBC) with differential, coagulation parameters, comprehensive metabolic panel (CMP), serum lactate concentration, arterial blood gas (ABG), and appropriate diagnostic radiographic imaging studies.

**Complications of Sepsis**

Recognition and treatment of sepsis complications, particularly organ failure, is essential to improve outcomes.

**TREATMENT AND OUTCOME EVALUATION**

**Desired Outcomes**

The primary treatment goal of sepsis is to prevent morbidity and mortality through rapid recognition and intervention. Treatment is aimed at early implementation of therapies, such as fluid

**The cumulative burden of sepsis complications is the leading factor of mortality. The risk of death increases 20% with failure of each additional organ. Severe sepsis averages two failed organs, with a mortality rate of 40%. The most common complications are respiratory and cardiovascular compromise, usually seen as acute respiratory distress syndrome (ARDS), hemodynamic compromise, and elevated serum lactate levels. Other complications include altered mentation, acute kidney injury (AKI) which may require renal replacement therapy, paralytic ileus, disseminated intravascular coagulation (DIC), and adrenal insufficiency.**

---

**Patient Encounter, Part 1**

**What information is suggestive of infection and/or sepsis?**

**What information do we need in order to confirm or diagnose sepsis in this patient?**
resuscitation and antimicrobials, reducing or eliminating organ dysfunction, eliminating the source of infection, avoiding adverse reactions of treatment, and providing cost-effective therapy.18–24

**General Approach to Treatment**

Similar to the emphasis placed on the expedited treatment of patients with acute myocardial infarction and cerebrovascular accidents, quick, quantitative intervention with appropriate therapies to achieve specific, measurable endpoints once a diagnosis of sepsis has been made is crucial to decrease morbidity and mortality.18,20

Pertinent approaches in the management of septic patients are as follows (Figure 82–1)24:

1. Prompt recognition of the septic patient and early implementation of therapies.

2. Fluid therapy, using crystalloids initially, to achieve quantitative therapeutic endpoints.

3. Early administration of broad-spectrum antimicrobial therapy.

4. Vasopressor therapy, using norepinephrine initially, to maintain hemodynamic stability (on average a mean arterial pressure of 65 mm Hg [8.6 kPa]) in patients with septic shock refractory to fluid resuscitation.

5. Intravenous (IV) hydrocortisone may be considered for patients who remain hemodynamically unstable despite adequate fluid resuscitation and vasopressor support.

6. Glycemic control via infusion of regular insulin to maintain glucose levels between 140 and 180 mg/dL (7.8 and 10.0 mmol/L).

**FIGURE 82–1.** Therapeutic approach to sepsis. (C&S, culture and sensitivity.)
7. Adjunctive therapies: blood product administration, sedation, analgesia, neuromuscular blockade, renal replacement therapy, deep vein thrombosis (DVT) prophylaxis, stress ulcer prophylaxis, and nutrition.

Treatment for sepsis focuses on infection, inflammation, hypoperfusion, and widespread tissue injury. Septic patients may require multiple simultaneous treatment regimens to achieve desired outcomes of decreased morbidity and mortality.

Initial Resuscitation

A landmark study of early goal directed therapy (EGDT) using a standardized protocol that required the use of a special catheter for central venous oxygen saturation monitoring decreased 28-day mortality in septic patients by approximately 16%. Three subsequent randomized controlled studies comparing EGDT to groups of patients receiving contemporary care (with or without the use of protocols) found no differences in mortality. These results may demonstrate that continued focus on early recognition and treatment of these patients may play a more important role than protocol-based therapy. Specifically the placement of central venous catheters for mixed venous oxygen saturation monitoring as well as administration of inotrope therapy and blood transfusions did not improve outcomes compared to standard care. The most current treatment goals of sepsis-induced hypoperfusion (hypotension or blood lactate level greater than or equal to 4 mEq/L [4 mmol/L]) during the first 6 hours include:

- Central venous pressure (CVP) 8 to 12 mm Hg (1.1–1.6 kPa)
- Mean arterial pressure (MAP) greater than or equal to 65 mm Hg (8.6 kPa)
- Urine output greater than or equal to 0.5 mL/kg/h

Emerging noninvasive techniques, such as the use of cardiac ultrasound, have recently shown reliability in assessing intravascular volume status through measuring inferior vena cava diameter changes and collapsibility. Resuscitation should also target the normalization of blood lactate levels in patients with an initially elevated blood lactate as a marker of improved tissue perfusion.

Fluid Therapy

Crystalloid fluids (such as 0.9% sodium chloride or lactated Ringer solutions) or colloids (albumin products) are used for resuscitation, and clinical studies comparing the fluids have found them to be equivalent. Crystalloids require more fluid volume, which may lead to more edema (utilize caution in patients at risk for fluid overload, eg, congestive heart failure and ARDS); however, albumin is significantly more expensive. Hydroxyethyl starches (HES), another type of colloid, should not be used due to studies demonstrating increased morbidity and mortality rates. A large, multicenter, randomized controlled trial comparing HES to Ringer acetate in patients with severe sepsis showed an increased 90-day mortality rate and a higher need for renal replacement therapy in patients administered HES for fluid resuscitation. For these reasons, crystalloids are preferred versus colloids for initial resuscitation, except in cases where large amounts of crystalloids are needed and hypervolemia may be harmful to the patient.

Administer an initial fluid challenge in patients with suspected sepsis-induced tissue hypoperfusion and hypovolemia with 30 mL/kg of crystallloid fluid. Most patients require aggressive fluid resuscitation during the first 24 hours because of persistent venodilation and capillary leak.

Anti-infective Therapy

Appropriate empiric antimicrobial therapy decreases 28-day mortality compared with inappropriate empiric therapy (24% vs 39%). Additionally, appropriate therapy administered within 1 hour of sepsis recognition also decreases complications and mortality. Empiric antimicrobial therapy should include multiple agents for most cases, depending on the likely site of infection and causative pathogens. Anti-infective clinical trials in sepsis and septic shock patients are scarce and have not demonstrated differences among agents; therefore, factors that determine selection are:

- Site of infection
- Causative pathogens
- Community- or nosocomial-acquired infection
- Immune status of patient
- Antibiotic susceptibility and resistance profile for the institution and local community. Clinicians should be cognizant of growing prevalence of bacterial resistance in community and health care settings.

Patient Encounter, Part 2: Medical History, Physical Exam, and Diagnostic Tests

PMH: Asthma diagnosed at 3 years of age
FH: Father had stroke at age 62; mother has history of hypertension and diabetes mellitus
SH: Teacher; nonsmoker; rare alcohol intake
Allergies: NKDA
Meds: Fluticasone/Salmeterol 250/50 mg one puff twice daily; albuterol 90 mcg inhaler two puffs every 4 hours as needed for shortness of breath
ROS: Unable to obtain; patient has become more confused
PE:
Within normal limits except as noted below
VS: BP 79/44 mm Hg, P 124 beats/min, RR 29 breaths/min, T 39.3°C (102.7°F)

Lungs: Decreased breath sounds, bilateral crackles
Labs: Serum creatinine 2.7 mg/dL (239 μmol/L); glucose 298 mg/dL (16.5 mmol/L); white blood cells: leukocytosis (15,000/mm³ [15 × 10⁹/L]) with left shift; lactic acid 5.1 mEq/L (5.1 mmol/L)
Cultures: Blood, urine, and respiratory cultures pending
Radiology: Bilateral pulmonary infiltrates seen on chest x-ray

According to the patient’s parameters, what does she have (ie, systemic inflammatory response syndrome, sepsis, or septic shock)?

Identify treatment goals.
Formulate an initial plan for therapy.
• Patient history (underlying disease, previous cultures or infections including any recent antibiotic therapy, and drug allergy/intolerance)
• Adverse reactions
• Cost

Anti-infective regimens should be broad-spectrum since delays in appropriate therapy result in increased mortality.

**Monitoring and Treatment Strategies to Maximize Efficacy and Minimize Toxicity for Antimicrobials**

- Administer broad-spectrum antimicrobials for initial therapy, as early as possible and within first hour of recognition of sepsis.
- Appropriate cultures should be obtained before initiating antibiotic therapy, but should not prevent prompt administration.
- Administer antibiotics that concentrate at the site of infection.
- Monitor patient parameters to ensure adequate dosing.
- Abnormal renal and hepatic function will increase drug concentration and predispose the patient to toxicity.
- Ensure antibiotic dosing is changed to normal doses once renal dysfunction has resolved to limit the development of treatment failure, antimicrobial resistance, or both.
- Septic patients may have increased volume of distribution due to initial large volume resuscitation.
- Reevaluate the initial dosing regimen daily to optimize activity, prevent development of resistance, reduce toxicity, and decrease costs.
- Initiate step-down therapy based on microbiologic cultures to: prevent resistance, reduce toxicity, and cost.
- Monotherapy is equivalent to combination therapy once a causative pathogen has been identified in the vast majority of cases. Empiric therapy should include combination regimens to ensure appropriate coverage of causative organisms.

**Duration of Anti-Infective Therapy**

Average duration of antimicrobial therapy for septic patients is 7 to 10 days. However, durations vary depending on the site of infection and response to therapy. Step-down therapy from IV to oral antimicrobials is recommended in most patients whom are hemodynamically stable, afebrile for 48 to 72 hours, have a normalized WBC, and able to take oral medications.

**Source Control**

Evaluate septic patients for the presence of a localized infection amenable to source control measures. Common source control measures include drainage and debridement, device removal, and prevention. Implementation of source control methods should be instituted as soon as possible following initial fluid resuscitation. The selection of optimal source control methods must weigh benefits and risks of the intervention. Source control measures may cause complications (bleeding, fistulas, and organ injury); therefore, the method with the least risk should be employed.

**HEMODYNAMIC SUPPORT**

**Vasopressors and Inotropic Therapy**

*Key Concept* When fluid resuscitation does not provide adequate arterial pressure and organ perfusion, vasopressors and/or inotropic agents should be initiated. Vasopressors are recommended in patients with a systolic blood pressure less than 90 mm Hg or MAP lower than 60 to 65 mm Hg (8.0–8.6 kPa), after failed treatment with crystalloids. Vasopressors and inotropes are effective in treating life-threatening hypotension and improving cardiac index, but complications such as tachycardia and myocardial ischemia require slow titration of the adrenergic agents to restore MAP without impairing stroke volume. Vasopressor therapy may also be required transiently to sustain life and maintain perfusion in the face of life-threatening hypotension, even when fluid resuscitation is in progress and hypovolemia has not yet been corrected. Agents commonly considered for vasopressor or inotropic support include norepinephrine, epinephrine, dopamine, phenylephrine, vasopressin, and dobutamine. Norepinephrine is the first-line vasopressor to correct hypotension in septic shock.

Norepinephrine is a potent α-adrenergic agent with less pronounced β-adrenergic activity. Doses of 0.01 to 3 mcg/kg/min can reliably increase blood pressure through vasoconstriction with small changes in heart rate or cardiac index. Norepinephrine is a more potent agent than dopamine in refractory septic shock. Norepinephrine induces less arrhythmias compared with dopamine.

Dopamine is an α- and β-adrenergic agent with dopaminergic activity. Low doses of dopamine (1–5 mcg/kg/min) maintain renal perfusion; higher doses (greater than 5 mcg/kg/min) exhibit α- and β-adrenergic activity and are frequently utilized to support blood pressure and to improve cardiac function, mainly through increasing stroke volume and heart rate. Because of the effects on heart rate, dopamine causes more tachycardia and thus increases potential for arrhythmias versus norepinephrine. Based on these data, dopamine should not be used routinely in the management of septic shock. Low doses of dopamine should not be used for renal protection as part of the treatment of severe sepsis.

Epinephrine is a nonspecific α- and β-adrenergic agonist that can increase cardiac index and produce significant peripheral vasoconstriction. Some human and animal studies suggest it can also increase lactate levels and impair blood flow to the splanchic system; however, studies comparing norepinephrine to epinephrine show no difference in mortality rates. Epinephrine should be considered the first alternative to norepinephrine in patients with persistent hypotension.

Phenylephrine is a fast-acting, short-acting pure α1-agonist. Phenylephrine is the least likely vasopressor to cause tachycardia, but may decrease stroke volume. Phenylephrine should be reserved for use in patients with high cardiac output in whom tachycardia or ischemia limits the use of other vasopressors or as salvage therapy.

Vasopressin levels are increased during hypotension to maintain blood pressure by vasoconstriction. However, there is
a vasopressin deficiency in septic shock. Low, fixed doses of vasopressin increase MAP, leading to the discontinuation of vasopressors. However, routine use of vasopressin with norepinephrine is not recommended because of no difference in mortality compared with norepinephrine monotherapy. Vasopressin is a direct vasoconstrictor without inotropic or chronotropic effects and may result in decreased cardiac output and hepatopulmonary flow. Vasopressin use may be considered in patients with refractory shock despite adequate fluid resuscitation and high-dose vasopressors. Dobutamine is recommended as the first-line inotropic agent. Dobutamine is a β-adrenergic inotropic agent that can be utilized for improvement of cardiac output and oxygen delivery. Doses of 2 to 20 mcg/kg/min increase cardiac index; however, heart rate increases significantly. Dobutamine should be considered in septic patients with adequate filling pressure and blood pressure, but low cardiac index. If used in hypotensive patients, dobutamine should be combined with vasopressor therapy.

Corticosteroids

Stress-induced adrenal insufficiency complicates 9% to 24% of septic patients and is associated with increased mortality. The role of steroid use in septic shock remains unclear. Previous studies have demonstrated a mortality benefit or quicker reversal of shock in patients with sepsis-induced adrenal insufficiency treated with hydrocortisone. However, a large, multicenter, randomized controlled trial (CORTICUS) showed no difference in mortality rates in septic shock patients treated with hydrocortisone. For these reasons, the use of IV hydrocortisone at a dose of 200 mcg/day should be reserved for patients who remain hemodynamically unstable despite fluid and vasopressor therapy. Patients should be weaned from steroid therapy when vasopressors are no longer required.

Glucose Control

The optimal blood glucose range in septic patients is unknown. Tight glycemic control (80–110 mg/dL [4.4–6.1 mmol/L]) improved survival in postoperative surgical patients, but did not show a benefit in medical critically ill patients. More recent studies, including the large NICE-SUGAR trial, do not demonstrate a mortality benefit in favor of tight glycemic control, but actually a higher incidence of severe hypoglycemia and increased mortality rates. Following initial stabilization of septic patients, current guidelines recommend initiating insulin therapy when two consecutive blood glucose measurements are greater than 180 mg/dL (10.0 mmol/L) and then maintaining a blood glucose range of 140 to 180 mg/dL (7.8–10.0 mmol/L). Blood glucose levels should be monitored frequently, every 1 to 2 hours, until glucose values and insulin infusion rates are stable, then every 4 hours thereafter.

Patient Encounter, Part 4

Three days later, the patient’s blood pressure begins to respond to therapy with a MAP remaining greater than 65 mm Hg (8.6 kPa) on minimal vasopressor support. What changes to the patient’s medication regimen do you recommend?

Adjunctive Therapies

Blood Product Administration

There are no trials showing the optimal hemoglobin concentration in patients with severe sepsis. However, based on other studies which included subgroups of septic patients, with the exception of myocardial ischemia, severe hypoxemia, acute hemorrhage, or ischemic coronary artery disease, it is recommended to target a hemoglobin concentration of 7 to 9 g/dL (70–90 g/L; 4.34–5.59 mmol/L) and red blood cell transfusion should occur when the hemoglobin concentration is less than 7 g/dL (70 g/L; 4.34 mmol/L). Erythropoietin stimulating agents, fresh frozen plasma, and antithrombin should not be administered, unless other compelling indications exist, to treat sepsis-induced abnormalities.

Sedation, Analgesia, and Neuromuscular Blockade

It is common for severe sepsis patients to require mechanical ventilation during their course of therapy. These patients may require analgesic or sedative agents to facilitate mechanical ventilation. Historically, concerns for patient safety and posttraumatic stress disorder emphasized the need for sedation in these patients. However, there continue to be ample data indicating that, while sedation is necessary, limiting exposure to certain sedative medications may improve morbidity and mortality rates. When sedation is needed, a standardized protocol targeting specific endpoints should be utilized.

Neuromuscular blockade usually is reserved for patients in whom sedation alone does not improve the effectiveness of mechanical ventilation. Neuromuscular blockers may lead to prolonged skeletal muscle weakness and should be avoided if possible especially if receiving concomitant corticosteroid therapy which can increase the risk of critical illness polynuropathy. Patients requiring neuromuscular blockade should be monitored, and intermittent bolus doses or continuous infusion should be utilized. Monitor depth of neuromuscular blockade with either train-of-four stimulation or other forms of clinical assessment when using continuous infusion. Patients with early, sepsis-induced ARDS with a PaO2/FiO2 less than 150 mm Hg (20.0 kPa), may benefit from a short course of a neuromuscular blocking agent to not exceed 48 hours.

Renal Replacement Therapy

Patients who develop acute kidney injury as a manifestation of severe sepsis may require some type of renal replacement therapy. There are no data currently that suggest superiority for either continuous or intermittent modalities of hemodialysis as both have demonstrated similar mortality rates. In patients who are hemodynamically unstable, continuous renal replacement therapy may be more beneficial due to less overall hypotension during therapy.

Deep Vein Thrombosis Prophylaxis

Combination pharmacologic and mechanical prophylaxis against venous thromboembolism is recommended for septic patients when possible. Low-dose unfractionated heparin, low-molecular-weight heparin (eg, enoxaparin or dalteparin), or pentasaccharide therapy (eg, fondaparinux) may be utilized. Graduated compression stockings or an intermittent compression device is recommended for patients with a contraindication to heparin products (thrombocytopenia, severe coagulopathy, active bleeding, or recent intracerebral hemorrhage).
**Patient Care Process**

### Patient Assessment:
- Based on physical exam and review of systems, determine whether the patient meets criteria for suspected sepsis.
- Review available diagnostic and laboratory data, especially CBC with differential, CMP, lactic acid, and patient specific factors including previous antimicrobial history and microbiologic cultures.
- Measure vital signs, including temperature, heart rate, respiratory rate, and blood pressure.

### Therapy Evaluation:
- Institute early intervention initially with crystalloid fluids. Understand which parameters indicate effective/ineffective therapy. Recommend additional resuscitation therapy if the patient remains hypotensive.
- Initiate appropriate, broad-spectrum antimicrobials that cover the most likely pathogens within the first hour of diagnosis.
- Evaluate the source of infection and make recommendations to remove potential sources.
- If patient remains hemodynamically unstable despite fluid administration, start vasopressor therapy and/or corticosteroids with potential inotropic therapy if required.

### Care Plan Development:
- Formulate appropriate dosing regimens of medications involved in therapy and revise as needed.
- Patient parameters may change frequently, thus requiring modifications of therapy. This may include the addition or deletion of adjunctive medications, such as antimicrobial agents, analgesics, sedatives, neuromuscular blockers, insulin, blood products, and renal replacement therapy.

### Follow-Up Evaluation:
- Continually monitor patient parameters to ensure optimal therapy to minimize morbidity and mortality.

### Stress Ulcer Prophylaxis

Patients with severe sepsis are at increased risk for developing a stress ulcer bleeding event. Stress ulcer prophylaxis using either a histamine-receptor antagonist (H-2 blocker) or proton pump inhibitor (PPI) is recommended in septic patients. Patients at greatest risk for stress ulcers include those who are coagulopathic, mechanically ventilated (greater than 48 hours), or hypotensive. Histamine-2 receptor antagonists (eg, ranitidine) are more efficacious than sucralfate. There is ongoing debate to determine if PPIs (eg, omeprazole) are more efficacious than H-2 blockers with low-quality data showing conflicting outcomes. Both, however, demonstrate equivalence in the ability to increase gastric pH. The benefit of prophylaxis must be weighed against the potential effect of increased stomach pH and development of infectious complications, such as hospital-acquired pneumonia and/or *Clostridium difficile* infection.

### Nutrition

Meeting the nutritional needs of septic patients can be challenging, especially in patients who are hemodynamically unstable. When possible, early initiation of enteral nutrition should be considered to maintain gut mucosa and potentially decrease the risk of bacterial translocation leading to infection. Patients who are hemodynamically unstable may not tolerate enteral nutrition and are at risk for gut ischemia. Parenteral nutrition alone or in conjunction with enteral nutrition should not be initiated in the first 7 days as this has not been shown to improve outcomes.

### Prognosis

There are various factors that influence outcome. Gram-negative bacteria are more likely to produce septic shock than gram-positive bacteria (50% vs 25%) and have a higher mortality rate than other pathogens. This may be related to the severity of the underlying condition. Patients with rapidly fatal conditions, such as leukemia, aplastic anemia, and burns, have a worse prognosis than patients with nonfatal underlying conditions, such as diabetes mellitus or chronic renal insufficiency. Other factors that worsen the prognosis of septic patients include advanced age, malnutrition, resistant bacteria, utilization of medical devices, and immunosuppression. Data for long-term mortality are lacking (it is estimated that the mortality for sepsis survivors within the first year is 20%). Patients may have prolonged physical disability related to muscle weakness and posttraumatic stress.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying pathophysiology of vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
2. Identify symptoms of vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
3. Identify the desired therapeutic outcomes for patients with uncomplicated and complicated vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
4. Recommend appropriate lifestyle modifications and pharmacotherapy interventions for patients with vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.
5. Recognize when long-term suppressive therapy is indicated for a patient with vulvovaginal candidiasis.
6. Recognize when topical versus oral treatment is indicated for a patient with oropharyngeal candidiasis, esophageal candidiasis, vulvovaginal candidiasis, and fungal skin infections.
7. Educate patients about the disease state, appropriate lifestyle modifications, and medication therapy required for effective treatment of vulvovaginal candidiasis, oropharyngeal candidiasis, esophageal candidiasis, and fungal skin infections.

INTRODUCTION

Superficial fungal infections, also referred to as mycoses, are common and treatable conditions seen in everyday practice. Treatment largely depends on the use of azole and allylamine antifungal agents, either topically or orally, depending on the site, severity, and immune status of the patient.

VULVOVAGINAL CANDIDIASIS

Vulvovaginal candidiasis (VVC), whether symptomatic or asymptomatic, refers to infections in women whose vaginal cultures are positive for Candida species.

EPIDEMIOLOGY AND ETIOLOGY

Vulvovaginal candidiasis, also known as moniliasis, is a common form of vaginitis, accounting for 20% to 25% of vaginitis cases. Although VVC is uncommon prior to menarche, an estimated 75% of women will have at least one occurrence of VVC.

According to the treatment guidelines of the Centers for Disease Control and Prevention (CDC), VVC can be classified as uncomplicated or complicated. Uncomplicated infections occur sporadically, cause mild to moderate symptoms, and occur in nonimmunocompromised women. Uncomplicated infections, most often caused by Candida albicans, often have no identifiable precipitating cause. Complicated infections, including recurrent, severe infections, and those in women with uncontrolled diabetes, debilitation, or immunosuppression, may be caused by nonalbicans or azole-resistant fungal organisms. Recurrent VVC, defined as four or more infections per year, occurs in less than 5% of women, is distinguishable from a persistent infection by the presence of a symptom-free interval between infections.

Candida albicans is the primary pathogen responsible for VVC, accounting for 66% of cases. Other cases are caused by nonalbicans species, including Candida glabrata, Candida tropicalis, Candida krusei, and Candida parapsilosis.

PATHOPHYSIOLOGY

The normal vaginal environment protects women against vaginal infections. Under the influence of estrogen, vaginal epithelium cornifies to reduce the risk of infection. Vaginal discharge, composed of exfoliated cells, cervical mucus, and colonized bacteria, cleans the vagina. The normal pH of vaginal secretions, near 4.0, is toxic to many pathogens and is maintained by Lactobacillus acidophilus, diphtheroids, and Staphylococcus epidermidis. Alterations in the vaginal environment, including pH changes, allow for overgrowth of organisms that are normally suppressed, increasing the risk of vulvovaginitis.

RISK FACTORS

Although no risk factors are consistently associated with conversion to symptomatic infection, a variety of factors may increase the risk of developing symptomatic VVC in certain women (Table 83–1).
Clinical Presentation and Diagnosis of VVC

Patients with VVC may present with vulvar and/or vaginal symptoms. Symptoms often develop the week before menses and resolve with the onset of menses.

Symptoms
- Vaginal itching
- Vaginal soreness
- Vaginal burning
- Irritation
- External dysuria
- Dyspareunia

Signs
- Nonodorous vaginal discharge (may vary from watery to curd-like)
- Yellow or yellowish green discharge
- Erythema and edema of the labia and vulva
- Fissures
- Pustulopapular lesions
- Normal cervix

Diagnostic Testing
- Microscopic investigation for the presence of blastospores or pseudohyphae; saline wet mount has a sensitivity of 40% to 50%, whereas a potassium hydroxide (KOH) preparation has a sensitivity of 50% to 70%. Asymptomatic vaginal colonization of Candida albicans is not diagnostic of VVC since 10% to 20% of women are asymptomatic carriers of Candida species. Asymptomatic vaginal colonization does not require treatment; therefore, the presence alone of Candida should not determine care.
- Vaginal pH less than or equal to 4.5; pH should remain normal in cases of fungal infection, whereas an elevated pH suggests bacterial infection.
- Candida cultures should be obtained only if signs and microscopy are inconclusive or in cases of recurrent VVC.

Possible Risk Factors Associated with VVC

<table>
<thead>
<tr>
<th>Risk Factor</th>
<th>Proposed Mechanism</th>
</tr>
</thead>
<tbody>
<tr>
<td>Broad-spectrum antibiotic use</td>
<td>Altered vaginal flora allowing overgrowth of Candida organisms; risk increases with duration of antibiotic use</td>
</tr>
<tr>
<td>Systemic corticosteroid or immunosuppressant use</td>
<td>Reduced vaginal protection by immunoglobulins</td>
</tr>
<tr>
<td>Sexual activity</td>
<td>VVC is often associated with the onset of sexual activity; partners may have penile or oral colonization; use of vaginal irritants or devices, including diaphragms and intrauterine systems, can irritate vaginal mucosa</td>
</tr>
<tr>
<td>Tight-fitting and nonabsorbent clothing</td>
<td>Promotes warm, moist environment for fungus growth</td>
</tr>
<tr>
<td>Elevated estrogen levels, hormonal contraceptives, and pregnancy</td>
<td>Estrogen enhances Candida adherence to vaginal epithelial cells and yeast- mycelial transformation; this is supported by the fact that infection rates are lower before menarche and after menopause (except in women taking hormone replacement therapy), whereas rates are higher during pregnancy</td>
</tr>
<tr>
<td>Vaginal pH</td>
<td>Changes in glycogen and lactic acid levels</td>
</tr>
<tr>
<td>Gastrointestinal reservoir of Candida organisms</td>
<td>Transfer of organism from rectum to vagina; irritation of the vulvovaginal area during sexual intercourse may enhance invasion of organisms</td>
</tr>
<tr>
<td>Diabetes</td>
<td>Enhanced binding of Candida to epithelial cells due to hyperglycemia; asymptomatic colonization is more common in patients with diabetes; elevated sugar levels may cause conversion to symptomatic infection</td>
</tr>
</tbody>
</table>

TREATMENT

The goals of treatment of VVC are as follows:
- Relief of symptoms
- Eradication of infection
- Reestablishment of normal vaginal flora
- Prevention of recurrent infections in complicated infections

Nonpharmacologic Treatments

In combination with pharmacologic treatment, the practitioner should recommend basic nonpharmacologic approaches to treatment and prevention of VVC:
- Keep the genital area clean and dry
- Avoid prolonged use of hot tubs
- Avoid constrictive clothing
- Avoid vaginal douching

Patient Encounter 1

A teenaged girl and her mother present to your clinic. The mother reports that her daughter has been complaining of itching in her vaginal area and a white discharge. After questioning the daughter, you determine that she has vaginal burning, soreness, and itching, accompanied by a curd-like discharge. She has never had a vaginal infection before. Upon further questions, you determine that the girl is a lifeguard and on the high school swim team, along with a long-distance runner. Despite the daughter’s denial of sexual activity, the mother is concerned that her daughter has contracted a sexually transmitted disease “from the water in the pool.” On examination, she has erythema of the labia and a nonodorous discharge.

What information is suggestive of VVC?

What additional information do you need to know before creating a treatment plan for this patient?
Wear underwear made of breathable materials, such as cotton. Avoid soaps and perfumes in the genital area. Although study results are conflicting, possibly due to the strain or concentration studied, the daily consumption of active Lactobacillus may reduce recurrence. Newer studies have found ingestion of Lactobacillus rhamnosus and Lactobacillus reuteri suppressed metabolic activity and killed C. albicans, whereas older studies found no difference in infection rates in women who ingested yogurt.

Pharmacologic Treatment of Uncomplicated VVC

For most cases of uncomplicated VVC, the CDC guidelines recommend a short course of therapy (1–3 days) with an oral or vaginal antifungal agent, either prescription or nonprescription. Nonprescription azole antifungal products are available as 1-night, 3-night, and 7-night regimens in a variety of formulations, including cream, suppository, and vaginal tablets (Table 83–2). Oral fluconazole offers the option of treatment with one dose administered without regard to time of day. Some practitioners opt to retreat with a second dose of fluconazole 3 days later. Due to the risk of severe hepatotoxicity, the use of oral ketoconazole should be reserved for severe fungal infections resistant to other antifungal options. Inability to resolve an infection may indicate a mixed infection, infection owing to a nonalbicans strain, an infection that is not fungal, or indicative of serious underlying conditions, such as diabetes or human immunodeficiency virus (HIV) infection. For these reasons, if infection does not resolve with a single antifungal course or if symptoms return within 2 months, practitioners should check cultures and further evaluate the patient’s health status.

**Table 83–2**

**Treatment Options for Uncomplicated VVC**

1-Day Therapies

- Butoconazole 2% sustained-release cream, 5 g intravaginally as a single application
- Fluconazole 150 mg, one tablet orally as a single dose
- Tioconazole 6.5% ointment, 5 g intravaginally as a single application

3-Day Therapies

- Butoconazole 2% cream, 5 g intravaginally for 3 nights
- Clotrimazole 100-mg vaginal tablet; two tablets for 3 nights
- Miconazole 200-mg vaginal suppository, one suppository for 3 nights
- Terconazole 0.8% cream, 5 g intravaginally for 3 nights
- Terconazole 80-mg vaginal suppository, one suppository for 3 nights

7- to 14-Day Therapies

- Boric acid 600-mg vaginal suppository, one suppository intravaginally twice daily for 14 days
- Clotrimazole 1% cream, 5 g intravaginally for 7–14 nights
- Clotrimazole 100-mg vaginal tablet, one tablet for 7 nights
- Miconazole 2% cream, 5 g intravaginally for 7 nights
- Miconazole 100-mg vaginal suppository, one suppository for 7 nights
- Nystatin 100,000-unit vaginal tablet, one tablet for 14 nights
- Terconazole 0.4% cream, 5 g intravaginally for 7 nights

**Table 83–3**

**Treatment Options for Maintenance Therapy**

Daily

- Boric acid 600 mg in gelatin capsule vaginally daily during menses (5 days)
- Itraconazole 100 mg orally once daily
- Ketoconazole 100 mg orally once daily

Weekly

- Clotrimazole 500 mg vaginal suppository once weekly
- Fluconazole 100 or 150 mg orally once weekly
- Terconazole 0.8% cream 5 g vaginally once weekly

Monthly

- Fluconazole 150 mg orally once monthly
- Itraconazole 400 mg orally once monthly

**Risk of Adverse Effects and Interactions**

Systemic adverse effects associated with vaginally administered azoles are less frequent than with oral products. With topical products, local discomfort such as burning, itching, stinginess, and redness may occur, particularly with the first application. In contrast, common adverse effects associated with fluconazole include headache, diarrhea, nausea, dizziness, abdominal pain, and taste alterations. Around 15% of patients experience gastrointestinal side effects with orally administered fluconazole.

Oral azoles are associated with significant drug interactions, particularly due to potent inhibition of cytochrome P-450 (CYP) 2C9 and moderate inhibition of CYP 3A4. For patients receiving only a few doses, these interactions do not pose a significant risk but may pose a risk with long-term suppressive therapy for recurrent infections.

**Treatment of Recurrent VVC**

The goal of treating recurrent VVC is control of the infection, rather than cure. First, any acute episodes are treated, followed by maintenance therapy. Although acute episodes of recurrent VVC will respond to azole therapy, some patients may require prolonged therapy to achieve remission. To achieve remission, 14 days of topical azole therapy or a second dose of oral fluconazole 150 mg repeated 3 days after the first dose can be used. The practitioner should consider that nonalbicans infections are more common in recurrent VVC; therefore, fluconazole and itraconazole resistance may make these agents less effective.

**Treatment Options for Maintenance Therapy**

Daily

- Itraconazole 100 mg orally once daily
- Ketoconazole 100 mg orally once daily

Weekly

- Clotrimazole 500 mg vaginal suppository once weekly
- Fluconazole 100 or 150 mg orally once weekly
- Terconazole 0.8% cream 5 g vaginally once weekly

Monthly

- Fluconazole 150 mg orally once monthly
- Itraconazole 400 mg orally once monthly
guidelines, oral fluconazole 100-, 150-, or 200-mg weekly for 6 months is first-line treatment. Cessation of suppressive therapy is associated with resurgence of symptomatic infection in 30% to 50% of women.

TREATMENT OF NONALBICANS INFECTIONS

Treatment response rates are lower for nonalbicans infections. Although an optimal regimen is unknown, use of nonfluconazole azole therapy for 7 to 14 days is recommended. For second-line therapy, boric acid 600 mg in a gelatin capsule administered vaginally daily for 2 weeks is recommended. This regimen provides mycologic cure rates of 40% to 100%, although local irritation often limits its use. Oral itraconazole 200-mg twice daily one day per month for 6 months is also effective. Topical 4% fluocytosine is also effective, but use should be limited due to the potential for resistance.

VVC DURING PREGNANCY

During pregnancy, VVC may prove difficult to treat due to elevated estrogen levels, lower response rates, and frequent recurrences, accompanied by concern for the fetus. Vaginal antifungals remain the preferred treatment during pregnancy, although therapy should continue for 1 to 2 weeks to ensure effectiveness. Most topical antifungals are classified as risk category C, whereas clotrimazole is classified as risk category B. Fluconazole’s risk category classification for the single 150-mg dose is risk category C but category D for all other doses due to case studies of congenital limb deformities with doses of 400 to 800 mg daily during the first trimester.

CULTURAL AWARENESS DURING TREATMENT OF VVC

As with all gynecologic issues, the practitioner is faced with cultural perceptions of female genitalia. In particular, practitioners are treating an increased number of patients who have undergone female genital mutilation. Female genital mutilation, formerly known as female circumcision, describes the intentional alteration or injury of female genitalia. More than 100 million women and girls, particularly in Africa and the Middle East, have undergone such procedures for cultural and religious reasons. Some authorities suggest using the term “genital cutting” when dealing with patients to avoid appearing judgmental. Women who have undergone this procedure suffer acute and chronic complications. Patients with female genital mutilation may suffer from recurrent VVC due to inadequate drainage of vaginal fluids. Regardless of the practitioner’s opinion on female genital mutilation, the practitioner must be sensitive to the patient’s feeling and cultural values.

OUTCOME EVALUATION

Whether using a topical or an oral agent, patients should notice relief of itching and discomfort within 1 to 2 days. The volume of discharge should also begin to decrease within a few days. The entire course of therapy should be continued even if symptoms have resolved. If the condition recurs within 4 weeks or more than four times per year, the patient should be further evaluated for possible non-Candida infections, resistant organism, or other complicating factors, along with assessment of need for long-term suppressive therapy.

Patient Care Process for VVC

**Patient Assessment:**
- Assess the patient’s symptoms to determine whether self-treatment with OTC antifungal therapy is appropriate. OTC preparations should only be recommended for patients who have previously been diagnosed with VVC.
- Review any available diagnostic data, including cultures and KOH preps.
- Obtain a thorough history of prescription, nonprescription, and natural drug product use. Is the patient taking any medications, such as steroids, antibiotics, or immunosuppressants, that may contribute to VVC? Is the patient taking any medications that may interfere with treatment? Any allergies?

**Therapy Evaluation:**
- Determine whether self-treatment with OTC antifungal therapy is appropriate.
- If the patient has had VVC previously, determine what treatments were helpful to the patient in the past.
- Determine whether long-term maintenance therapy is necessary.
- Evaluate the patient for the potential for adverse drug reactions, drug allergies, and drug interactions.
- Determine whether patient has prescription coverage.

**Care Plan Development:**
- Stress the importance of adherence with the antifungal regimen, including lifestyle modifications.
- Educate the patient on lifestyle modifications that may prevent recurrence, including wearing loose clothing, increased consumption of yogurt containing live cultures, and wearing cotton underwear.
- Provide patient education pertaining to vulvovaginal candidiasis and antifungal therapy, including causes, medication administration, adverse effects of vaginal agents on latex condoms, and potential adverse effects.
- Discuss warning signs to report to a practitioner such as recurrent or difficult-to-cure infections or infections with malodorous discharge.

**Follow-Up Evaluation:**
- Follow-up only necessary of treatment failure or recurrence.

OROPHARYNGEAL AND ESOPHAGEAL CANDIDIASIS

Oropharyngeal candidiasis (OPC) is a common fungal infection, often associated with immune suppression. If left untreated, it will progress to more serious oral disease, such as esophageal candidiasis.

**EPIDEMIOLOGY AND ETIOLOGY**

The occurrence of oropharyngeal and esophageal candidiasis is an indicator of immune suppression, often developing in infants, the elderly, and the immunocompromised. One-third to
one-half of geriatric inpatients develop oropharyngeal candidiasis. Denture stomatitis is present in approximately 40% of denture wearers, more commonly in women than men. Oral candidiasis is the most commonly reported adverse drug event reported by patients receiving inhaled corticosteroids, with the prevalence of esophageal candidiasis reaching 37% among patients treated with inhaled corticosteroids. The incidence of esophageal candidiasis is highest among patients receiving high doses of corticosteroids or with diabetes.

The prevalence of HIV infection plays a significant role in the incidence of oropharyngeal and esophageal candidiasis. In the 1980s, the incidence of oropharyngeal candidiasis increased five-fold, in association with the spread of HIV infections. Although HIV infection remains a risk factor for candidiasis, the introduction of highly active antiretroviral therapy precipitated a decline in the incidence of oral candidiasis to 45.9% to 79.1%, varying by geographic location, race, and therapy.

Oropharyngeal candidiasis remains the most common opportunistic infection in patients with HIV. For the majority of patients, it is the first manifestation of HIV infection. The incidence of oropharyngeal infection increases with decreasing CD4⁺ lymphocyte counts, with an incidence of 59% in patients with a CD4⁺ count less than 350 cells/mm³ (350 × 10⁶/L). Although oropharyngeal candidiasis represents the first manifestation of HIV infection in less than 10% of cases, it is the most common acquired immunodeficiency syndrome (AIDS)-defining disease. The CDC classifies esophageal candidiasis as a Stage 3-defining opportunistic infection in HIV. As with oropharyngeal candidiasis, the incidence of esophageal candidiasis increases with decreasing CD4⁺ counts, therefore is a measure of declining CD4⁺ count or treatment failure.

*Candida albicans* accounts for 80% of cases of OPC and esophageal candidiasis. Over the last 20 years, an increasing incidence of *C. albicans* resistance has been accompanied by an increased incidence of nonalbicans species infections, including *Candida glabrata, Candida tropicalis, Candida krusei*, and *Candida parapsilosis*. In patients with cancer and HIV, the prevalence of *Candida glabrata* infections or mixed *Candida albicans* and *Candida glabrata* infection has been increasing. Such infections tend to be more severe and require larger doses of antifungal agents for treatment.

### PATHOPHYSIOLOGY

Similar to VVC, the development of OPC occurs when the normal environment is altered. *Candida* organisms frequently colonize the oropharynx and mucous membranes. These organisms do not become pathogenic until the environmental balance is disturbed. This occurs in the setting of broad-spectrum antibiotic use, tissue damage (due to chemotherapy, catheter tubing, trauma, or smoking), hyposalivation, or immune deficiency.

### RISK FACTORS

Risk factors for OPC can be found in Table 83–4.

### CLINICAL PRESENTATION AND DIAGNOSIS

See text boxes for clinical presentation and diagnosis of OPC and esophageal candidiasis.

### TREATMENT

Along with selecting an effective treatment, selection of an appropriate antifungal agent requires consideration of location and severity of infection, medication adherence, potential drug interactions, concomitant medical conditions, and presence of suprue or dextrose. Topical agents require frequent dosing and prolonged contact time with oral mucosa. Rough surfaces of tablets and troches may irritate sensitive mucosa. Patients with xerostomia may have inadequate saliva to dissolve troches. Topical agents containing sucrase or dextrose may increase the risk of caries or cause elevated blood sugar in patients with diabetes. Along with being expensive, oral azoles exhibit an increased risk of toxicity and drug interactions due to inhibition of CYP-450.

Because oropharyngeal and esophageal candidiasis are signs of immunocompromise, the immune status of the patient should be considered in the therapeutic care plan. For HIV-infected patients, this should also include an evaluation of the patient’s antiretroviral therapy because fungal infections may represent immune status deterioration.

#### Key Concept

For low-risk patients, topical agents are first-line therapy for oropharyngeal candidiasis, although systemic agents may be used for severe or unresponsive cases. Infectious Disease Society of America (ISDA) guidelines recommend nystatin suspension four times per day or clotrimazole troches 10 mg five times per day for mild infections. Once-daily oral fluconazole is reserved for moderate-to-severe cases. Two weeks of oral itraconazole 200-mg or posaconazole 400-mg daily, voriconazole 200-mg twice daily, or amphotericin-B suspension are alternatives, typically reserved for refractory cases.

For non–HIV-infected patients who have suppressed immune systems, the practitioner must consider the patient’s risk of dissemination. Patients with cell-mediated immune deficiency but near-normal granulocyte function, such as patients with diabetes, solid organ transplant, or solid tumors, are at low risk for dissemination. The risk of dissemination is higher in patients who develop neutropenia, including patients with leukemia or bone

Clinical Presentation and Diagnosis of Oropharyngeal Candidiasis

OPC is often a presumptive diagnosis based on signs and symptoms, along with the resolution of them after treatment with antifungal agents.

**Symptoms**
- Sore, painful mouth and tongue
- Burning tongue
- Dysphagia
- Metallic taste

**Signs**
Signs vary depending on the type of oropharyngeal candidiasis.
- Diffuse erythema on the surface of buccal mucosa, throat, tongue, and gums
- White patches on tongue, gums, or buccal mucosa; removal of patches reveals erythematous and bloody tissue; ability to remove patches distinguishes OPC from oral hairy leukoplakia
- Angular cheilitis presents with small cracking lesions, erythema, and soreness at the corners of the mouth; associated with vitamin and iron deficiency

**Diagnostic Testing**
Diagnosis is primarily based on identification of characteristic lesions. Although rarely necessary, diagnostic testing is possible if a definitive diagnosis is required.
- Cytology, although presence of *Candida* is not diagnostic because colonization is common
- Culture to identify species of yeast or presence of resistance
- Biopsy

The significant morbidity associated with esophageal candidiasis warrants aggressive treatment.

The ISDA recommends 2 to 3 weeks of fluconazole 200 to 400 mg for esophageal candidiasis, with an echinocandin or amphotericin-B as alternatives in patients unable to tolerate oral therapy, or with resistant or refractory disease. Itraconazole 200-mg daily, posaconazole 400-mg twice daily, or voriconazole 200-mg twice daily are considered second-line therapy. If immunocompromised patients experience frequent or severe recurrences, particularly of esophageal candidiasis, chronic maintenance therapy with fluconazole 100 to 200 mg daily should be considered.

Clinical Presentation and Diagnosis of Esophageal Candidiasis

**Symptoms**
- Fever
- Odynophagia
- Dysphagia
- Retrosternal pain

**Signs**
- Fever
- Hyperemic or edematous white plaques
- Ulceration of esophagus
- Increased mucosal friability
- Narrowing of lumen

**Diagnostic Testing**
Unlike OPC, diagnosis of esophageal candidiasis is not based solely on clinical presentation, instead requiring endoscopic visualization of lesions and culture confirmation. Due to the invasive nature of these procedures, most practitioners opt to treat the infection presumptively, reserving endoscopic evaluation for patients who fail therapy.
- Cytology and culture to identify species of yeast or presence of resistance
- Barium esophagogram
- Endoscopy revealing whitish plaques with progression to superficial ulceration of the esophageal mucosa
- Mucosal biopsy
OUTCOME EVALUATION

- Patients should notice symptomatic relief within 2 to 3 days of initiating therapy. Complete resolution typically occurs within 7 to 10 days. The entire course of therapy should be continued even if symptoms have resolved. If the condition does not resolve or worsens, the patient should be referred to a specialist for aggressive therapy.
- Short courses of oral azoles are associated with gastrointestinal upset, whereas courses lasting longer than 7 to 10 days are associated with increased risk of hepatotoxicity and CYP-450 drug interactions. In patients receiving prolonged therapy lasting more than 3 weeks, periodic monitoring of liver function tests should be considered.
- Immunocompetent patients generally do not require reassessment after treatment. Patients with neutropenia exhibit an increased risk of dissemination of infection and therefore should be monitored for signs of systemic fungal infection. Due to an increased risk of recurrence, HIV-positive patients should routinely be evaluated for recurrence at each visit.

Patient Encounter 2

A 29-year-old man presents to your clinic stating that he noticed “this funny white stuff” in his mouth, along with “burning and soreness in my mouth.” He also mentions that he has a metallic taste in his mouth.

On initial examination, he has white patches on his tongue, gums, and buccal mucosa. These patches are easily removed, revealing erythematous tissue underneath.

His medical record shows that he recently completed a course of azithromycin and steroids for pneumonia.

What additional information do you need to know before creating a treatment plan for this patient?
What underlying medical conditions might make him susceptible to fungal infections?
How is the treatment care plan altered if the patient has a history of frequent and severe OPC? If the patient is HIV-positive? If the patient is neutropenic?

MYCOTIC INFECTIONS OF THE SKIN, HAIR, AND NAILS

Tinea infections are superficial fungal infections in which the pathogen remains within the keratinous layers of the skin or nails (Table 83–5). Typically these infections are named for the affected body part, such as tinea pedis (feet), tinea cruris (groin), and tinea corporis (body). Tinea infections are commonly referred to as ringworm due to the characteristic circular lesions. In actuality, tinea lesions can vary from rings to scales and single or multiple lesions.

EPIDEMIOLOGY AND ETIOLOGY

Tinea infections are second only to acne in frequency of reported skin disease. The common tinea infections are tinea pedis, tinea corporis, and tinea cruris. Tinea pedis, the most prevalent cutaneous fungal infection, afflicts more than 25 million people annually in the United States.

Patient Care Process of Oropharyngeal Candidiasis

Patient Assessment:
- Assess the patient’s symptoms to determine whether symptoms are consistent with oropharyngeal or esophageal candidiasis.
- Review any available diagnostic data, including cultures.
- Evaluate for risk factor, such as immunocompromise.
- Review the medical history. Does the patient have compelling indications or contraindications for specific antifungal treatment?
- Review available laboratory tests, especially liver function.
- Obtain a thorough history of prescription, nonprescription, and natural drug product use. Is the patient taking any medications that may contribute to candidiasis? Is the patient taking any medications that may interfere with treatment?
- Determine if the patient has any allergies.

Therapy Evaluation:
- If the patient has had oropharyngeal or esophageal candidiasis previously, determine what treatments were helpful to the patient in the past.
- If the patient has had oropharyngeal or esophageal candidiasis previously, determine whether the patient has risk factors for recurrent infection.
- Determine whether long-term suppressive therapy is necessary.
- Evaluate the patient for the potential of adverse drug reactions, drug allergies, or drug interactions.

Care Plan Development:
- Stress the importance of adherence with the antifungal regimen until complete.
- Provide patient education pertaining to oropharyngeal or esophageal candidiasis and antifungal therapy, including causes, risk factors, medication administration, potential adverse effects, potential medication interactions.
- Discuss warning signs to report, include recurrence or worsening symptoms.

Follow-Up Evaluation:
- Follow-up if symptoms do not resolve within 7 days or if symptoms worsen.
- Follow-up on any identifiable precipitating cause, such as immunocompromise.
### Table 83–5

**Signs, Symptoms, and Risk Factors of Superficial Fungal Infections**

<table>
<thead>
<tr>
<th>Infection</th>
<th>Symptoms, Signs, and Risk Factors</th>
</tr>
</thead>
</table>
| Tinea pedis    | - Involves plantar surface and interdigital spaces of foot  
- Interdigital infections produce itching; presents as fissures, scaling, or macerated skin; can occur between any toes but most often between fourth and fifth toes; may cause foul smell due to superinfection with *Pseudomonas* or diphtheroids  
- Hyperkeratotic infections present with slivery white scales on a thickened, red base; usually covers entire foot; occasionally may also affect hand  
- Vesiculobullous tinea pedis presents as pustules or vesicles on soles of feet; associated with maceration, itching, and thickening of sole; may cause lymphangitis and cellulitis; most common during summer months  
- Ulcerative tinea pedis presents as macerated, denuded, and weeping ulcers on soles; may produce extreme pain and erosion of interdigital spaces; typically complicated by opportunistic gram-negative infections  
- Risk factors include occlusive footwear, foot trauma, and use of public showers |
| Tinea manuum   | - Infection of the interdigital and palmar surfaces  
- Presents as white scales in palmar folds; may also develop scales on remainder of palm; may present as singular plaque  
- More commonly affecting only one hand  
- Presents with hyperkeratotic skin |
| Tinea cruris   | - Presents with follicular papules and pustules on the medial thigh and inguinal folds  
- Ringed lesions may extend from inguinal fold over adjacent inner thigh  
- Lesions usually spare the penis and scrotum, in contrast to candidiasis  
- Frequency increases during summer  
- Primarily develops in young men  
- Risk factors include tight-fitting clothing, excessive sweating, poor hygiene, increased humidity and temperatures  
- Commonly referred to as “jock itch” |
| Tinea corporis | - Presents with circular, scaly patch with enlarged border  
- Lesions may have red papules or plaque in center that clears, leaving hypopigmentation or hyperpigmentation  
- Itching may be present  
- Commonly referred to as ringworm of the body  
- Risk factors include animal to human contact |
| Tinea versicolor | - Characterized by skin depigmentation but can present as hyperpigmentation, particularly in dark-skinned patients  
- Typically occurs in areas with sebaceous glands, including neck, trunk, and arms  
- Depigmentation may persist for years  
- Primarily develops in young and middle-aged adults  
- Risk factors include application of oil, greasy skin, high ambient temperature, high relative humidity, tight-fitting clothing, immunodeficiency, malnutrition, hereditary predisposition |
| Tinea barbae   | - Infection of beard area |
| Tinea capitis  | - Infection of the head and scalp  
- May be asymptomatic initially, then progresses to inflammatory alopecia  
- “Black dot” alopecia may develop due to breakage of hair at the root  
- May form kerions (nodular swellings)  
- Scaling or favus may develop on scalp  
- Cervical lymphadenopathy is common  
- Primarily found in infants, children, and young adolescents, often in African American and Hispanic populations  
- Can be spread from person to person or animal to person  
- Infection of nail plate and bed  
- Nail becomes opaque, thick, rough, yellow or brownish, and friable; nail may separate from bed  
- Toenails affected more frequently than fingernails  
- Prevalence increases with advanced age |

Fungal skin infections are primarily caused by dermatophytes such as *Trichophyton*, *Microsporum*, and *Epidermophyton*. *Trichophyton rubrum* accounts for more than 75% of all cases in the United States. To a lesser extent, *Candida* and other fungal species cause skin infections. With tinea infections, the causative dermatophyte typically invades the stratum corneum without penetration into the living tissues, leading to a localized infection.

### PATHOPHYSIOLOGY

The primary mode of transmission of tinea infections is direct contact with other persons or surface reservoirs. Upon contact, the dermatophytes attach to the keratinized cells, leading to thickening of the cells. Although infection remains localized, bacterial superinfections may develop.

The pathophysiology of onychomycosis depends on the clinical type. With the most common form of onychomycosis, distal
lateral subungual, the fungus spreads from the plantar skin. The fungus invades the underside of the nail through the distal lateral nail bed, leading to inflammation of the area. In cases of white superficial onychomycosis, the fungus invades the surface of the nail plate directly. With white superficial onychomycosis, the nail bed and hyponychium are infected secondarily. Proximal subungual onychomycosis infections begin in the cuticle and the proximal nail fold, then penetrate the dorsum of the nail plate.

RISK FACTORS
- Prolonged exposure to sweaty clothing
- Excessive skin folds
- Sedentary lifestyle
- Warm, humid climate
- Use of public pools
- Walking barefoot in public areas
- Skin trauma
- Poor nutrition
- Diabetes mellitus
- Immunocompromise
- Impaired circulation

TREATMENT
Nonpharmacologic Therapy
- Because fungi thrive in warm, moist environments, the practitioner should encourage patients to wear loose-fitting clothing and socks, preferably garments made of cotton or other fabrics that wick moisture away from the body. Avoid clothing made with synthetic fibers or wool.
- Sweaty or wet clothing should be removed as soon as possible.
- Clean the infected area daily with soap and water.
- The infected area should be dried completely prior to dressing, paying particular attention to skin folds.

Pharmacologic Therapy of Tinea Infections

KEY CONCEPT Since dermatophyte hyphae seldom penetrate into the living layers of the skin, instead remaining in the stratum corneum, most infections can be treated with topical antifungals. Infections covering large areas of the body, infections involving nails or hair, chronic infections, or infections not responding to topical therapy may require systemic therapy. Treatment is typically initiated based on symptoms, rather than on microscopic evaluation. For infections accompanied by inflammation, combination therapy with a topical steroid can be considered (Tables 83–6, 83–7, and 83–8).

Typically, tinea pedis requires treatment one to two times daily for 4 weeks, whereas tinea corporis and tinea cruris require topical treatment one to two times daily for 2 weeks. When applying treatment, the medication should be applied at least 1 in beyond the affected area. Treatment of infection should continue at least 1 week after resolution of symptoms. Many practitioners opt to initiate therapy with nonprescription clotrimazole, tolnaftate, miconazole, or terbinafine, reserving prescription topical agents, such as naftifine, ciclopirox, and butenafine, for second-line therapy or refractory cases and systemic therapy for refractory cases.

When recommending topical therapy, the selection of vehicle is based on the type of lesion and location of the infection. Solutions and lotions are recommended for hairy areas and oozing lesions, whereas creams and ointments should be avoided in these areas. Creams are better for moderately scaling and nonoozing lesions. For hyperkeratotic lesions, ointments can be considered. The selected formulation should be applied to the affected area after it is cleaned and dried. The medication should be rubbed into the infected area for improved penetration. Because most patients do not rub in sprays and powders, penetration of the epidermis is minimal, making them less effective than other formulations. Sprays and powders should

Patient Encounter 3
A middle-aged man presents to the clinic complaining of painful red areas on his feet, particularly between his toes. He said this has been going on for a few weeks and he thought it might be athlete’s foot so he sprayed antifungal powder inside his running shoes, rather than on his feet “since my feet are in those shoes for hours each day when I run anyway.” When that did not work, the raw skin became so painful that he had to stop training for his next ultra-marathon.

What information is suggestive of tinea pedis?
What risk factors are present for tinea pedis?
What nonpharmacologic approaches can be recommended to prevent recurrence?

- To allow circulation of air, the infected area should not be bandaged.
- For foot infections, cotton socks are recommended, although these should be changed two to three times a day to reduce moisture.
- To prevent spread, towels, clothing, and footwear should not be shared with other persons.
- Wear protective footwear in public showers and pool areas.
be considered as adjuvant therapy with a cream or lotion or as prophylactic therapy to prevent recurrence.\(^7\)

Due to the severity of infection and inflammation, tinea capitis does not adequately respond to topical agents; therefore, oral agents for 6 to 8 weeks are recommended. Griseofulvin has long been considered the treatment of choice due to its ability to achieve high levels within the stratum corneum. Itraconazole has also demonstrated effectiveness. Due to its lipophilicity, itraconazole achieves high dermal concentrations that are maintained for 4 weeks after discontinuation of therapy.

### Treatment of Onychomycosis

For onychomycosis, a chronic infection that rarely remits spontaneously, adequate treatment is essential to prevent spread to other sites, secondary bacterial infections, cellulitis, or gangrene.** Key Concept **Due to the chronic nature and impenetrability of nails, topical agents have low efficacy rates for treating onychomycosis. Oral agents that can penetrate the nail matrix and nail base, such as itraconazole and terbinafine, are more effective than ciclopirox lacquer, efinaconazole solution, or tavaborole solution. Itraconazole (200 mg twice daily for 1 week per month or 200 mg daily for 12 weeks) and terbinafine (250 mg daily for 12 weeks) demonstrate mycological cure rates of 71% and 77%, respectively, whereas the cure rate range from 29% to 36% for ciclopirox, approximately 55% for efinaconazole, and 35% for tavaborole.\(^23\) For patients with liver disease or who are unable to use oral agents, ciclopirox lacquer, efinaconazole solution, and tavaborole solution remain reasonable alternatives, despite requiring 48 weeks of therapy. Due to low efficacy, griseofulvin should only be considered as second-line therapy with therapy continued for 4 months for fingernail infections or 6 months for toenail infections.

The FDA has released warnings pertaining to itraconazole and terbinafine as there is a small but real risk of developing congestive heart failure with itraconazole therapy due to its negative inotropic effects. Itraconazole should not be administered to patients with ventricular dysfunction such as congestive heart failure. The FDA also released warnings that itraconazole and terbinafine are associated with serious hepatic toxicity, including liver failure and death. Liver failure associated with these medications has occurred in patients with no preexisting living disease or serious underlying medical conditions. Treatment with itraconazole or terbinafine for prolonged periods requires laboratory monitoring of liver function tests before initiation of therapy and at monthly intervals.

Patient Care Process for Mycotic Infections

Patient Assessment:
- Assess the patient’s symptoms to determine whether self-treatment with OTC antifungal therapy is appropriate. Exclusions for self-treatment include infection of nails or hair, unsuccessful initial treatment, worsening condition, signs of secondary bacterial or systemic infection, large infected areas, or chronic medical conditions such as diabetes, immunosuppression, or impaired circulation.
- Review any available diagnostic data, including cultures and KOH preps.
- Obtain a thorough history of prescription, nonprescription, and natural drug product use. Any allergies?

Therapy Evaluation:
- If the patient has had a mycotic infection previously, determine what treatments were helpful to the patient in the past.
- Determine whether long-term prophylactic therapy is necessary to prevent recurrence.
- Determine whether the patient has prescription coverage.

Care Plan Development:
- Evaluate the patient for the potential for adverse drug reactions, drug allergies, and drug interactions.
- Educate the patient on lifestyle modifications that will prevent recurrence, including keeping the area dry, wearing shower shoes, washing clothing in hot water, using drying powders, avoiding sharing towels or clothing, and wearing loose-fitting clothing.
- Provide the patient education pertaining to mycotic infections and antifungal therapy, including causes, medication application or administration, length of therapy, how to avoid spread of infection or recurrence, and potential adverse effects.
- Discuss dietary modifications that are necessary with oral agents.
- Discuss medications that may interact with antifungal therapy, particularly with oral agents used for nail infections.
- Discuss warning signs to report such as recurrent or difficult-to-cure infections, infections with malodorous discharge or bleeding.
- Stress the importance of adherence with the antifungal regimen.

Follow-Up Evaluation:
- Follow-up if unresolved or worsens with treatment.

Cultural Awareness When Treating Mycotic Infections

Awareness of cultural beliefs related to feet and hands is essential when treating patients with fungal infections. In Arab countries, showing the bottom of the foot is a grave insult. The foot is considered the dirtiest part of the body. As such, patients from these countries may be hesitant to show their feet to the practitioner. In other countries, the open palm “high five” gesture is considered insulting. When treating patients with infections on the hand, the practitioner should refrain from making this gesture while discussing the patient’s hand infection.

OUTCOME EVALUATION

For infections of the skin, patients should notice relief of symptoms, including pruritus, scales, and inflammation, within 1 to 2 weeks. Therapy should be continued at least 1 week after complete resolution of symptoms. If the condition worsens on topical therapy, the patient should be treated with oral therapy.

For onychomycosis, relief of symptoms is slow. The infected nail will need months to grow out. The practitioner should advise the patient not to become frustrated by the slow resolution. Despite the slow progress, the antifungal agent is curing the infection. The practitioner should also advise the patient that even after the infection is cured, the nail may not look “normal.”

Abbreviations Introduced in This Chapter

AIDS Acquired immunodeficiency syndrome
CDC Centers for Disease Control and Prevention
HIV Human immunodeficiency virus
KOH Potassium hydroxide
OPC Oropharyngeal candidiasis
OTC Over the counter
PAS Periodic acid-Schiff test
VVC Vulvovaginal candidiasis

INTRODUCTION

Invasive fungal infection or invasive mycoses are general terms for diseases caused by invasion of living tissue by fungi. In contrast to superficial mycoses (see Chapter 83), invasive fungal infections are much less common, but are of greater medical concern because of their disproportionately higher severity and mortality. Approximately 1.5 million people die each year from the 10 most common invasive fungal infections, which is higher than World Health Organization mortality estimates for tuberculosis (1.4 million) or malaria (1.2 million).

Invasive fungal infections are broadly categorized as either primary or opportunistic mycoses. Primary invasive fungal infections develop following exposure to fungal spores or conidia in the soil that, when disturbed, can become aerosolized and inhaled leading to infection, even in an immunocompetent patient exposed to a sufficient inoculum. Because these fungi are in specific soil types in select geographic areas, they are also referred to as endemic fungi. In the United States, three Genera (Histoplasma capsulatum, Blastomyces dermatitidis, and Coccidioides immitis/ Coccidioides posadasii) account for most of these infections (see Table 84–1).

In contrast, opportunistic fungal infections are most frequently encountered in setting of compromised host immune defenses, and are caused by a wider spectrum of less virulent fungal species that rarely cause infection in healthy patients (see Table 84–1). Hence, the spectrum, severity, and outcome of opportunistic fungal infections are strongly influenced by the degree, type, and severity of host immunosuppression. As a general rule, opportunistic fungal infections are difficult to diagnose, but often fatal if not diagnosed early and treated aggressively.

Occasionally, opportunistic fungal pathogens may be associated with outbreaks of invasive disease in otherwise nonimmunocompromised patients, especially if they are inadvertently inoculated into patients from contaminated drug solutions or medical devices. For example, in 2012 an outbreak of fungal meningitis and articular infections (n=751 cases) in 20 states was eventually traced by the Centers for Disease Control and state health departments to contaminated preservative-free methylprednisolone solution used for epidural and articular injections in patients with chronic back or joint pain. The dematiaceous mold eventually linked to the fungal meningitis cases, Exserohilum rostratum, had rarely been described as a human pathogen prior to the outbreak.

EPIDEMIOLOGY AND ETIOLOGY

Endemic mycoses are capable of infecting otherwise healthy individuals. In immunocompromised patients, endemic fungal infections present with a more fulminant course (in the case of primary infections, or reactivate to cause life-threatening infection). Because initial symptoms of an endemic fungal infection are nonspecific and produce symptoms indistinguishable from other slowly progressing infections (e.g., tuberculosis), a careful patient history concerning travel and activities that may have resulted in exposure to endemic fungi is essential for early diagnosis.

Two of the most common endemic fungal infections (histoplasmosis and North American blastomycosis) are found in overlapping regions in the eastern and central river basins of the United States (Figure 84–1). H. capsulatum var. capsulatum, the causative fungus of histoplasmosis, grows heavily in soil contaminated with bird or bat excreta, which serve to enhance sporulation of the fungus. Infections have been associated with activities that disturb soil contaminated with this excreta, including cave exploration (spelunking), working in or demolishing chicken coops or older buildings, or cleaning working in...
Invasive Mycoses

**Primary (Endemic) Invasive Fungi**
- *Histoplasma capsulatum*
- *Coccidioides immitis/Coccidioides posadasii*
- *Blastomyces dermatitidis*

**Opportunistic Invasive Fungi**

### Yeast
- *Candida* species (e.g., *C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. krusei,* and others)
- *Cryptococcus neoformans*
- *Trichosporon* spp. and others

### Mold
- *Hyalohyphomycoses (nondematiaceous)*: *Aspergillus fumigatus, Aspergillus terreus, Aspergillus flavus,* and other species
- *Fusarium solani* and *Fusarium oxysporum*
- *Mucorales (formally zygomycosis) (Mucor, Absidia, Rhizopus, Cunninghamella, and Rhizomucor)*
- *Penicillium* species
- *Phaeohyphomycoses (dematiaceous)*: *Pseudallescheria boydii (Scedosporium spp.), Bipolaris, Alternaria, Exserohilum rostratum*

### Other
- *Pneumocystis jiroveci (formerly P. carinii)*

*Most common.

**Pathophysiology**

Endemic fungi share several key biologic and ecologic characteristics that contribute to their pathogenicity in humans. All endemic fungi exhibit temperature-dependent dimorphism, meaning they can propagate as either yeast (single cells that reproduce by budding into daughter cells) or molds (multicellular filamentous fungi that reproduce through production of conidia or spores). At environmental temperatures (25–30°C [77–86°F]), *H. capsulatum, B. dermatitidis,* and *C. immitis* grow in the mold form, producing 2- to 10-μm round- to oval-shaped (*Histoplasma* and *Blastomyces*) or barrel-shaped conidia (*Coccidioides*) that are dispersed throughout the environment and in air currents. At physiologic temperatures, the conidia germinate into yeast (*Histoplasma* and *Blastomyces*) or in specialized cell forms called spherules (*Coccidioides*) that are resistant to killing by alveolar macrophages and neutrophils in the host lung.

Control of infection by the host requires the development of antigen-specific T-lymphocyte response that enhances macrophage fungicidal activity and formation of a granuloma to contain the infection.
Dissemination of the fungi to bone marrow may result in verrucose (wart-like) skin lesions on sun-exposed areas. Dissemination outside the lung is common in patients with fulminant pneumonia, which may be seen with high inoculum exposures, resulting in diffuse lung infiltrates that precede acute respiratory distress syndrome (ARDS) and respiratory failure.

**Signs and Symptoms**

- Rheumatologic symptoms such as severe arthritis, pericarditis, and erythema nodosum may be seen in 10% to 30% of patients with endemic fungi.
- Dissemination outside the lung is common in patients with suppressed cellular immunity and frequently produces signs of progressing infection.
- Ulcerative oral and cutaneous lesions may also arise with any endemic fungal infections.
- Verrucose (wart-like) skin lesions on sun-exposed areas on the face are particularly suggestive of progressing blastomycosis and are frequently mistaken for cutaneous malignancy.
- Dissemination of the fungi to bone marrow may result in anemia or thrombocytopenia.
- Hepatomegaly, splenomegaly, and adrenal insufficiency can also occur with dissemination of the endemic fungi to these internal organs.
- Seizures, meningeal signs, and hydrocephalus are common findings with dissemination of the infection to the CNS and portend an especially poor prognosis in the setting of disseminated coccidioidomycosis.

Definitive diagnosis of an endemic fungal infection requires growth of the fungus from body fluids or tissue, or evidence of cellular or tissue invasion in clinical samples by histopathology. However, cultures may only be positive in the setting of high inoculum exposures, pneumonia, or disseminated disease. Serologic testing is helpful in the diagnosis and management of patients with histoplasmosis or coccidioidomycosis, but lacks specificity for diagnosis of *B. dermatitidis*. In general, a fourfold rise in antibody or complement fixation titers of *Histoplasma* or *Coccidioides* or any titer greater than 1:16 suggests active infection. However, many clinicians still consider titers as low as 1:8 as evidence of active disease because undetectable titers may...

**Patient Encounter 1, Part 1: Endemic Fungal Infection**

A 54-year-old African American woman from Phoenix, Arizona, with a history of steroid-refractory Crohn disease presents with a 3-week history of cough, fever, night sweats, and 7-kg weight loss. Approximately 6 weeks before this presentation, she was treated with infliximab and a 7-day course of amoxicillin-clavulanate. The patient complains of fatigue but is afebrile (37°C), with a normal resting respiratory rate. Laboratory studies revealed anemia (hemoglobin less than 8.7 g/dL [87 g/L or 5.40 mmol/L]). A chest x-ray taken 1 week ago is reported as normal.

**What information is suggestive that this patient may have an endemic fungal infection?**

**What is the most likely endemic fungal pathogen based on this patient’s area of residence?**

---

**CLINICAL PRESENTATION AND DIAGNOSIS**

Histoplasmosis and coccidioidomycosis are frequently asymptomatic infections in immunocompetent patients or present as a self-limiting, influenza-like or mild lower-respiratory tract illness 1 to 3 weeks after inhalation of conidia. The clinical presentation of blastomycosis can range from asymptomatic infection to acute or chronic pneumonia that develops 30 to 40 days after exposure, to full-blown disseminated disease.

More severe endemic fungal disease presents as persistent pneumonia despite antibiotic therapy that is accompanied by fever, chills, cough, arthralgia, night sweats, and weight loss that may be indistinguishable from other chronic infections such as pulmonary tuberculosis. **Key Concept** The diagnosis of endemic fungal infection is often prompted by a patient history of prolonged infectious symptoms, travel or residence in an endemic area, and/or participation in activities that result in exposures to soil contaminated by endemic fungi.

**Radiographs**

- Chest radiographs often reveal either diffuse or nodular infiltrates in the lung, accompanied by enlargement of the hilar and/or mediastinal lymph nodes.

---

**FIGURE 84–2.** Histopathology of endemic mycoses in tissue. (A) Histoplasmosis (yeast), (B) Blastomycoses (broad-based budding yeast), (C) Coccidioidomycoses (spherules with endospores).
be present in one-third of all active infections.\(^5\) Enzyme-linked immunosorbent assays (ELISAs) have been developed for direct detection of *Histoplasma* antigens in serum and urine. Serial antigen testing can also provide a means for assessing response of histoplasmosis to antifungal therapy and detection of relapsing disease.\(^3\)

**TREATMENT**

**KEY CONCEPT** The approach to antifungal therapy in patients with endemic fungal infections is determined by the severity of clinical presentation, the patient’s underlying immunosuppression, and potential toxicities and drug interactions associated with antifungal treatment. Immune-competent patients with mild disease following exposure to *H. capsulatum* or *C. immitis* often experience a benign course of infection that does not require antifungal therapy. Persons of Filipino or African descent have a higher risk for dissemination with *C. immitis*, and this may also be taken into consideration for more aggressive treatment.\(^5\) Approximately 9% of patients exposed to coccidioidomycosis (defined by positive IgM or IgG serology) develop pneumonia requiring hospitalization, and 1% may develop infections of the CNS, which are difficult to treat if not incurable.\(^5\)

Patients with mild disease may be initially followed in the outpatient setting with serial antigen or serologic studies to confirm resolving infection. Patients without clinical improvement within the first month can be treated with oral itraconazole for 6 to 12 weeks (Table 84–2).\(^3,5\) Broader-spectrum triazoles such as voriconazole and posaconazole, and in the future possibly isavuconazole, appear to have clinically-useful activity against endemic fungi; but have limited data to recommend their routine first-line use. Fluconazole (400–800 mg/day) is somewhat less effective than itraconazole (higher relapse rates), but has fewer GI adverse effects and drug interactions versus itraconazole. Echinocandins and flucytosine are not clinically useful agents for the treatment of endemic mycoses.

CNS, central nervous system; IV, intravenous; PO, oral.

*CrCl more than 50–90 mL/min (0.83–1.50 mL/s), 100% of dose; CrCl 10–50 mL/min (0.17–0.83 mL/s), 50% of dose; CrCl less than 10 mL/min (0.17 mL/s) 50%.*
Patients with progressive symptoms for longer than 2 weeks, greater than 10% weight loss, extensive pneumonia, or serologic titers greater than 1:8 of histoplasmosis or coccidioidomycosis are candidates for immediate antifungal therapy. Any patient with underlying immunosuppression should also receive immediate antifungal therapy. The following signs and symptoms are considered to be indicators of severe disease that require hospitalization and initial treatment with systemic amphotericin B (see Table 84–2). 3–5

- Hypoxia indicated by a partial pressure of oxygen less than 80 mm Hg (10.6 kPa)
- Hypotension (systolic blood pressure less than 90 mm Hg)
- Impaired mental status
- Anemia (hemoglobin less than 10 g/dL [100 g/L or 6.2 mmol/L])
- Leukopenia (less than $1 \times 10^9$/mm$^3$ [$1 \times 10^9$/L])
- Elevated hepatic transaminases (greater than five times upper limit of normal) or bilirubin (greater than 2.5 times upper limit of normal)
- Coagulopathy
- Evidence of dissemination, including cutaneous manifestations
- Meningitis

All patients with blastomycosis require antifungal treatment, even though patients with mild disease can be managed as outpatients with oral itraconazole. 4 Patients with evidence of severe pulmonary disease or dissemination require initial treatment in the hospital with amphotericin B–based regimens until they are clinically stable, whereupon they can complete a 6- to 12-month treatment course as outpatients with oral triazoles. 5 Methylprednisolone (0.5–1 mg/kg daily IV) may be administered during the first 1 to 2 weeks of antifungal therapy if the patient develops respiratory complications, including hypoxemia or significant respiratory distress.

**OUTCOME EVALUATION**

Response to antifungal therapy may be slow in patients with a prolonged history of infection or severe manifestations. However, gradual improvements in symptoms and reduction in fever are indicators of response to treatment. For histoplasmosis and coccidioidomycosis, decreasing antigen titers or serology are indicative of response to antifungal therapy. 6

Antifungals used for the treatment of endemic mycoses can be associated with clinically significant drug interactions and toxicities, especially with the prolonged treatment courses that are often required for endemic mycoses. Itraconazole is available as a capsule formulation and as a cycloextrin-solubilized solution. The liquid formulation of itraconazole has several advantages over the capsule: It has a better oral bioavailability and does not require the low gastric pH that is required for dissolution and absorption of the capsule. However, the oral solution is somewhat dilute, has an unpalatable aftertaste (an issue when taking months of therapy), and has a much higher rate of GI intolerance. Therefore, the capsule formulation is often preferred provided patients are not on acid-suppression therapy (ie, proton pump inhibitors, histamine antagonists, or antacids).

Posaconazole is formulated as a micronized suspension that is best absorbed when taken with high-fat meals and when taken in divided doses up to 800 mg/day. A delayed-release tablet formulation with improved bioavailability and fewer gastric pH–associated drug interactions has been introduced, and is probably the preferred oral treatment formulation in most patients unless the patient cannot swallow the tablet. 8 Absorption of voriconazole is not affected by gastric pH, but is generally administered 1 hour prior to or 2 hours after eating.

Drug interactions are an important concern in patients taking long-term triazole therapy. Itraconazole and voriconazole are substrates of the cytochrome P450 (CYP) 3A4 enzyme. 7 Coadministration of itraconazole, voriconazole, and to lesser extent fluconazole and posaconazole, with inducers of this CYP 3A4 (eg, rifampin, phenytoin, and phenobarbital) increases drug clearance resulting in ineffective plasma and tissue concentrations of the drug. 9 In general, coadministration of the broader spectrum triazoles (itraconazole, voriconazole, posaconazole) with these inducers must be avoided. Itraconazole, voriconazole, and posaconazole are also potent inhibitors of CYP 3A4, which predisposes these agents to a large number (estimated greater than 2000) of clinically significant pharmacokinetic drug–drug interactions. 7

Posaconazole is also a substrate and inhibitor of P-glycoprotein, although the impact of this pathway on drug absorption or distribution into some anatomically protected sites such as the CNS is unknown. 10 Consequently, all patients should have their medication profile carefully reviewed prior to initiating and stopping triazole antifungals, preferably with the aid of a computerized drug–drug interactions database. Even in the absence of drug interactions, serum drug levels of the broader spectrum triazoles (itraconazole, voriconazole, posaconazole) are often unpredictable. 11 Serum drug concentration monitoring has been recommended in patients receiving triazole antifungals for documented infections, or when inadequate serum concentrations are suspected because of altered absorption, drug interactions. Suspected toxicities, especially CNS toxicity during voriconazole therapy, may also be indicative of excessive drug levels that can be detected by therapeutic drug monitoring (Table 84–3).

All azole antifungals carry the potential for rash, photosensitivity, and hepatotoxicity. In general, hepatotoxicity is mild and reversible, presenting as asymptomatic increases in liver transaminases, and less frequently increases in total bilirubin. Fulminant hepatic failure is less common and typically mediated by immunologic mechanisms. Therefore, serial monitoring of liver function is recommended in all patients receiving triazole antifungals. Long-term therapy with itraconazole has also been associated with reversible adrenal suppression and cardiomyopathy due to negative inotropic effects of the drug. Long-term therapy with voriconazole can be associated with severe phototoxic reactions and cutaneous erythema in sun-exposed skin, which may not be preventable with sunscreen alone. These reactions have been linked to development of squamous cell carcinoma or melanoma. 12 Patients should be instructed to avoid sun exposure while on voriconazole therapy and have frequent

---

**Patient Encounter 1, Part 2: Endemic Fungal Infection**

**Patient management**

The patient’s serum titer for coccidioidomycosis returns as greater than 1:8. Based on the information presented, select an appropriate treatment plan for the patient’s infection.

4Pediatric patients display accelerated linear clearance of voriconazole. Therefore, higher daily voriconazole dosing (7 mg/kg every 12 hours) without a loading dose are recommended to achieve similar exposures to adults. Some children may require doses as high as 12 mg/kg every 12 hours to achieve similar serum drug exposures to adults. Therefore, therapeutic drug monitoring is recommended.

Amphotericin B remains the mainstay of treatment of patients with severe endemic fungal infections. The conventional deoxycholate formulation of the drug can be associated with substantial infusion-related adverse effects (eg, chills, fever, nausea, rigors, and in rare cases hypotension, flushing, respiratory difficulty, and arrhythmias). As-needed premedication with low doses of hydrocortisone, acetaminophen, nonsteroidal anti-inflammatory agents, and meperidine are used to reduce acute infusion-related reactions. Venous irritation associated with the drug can also lead to thrombophlebitis; hence, central venous catheters are the preferred route of administration in patients receiving more than a week of therapy.

The most severe adverse effect associated with amphotericin B therapy is nephrotoxicity, which occurs through the renal vascular effects of the drug (constriction of the afferent arterioles in the kidney tubule) and direct toxicity to the kidney tubular membrane. Generally, nephrotoxicity with amphotericin B is reversible provided the drug is stopped. However, treatment interruptions can be problematic in patients with severe infections. Precipitous decreases in glomerular filtration may occur in patients with marked dehydration or during aggressive diuresis. Infusion of normal saline before and after amphotericin B, a practice known as “sodium loading,” can blunt precipitous decreases in renal perfusion pressure and slow the rate of decline in the glomerular filtration rate but may not be tolerated in patients with poor cardiac function. Administration of amphotericin B by continuous infusion reduces the nephrotoxicity of the drug but is generally not advocated because of unproven efficacy. Toxicity can be delayed by avoiding the use of other drugs with known tubular toxicity such as aminoglycosides, cyclosporine, cisplatin, or foscartern. Generally, tubular toxicity manifests in patients with severe wasting of potassium and magnesium in the urine. Therefore, patient electrolytes must be carefully monitored and potassium and magnesium supplementation is always necessary. Hypokalemia and hypomagnesaemia frequently precede decreases in glomerular filtration (increased serum creatinine), especially in patients who are adequately hydrated.

Continued tubular damage eventually results in decreases in renal blood flow and glomerular filtration through tubuloglomerular feedback mechanisms that further constrict the afferent arteriole.

During the 1990s, amphotericin B was reformulated into three different lipid-based formulations (Abelcet, AmBisome, and Amphotec) that have reduced rates of nephrotoxicity compared with the conventional deoxycholate formulation (Fungizone). Two of the formulations (Abelcet and AmBisome) have lower rates of infusion-related reactions. Although these lipid formulations are generally considered to be as effective as conventional amphotericin B deoxycholate, they are not dosed equivalently to the standard formulation (see Table 84–2).

PROPHYLAXIS

Primary prophylaxis, before development of infection, is generally not recommended for endemic fungi, but may be considered in specific situations, including the following:

1. Patients with HIV infection with CD4+ cell counts less than 150 cells/mm³ (150 × 10⁶/L) (histoplasmosis) or less than 250 cells/mm³ (250 × 10⁶/L) (coccidioidomycosis) living in regions with high endemic case rates (more than 10 cases per 100 patient-years), or in any patient with positive IgM or IgG antibodies. The recommended regimen is itraconazole 200 mg daily.
2. Secondary prophylaxis or suppressive therapy with itraconazole 200 mg daily is recommended to prevent recurrence of blastomycosis in immunosuppressed patients if immunosuppression cannot be reversed.4
3. In patients with prior CNS disease, fluconazole or voriconazole are preferred over itraconazole and posaconazole due to the lower penetration of itraconazole and posaconazole into the CNS.5

OPPORTUNISTIC MYCOSES

**KEY CONCEPT** Commensal or environmental fungi that are typically harmless can become invasive mycoses when the host immune defenses are impaired. Host immune suppression and risk for opportunistic mycoses can be broadly classified into three categories:

1. Quantitative or qualitative deficits in neutrophil function
2. Deficits in cell-mediated immunity
3. Disruption of the integument and/or microbiologic barriers

Quantitative defects in neutrophils (neutropenia) resulting from neoplastic diseases, cytotoxic chemotherapy, marrow transplantation, or bone marrow aplasia are among the most common risk factors for opportunistic mycoses. Qualitative defects may be seen in certain disease states (eg, advanced diabetes mellitus and chronic granulomatous disease) or with high-dose corticosteroid therapy. Deficits in T-cell–mediated immunity associated with HIV infection, high-dose corticosteroid therapy, calcineurin inhibitors or other immunosuppressive drugs, chemotherapy, transplantation, bone marrow failure, and other immunodeficiencies have become increasingly prevalent with the prolonged survival of transplant patients or other chronically-immunosuppressed populations.

Immune deficits arising from disruption of the integument or GI/genitourinary barriers can also predispose patients to fungal infections. The most common types of barrier disruptions include surgery or infections/perforation of the abdominal vissus, use of central venous and urinary catheters, parenteral nutrition, and mucositis associated with cytotoxic chemotherapy and antibiotic therapy. Broad-spectrum antibacterial therapy disrupts the protective microbiologic flora of the gut, which allows overgrowth of Candida species that can translocate to the bloodstream and invade internal organs.

All of the opportunistic mycoses are difficult to diagnose and often must be treated empirically before diagnosis is proven. Deciding when to initiate antifungal therapy and what opportunistic pathogens to cover is a decision governed largely by the cumulative immune deficits of the host, local epidemiology and experience, or clinical or diagnostic clues suggestive of incipient infection.

INVASIVE CANDIDIASIS

EPIDEMIOLOGY AND ETIOLOGY

Candida species are the most common opportunistic fungal pathogens encountered in hospitals, ranking as the third to fourth most common cause of nosocomial bloodstream infections in the United States.17 The incidence of nosocomial candidiasis has increased steadily since the early 1980s, with the widespread use of central venous catheters, broad-spectrum antimicrobials, and other advancements in the supportive care of critically ill patients. In the 1980s, C. albicans accounted for more than 80% of all bloodstream yeast isolates cultured from patients. By the late 2000s, this relative frequency of C. albicans had decreased to less 50% in national surveys of bloodstream infections with increasing proportion of infections caused by non-albicans species.17,18 Because of the inherent resistance (eg, C. krusei) or diminished susceptibility (eg, C. glabrata) of many of the non-albicans species, the introduction of fluconazole in the early 1990s is often cited as the key element driving the shift in the microbiology of invasive candidiasis. Nevertheless, other factors, including central venous catheters, higher intensity of cytotoxic/mucotoxic chemotherapy, and broad-spectrum antibiotic therapy have also contributed to this trend.19

**KEY CONCEPT** Familiarity with the local epidemiology and frequency of non-albicans Candida species in the institution or intensive care unit (ICU) is essential before selecting empiric antifungal therapy for invasive candidiasis, as fluconazole is not recommended for the treatment of C. glabrata and C. krusei infections, and echinocandin resistance among C. glabrata is increasing in some centers.

CLINICAL PRESENTATION AND DIAGNOSIS

Invasive candidiasis encompasses several infectious syndromes broadly categorized as candidemia or deep-seated infections (infections of tissue sites beneath mucosal surfaces).20 Approximately one-third of all patients with invasive candidiasis fall within three groups at the time of diagnosis: (1) patients with uncomplicated candidemia in the absence of deep-seated candidiasis; most frequently arising from an infected catheter; (2) candidemia associated with deep-seated candidiasis, most frequently arising from the gastrointestinal tract or secondary seeding from a separate infection site; and (3) deep-seated candidiasis without candidemia.20

Focal deep-seated invasive candidiasis can involve virtually any organ, even following apparently uncomplicated catheter-related bloodstream infections. The most common sites of infection are the kidney, eye, and bone. Candida in the urine can be an indication of renal candidiasis or an obstructing fungus ball; however, it must be distinguished from more benign colonization of the urinary tract, especially in patients with chronic indwelling urinary catheters.21 Similarly, Candida species isolated for respiratory samples (sputum, bronchoalveolar lavage) are indicative of colonization, and almost never reflect true pneumonia, which is an uncommon clinical entity. All patients with candidemia should undergo an eye examination to rule out Candida endophthalmitis, which can be sight threatening if not recognized early and may require direct installation of antifungal therapy for adequate treatment.21

Invasive candidiasis is most frequently diagnosed by blood culture, which probably identifies the majority of patients with candidemia alone, fewer patients with mixed of deep-seated disease and intermittent candidemia, and virtually no patients who have infection limited to deep tissues at the time of culture.20 As a result, half of all episodes of invasive candidiasis are not detected by blood cultures alone. Therefore, a negative blood culture cannot rule out the possibility of invasive candidiasis, especially in patients with multiple underlying risk factors for the infection. The development of new diagnostic tools that do not exclusively rely on microbiological isolation of Candida has become a major research focus for improving diagnosis of the infection, especially deep-seated disease.20

Novel serodiagnostic tests have been developed for the detection Candida cell wall antigens, or nucleic acids of Candida.
species, in the hope of improving the detection of invasive disease missed by blood cultures. Currently, the most frequently used test is the Fungitell (1→3)-β-D-glucan test, Associates of Cape Cod Inc.). False-positive results may occur, however, in patients with gram-negative bacteremia, certain gauze dressing or dialysis membranes, or patients heavily colonized with Candida species.

Laboratory identification of Candida in clinical samples must be performed to the species level whenever possible, as Candida species differ considerably in their susceptibility to antifungal agents. Rapid discrimination of C. albicans from common non-albicans Candida species can be accomplished by the germ-tube test, which presumptively identifies C. albicans by the early formation (less than 4 hours) of a hyphae-like structure when the yeast is incubated in serum at 37°C (98.6°F). Definitive species identification, however, may require an additional 48 to 72 hours after the organism is isolated on agar, but can be accelerated with fluorescent in situ hybridization (FISH) of Candida species-specific DNA sequences. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) and magnetic-resonance based technologies have shown some promise in the early identification of Candida species in whole blood specimens in as little as 3 hours, which could shorten the time to earlier diagnosis.

C. albicans remains the most common cause of invasive candidiasis and is the most virulent of Candida species, but is the most susceptible to commonly used antifungals including fluconazole. Like C. albicans, C. tropicalis is a relatively virulent species associated with the highest mortality rates, but has similar susceptibility profiles as C. albicans. C. parapsilosis is a less virulent species seen frequently in neonates and in adults with central venous catheters. However, many C. parapsilosis isolates form thick biofilms on prosthetic materials and catheters that make the organism difficult to eradicate. C. parapsilosis is generally susceptible to most antifungals, including fluconazole, although mean inhibitory concentrations (MICs) for echinocandins are higher than for other Candida species. C. krusei is considered to be uniformly resistant to fluconazole, although most isolates retain susceptibility to voriconazole and posaconazole.

C. glabrata has become a common cause of breakthrough infection on fluconazole prophylaxis, and increasingly during treatment with echinocandins. Although C. glabrata is generally less virulent than other C. albicans, infections with this organism are typically seen in older patients with poor performance status, and therefore mortality remains high. The marginal susceptibility of C. glabrata to fluconazole and increasing echinocandin resistance fueled a growing clinical need for susceptibility testing of this species, as some isolates may demonstrate resistance to multiple antifungal classes. Generally, fluconazole-resistant strains of C. glabrata should be assumed to be cross-resistant to other triazoles.

**TREATMENT**

Six antifungals (amphotericin B, fluconazole, voriconazole, caspofungin, micafungin, and anidulafungin) have been studied as monotherapy in prospective, randomized comparative clinical trials for the treatment of invasive candidiasis. In a patient-level meta-analysis of these trials, increasing patient age, increasing APACHE II score, use of immunosuppressive therapy, and infection with Candida tropicalis were independent risk factors for patient mortality. On the other hand, removal of central venous catheters in patients with candidemia and treatment with an echinocandin were variables associated with reduced patient mortality. Based on these findings and treatment guidelines endorsed by the Infectious Diseases Society of America, echinocandins are recommended as the preferred initial treatment for invasive bloodstream candidiasis, even less “critically-ill” patients. Timely initiation of antifungal therapy for invasive candidiasis is critical, as any delay in the initiation of antifungal therapy once a patient has a positive blood culture increases the potential for metastatic seeding of organs and mortality. Clinically stable patients can be transitioned to oral fluconazole or other triazoles once the infecting isolate has been identified and susceptibility is known.

The efficacy of echinocandins for deep-tissue candidiasis is less well established compared to bloodstream infections, and higher failure rates have been reported for infections located in anatomical sites where echinocandin penetration is limited (ie, meninges, endophthalmitis, urine). For other forms of deep tissue candidiasis, triazoles or lipid amphotericin B formulation may be preferable as initial therapy until diagnosis and culture results are available, depending on the suspected organs involved and the clinical severity of illness. Frequently patients are transitioned to oral triazole therapy once stable because of the long-treatment courses that are often required (4–6 weeks minimum) for deep-seated infections.

Another important caveat for empiric use of echinocandins is that cryptococcosis, endemic fungi, or other rare yeast (eg, Trichosporon species) occasionally produce fungemia in lymphopenic patients that may initially be mistakenly assumed to be Candida. Therefore, initial treatment with a lipid amphotericin B formulation may be judicious in profoundly lymphopenic patients (ie., CD4+ less than 250/mm³ [250 × 10⁶/L]) with yeast in blood cultures until fungal identification is confirmed, as echinocandins have poor activity against non-Candida yeast.

Echinocandins (ie, caspofungin, micafungin, or anidulafungin); voriconazole; or lipid amphotericin B formulation are often administered as empiric treatment for Candida spp in patients with prolonged neutropenia (ie, absolute neutrophil count less than 500 PMN/mm³ [500 × 10⁶/L] for greater than 7 days) with fever. Fluconazole may be an acceptable option...

</table>
in patients expected to have short duration of neutropenia (less than 2 weeks) not receiving systemic antifungal prophylaxis with a triazole. Lipid amphotericin B formulations, an echinocandin, or voriconazole are preferred if the patient has or is expected to have prolonged neutropenia (ie, greater than 2 weeks) because of the increased risk for mold infections. If patients are receiving fluconazole prophylaxis, breakthrough infections with *C. glabrata*, and less frequently *C. krusei*, are possible and should be initially treatable with an echinocandin or amphotericin B.

Urinary candidiasis is a term for an ill-defined group of syndromes that can range from benign colonization (candiduria) in the bladder to invasive disease of the renal parenchyma. Asymptomatic candiduria in nonneutropenic patients does not require antifungal therapy, as transient clearance of *Candida* from the urine of asymptomatic patients has no demonstrable clinical benefit. Patients should receive 7 to 14 days of antifungal therapy for urinary candidiasis if they are (a) symptomatic, (b) have clinical or laboratory evidence of infection, (c) are neutropenic, (d) are low-birth-weight infants; (e) will undergo urologic manipulations, or (f) have renal allografts. Removal of urinary tract instruments, including Foley catheters and stents, is essential to prevent relapse.

The preferred therapy is fluconazole 200 mg daily, although IV amphotericin B deoxycholate 0.3 to 1 mg/kg/day is also effective. Other antifungal agents (with the exception of flucytosine) do not achieve appreciable concentrations in the urine and therefore should not be considered first-line treatments for urinary candidiasis. Irrigation with amphotericin B is not effective for infections above the bladder and should not be used in higher risk patients with the exception of its use as a diagnostic tool for confirming a localized infection of the bladder. *Candida* infections of the renal parenchyma secondary to metastatic seeding from the bloodstream are treated in a similar fashion to candidemia.

**Flucytosine renal dosing adjustments:** CrCl greater than 50–90 mL/min (0.83–1.50 mL/s), 100% of dose; CrCl 10–50 mL/min (0.17–0.83 mL/s), 50% of dose; CrCl less than 10 mL/min (0.17 mL/s) 50%.

**Anidulafungin** 200 mg loading dose day 1, then 100 mg daily, caspofungin 70 mg loading dose day 1, then 50 mg daily; or micafungin 100 mg daily.

**Flucytosine renal dosing adjustments:** CrCl greater than 50–90 mL/min (0.83–1.50 mL/s), 25 mg/kg every 12 hours; CrCl 10–50 mL/min (0.17–0.83 mL/s), 25 mg/kg every 12–24 hours; CrCl less than 10 mL/min (0.17 mL/s) 25 mg/kg every 24 hours. Therapeutic drug monitoring is required for safe use of flucytosine (see Table 84–3).

Patient Encounter 2, Part 2: Invasive Candidiasis

The patient was started on fluconazole 400 mg/day, but 4 days later has persistent fever and develops hypotension and decreased urine output. Blood cultures are now growing a germ tube–negative yeast. Laboratory studies revealed a white blood cell count of 14,200/mm³ (14.2 × 10⁹/L), aspartate aminotransferase 68 IU/L (1.13 μkat/L), alanine aminotransferase 75 IU/L (1.25 μkat/L), alkaline phosphatase 168 IU/L (2.80 μkat/L), and normal bilirubin. Serum creatinine has increased from 1.2 to 1.8 mg/dL (106–159 μmol/L) over the last 3 days.

What factors suggest empiric antifungal therapy should be changed in this patient?

What other procedures should be recommended in this patient to improve management and response to antifungal therapy?
therapy is ineffective. Triazole antifungals (fluconazole, itraconazole solution, or voriconazole), echinocandins, or IV amphotericin B (in cases of unresponsive infections) are effective treatment options. Parenteral therapy should be used in patients who are unable to take oral medications.17

OUTCOME EVALUATION

Response to antifungal therapy in invasive candidiasis is often more rapid than for endemic fungal infections. Resolution of fever and sterilization of blood cultures are indications of response to antifungal therapy with the caveat that the growth of Candida from blood cultures is often delayed by 48 to 72 hours. Adverse effects associated with antifungal therapy are similar in these patients as described earlier, except some toxicities may be more pronounced in critically ill patients with invasive candidiasis. Nephrotoxicity and electrolyte disturbances with amphotericin B can be especially problematic and may not be avoidable even with lipid amphotericin B formulations. Therefore, current treatment guidelines favor less-toxic treatment options, such as the echinocandins, especially in higher-risk patients. Decisions to use one class of antifungal agents over the other are principally driven by concerns of non-albicans species, patient tolerability, or history of prior fluconazole exposure (risk factor for non-albicans species.) and local susceptibility patterns; especially institutional rates of fluconazole (triazole) and echinocandin-resistance.

PROPHYLAXIS

Fluconazole (400 mg/day) has been studied as a prophylactic regimen to prevent invasive candidiasis in patients with prolonged (greater than 2 weeks) neutropenia.21 Placebo-controlled, prospective randomized trials performed in the 1990s demonstrated that fluconazole was effective in reducing the frequency, morbidity, and, in some trials, mortality due to invasive candidiasis in neutropenic patients if administered until marrow recovery. However, the major limitation with fluconazole is its lack of mold coverage needed for high-risk patients with prolonged (ie, greater than 3 weeks) neutropenia.22 Itraconazole, voriconazole, posaconazole, and the echinocandin micafungin have demonstrated a benefit in reducing the incidence of invasive candidiasis when used for prophylaxis in hematopoietic cell transplant recipients until engraftment; however, all of the drugs have limitations with respect to prolonged administration in high-risk patients. Therefore, the approach toward antifungal prophylaxis is highly institution-specific depending on the patient population, epidemiology of invasive fungal infections, and options for outpatient IV drug therapy.

Use of antifungal prophylaxis for invasive candidiasis in non-neutropenic patients remains an area of controversy. Fluconazole prophylaxis can reduce the incidence but not necessarily mortality associated with invasive candidiasis in select high-risk transplant populations (eg, liver, pancreatic, or small-bowel transplantation) or subsets of ICU patients at high risk for infection (ie, neonatal intensive care).21 However, prophylaxis can result in excessive antifungal use in lower-risk patients; therefore, many experts have advocated preemptive (ie, starting therapy based on biomarkers of infection such as serum β-glucan) or empirical (symptoms of infection) treatment approaches in this population in lieu of prophylaxis.

Nevertheless, a multi-institutional prospective randomized trial of administering empirical fluconazole (800 mg/day versus placebo) in ICU patients with persistent fever, did not demonstrate significant benefits in reducing the incidence or mortality associated with invasive candidiasis.29 Similarly, a recent multi-institutional study that focused on ICU patients identified as “high risk” for invasive candidiasis using a validated clinical risk prediction score failed to demonstrate significant reductions in the incidence or mortality of invasive candidiasis with caspofungin prophylaxis.30 However, patients who were treated with an echinocandin after developing a positive serum β-glucan appeared to have lower rates of progression to documented invasive candidiasis. Therefore, many questions persist regarding the optimal approach for preventing or preemptive treating invasive candidiasis in non-neutropenic ICU patients.

CRYPTOCOCCOSIS

EPIDEMIOLOGY

Cryptococcus neoformans is an encapsulated yeast that can infect apparently normal hosts but is more frequently associated with severe infections in immunocompromised patients. C. neoformans is divided into two varieties based on serotype: C. neoformans var. neoformans (serotypes a and d) that is associated with infections in immunocompromised patients, and C. neoformans var. gattii (serotypes b and c) that is associated with infections in healthy hosts. C. neoformans var. gattii is found predominantly in tropical and subtropical climates with eucalyptus trees, and has been linked to infectious outbreaks around Vancouver Island and the US Pacific Northwest. C. neoformans var. neoformans is found worldwide and is associated with pigeon droppings and other avian excreta. Before the AIDS pandemic, cryptococcosis was a relatively uncommon disease, but became a leading cause of meningitis among HIV-infected patients. Although the incidence of this infection has declined in developed countries with the widespread use of highly active antiretroviral therapy (HAART), C. neoformans remains an important pathogen in the developing regions with high rates of AIDS and also in immunocompromised patients, including transplant and cancer patients who may present with initially indolent pulmonary forms of the infection.

CLINICAL PRESENTATION AND DIAGNOSIS

C. neoformans is acquired primarily through inhalation of the desiccated yeast particles found in the environment. Inhaled cells reach distal alveolar spaces where they gradually rehydrate and form their characteristic polysaccharide capsules that enable resistance to phagocytosis. Defects in cellular immunity allow reconstitution of the protective capsule and multiplication of yeast in the lungs. Although alveolar macrophages phagocytose the yeast, containment and killing require a coordinated response between innate and adaptive humoral (complement and anticytotoxicoccal antibodies) and T-cell-mediated host responses.9 Deficiencies in cell-mediated immunity allow the yeast to survive as a facultative intracellular pathogen in macrophages as they migrate from the lung to draining lymph nodes, leading to dissemination via the bloodstream to the meninges.

Unlike most opportunistic fungi, true virulence factors have been identified for C. neoformans. The capsules, including the soluble polysaccharides released from the yeast cells during infection, impair phagocytosis and binding of anticytotoxicoccal antibodies. Primary cryptococcal infection begins in the lung, presenting as a mildly symptomatic or asymptomatic infection
that resolves spontaneously or undergoes encapsulation in non-calcified lung nodules. It is common for these isolated nodules to be detected on chest x-rays during routine workup. Diagnosis of primary cryptococcosis is only made if the nodule is aspirated or removed because of concerns of primary lung cancer.

In the immunocompromised host, infection of the lung may present with more diffuse, bilateral, and interstitial disease that mimics the presentation of P. jiroveci (carinii) pneumonia (PCP). Dissemination to other organs, particularly the CNS, eye, and possibly the skin, is more likely to occur in patients with severe deficits in cell-mediated immunity. Fever, cough, dyspnea, and pleural pain are common at presentation, with accompanying hypoxemia that can rapidly evolve to acute respiratory failure. Because the features of diffuse pulmonary cryptococcosis overlap with other opportunistic pathogens, early diagnosis requires bronchoalveolar lavage or transbronchial biopsy, which can effectively diagnose 80% to 100% of cases. The clinical course of diffuse cryptococcal pneumonia can be as severe as PCP, with mortality rates approaching 100% in untreated patients by 48 hours.

*C. neoformans* readily disseminates from the lung to the CNS, specifically the leptomeninges, and occasionally the parenchyma of the brain. The clinical characteristics of cryptococcal meningitis differ somewhat, however, between patients with and without underlying AIDS. In patients without AIDS, disease presentation is more insidious, and symptoms such as dizziness, irritability, decreased comprehension, and unstable gait may present many weeks to months before the diagnosis is established. Patients with AIDS generally present much later in the course of disease with severe meningoencephalitis. The most common signs and symptoms on presentation are fever, headache, meningismus, photophobia, mental status changes, and seizures. CT or more sensitive MRI may reveal cerebral edema, multiple areas of enhanced nodules, or a single mass lesion (cryptococcoma). Examination of the cerebrospinal fluid (CSF) often reveals increased opening pressure upon lumbar puncture, but glucose, protein, and leukocyte levels can be normal.

**LABORATORY DIAGNOSIS**

Clinical diagnosis is confirmed by cultures from the blood, CSF, or other clinically relevant fluids or tissue. *C. neoformans* can be directly visualized in the CSF when stained with India Ink, which is excluded by the yeast capsule (Figure 84–3B). However, infection is most frequently diagnosed (Figure 84–3B), by detection of cryptococcal antigen in either serum or CSF, which has high sensitivity and specificity (greater than 95%) and correlated with fungal burden. A positive serum antigen test of greater than 1:16 strongly suggests cryptococcal infection, and greater than or equal to 1:8 is indicative of active disease. Antigen titers in serum are positive in 99% of patients with cryptococcal meningitis and typically exceed titers of 1:2048 in patients with AIDS. However, the time course of cryptococcal antigen elimination is unknown, and a positive test result can persist for many years. Changes in the CSF cryptococcal antigen titers have limited value in the monitoring of drug therapy for cryptococcal meningitis, although it is expected that a decrease should be seen after 2 or more weeks of antifungal therapy.

**TREATMENT**

Cryptococcal meningitis is fatal if left untreated. Because pneumonia frequently precedes dissemination of disease and subsequent meningitis, all patients with culture-, histopathology-, or serology-proven disease should receive antifungal therapy. In patients with isolated pulmonary cryptococcosis, fluconazole is generally considered to be the therapy of choice (see Table 84–2). Alternatively, itraconazole, voriconazole, or combination therapy (fluconazole plus flucytosine) has also been used with some success, but these regimens are generally considered inferior to amphotericin B and are recommended only for persons unable to tolerate or unresponsive to standard treatment. Echinocandins do not have activity against *C. neoformans*.

Disseminated or CNS cryptococcosis requires a more aggressive treatment approach. Pretreatment predictors of poor outcome with antifungal therapy include the following:

- Progressive underlying disease or immune dysfunction
- Abnormal mental status at the time of presentation
- Increased opening pressure on lumbar puncture (greater than 260 mm H₂O [2.55 kPa])
- High fungal burden as reflected by a CSF antigen titer (in AIDS patients) of greater than 1:2048

Clinical trials performed by the National Institute of Allergy and Infectious Diseases (NIAID) Mycoses Study Group defined the standard treatment regimen for cryptococcal meningitis consisting of 2 weeks of induction antifungal therapy with combination amphotericin B (0.7 mg/kg/day) plus flucytosine (100 mg/kg/day) for cryptococcal meningitis, followed by consolidation therapy with fluconazole (400 mg daily) for 8 weeks (see Table 84–2). However, other combinations of either fluconazole plus flucytosine, or fluconazole plus amphotericin B were sometimes recommended due difficulties in obtaining flucytosine (especially in developing countries) and toxicity (see Table 84–2).

**KEY CONCEPT** In a landmark study addressing which combination is best for cryptococcal meningitis, there were significantly fewer deaths in patients receiving amphotericin B plus flucytosine versus patients receiving amphotericin B alone or a combination of amphotericin B plus fluconazole. Notably, the amphotericin B–flucytosine combination was associated with more rapid clearance of yeast from the CSF versus other regimens.
PROPHYLAXIS

- Fluconazole (200 mg/day) is recommended as maintenance therapy for life in patients with persistent underlying immune dysfunction to prevent recurrent cryptococcal meningitis.\(^{31}\) Available data suggest it is safe to discontinue maintenance therapy in AIDS patients who have had a sustained immunologic response on effective antiretroviral therapy (ie, CD4\(^+\) count greater than 100 cells/microliter (100 × 10\(^6\)/L) with undetectable or very low viral RNA) if they have received at least 12 months of antifungal therapy.\(^{31}\) Occasionally, initiation of HAART can result in the reactivation of a subclinical, immunologic manifestation of cryptococcal infection (or other opportunistic infections). Manifestations of this immune reconstitution inflammatory syndrome (IRIS) may include exacerbations of meningitis or necrotizing pneumonia. Antifungal therapy plus a nonsteroidal anti-inflammatory agent or prednisone has been used successfully in patients with cryptococcal-associated immune reconstitution syndrome.\(^{33}\) However, the optimal management of this recently defined clinical entity remains unknown.

INVASIVE ASPERGILLOSIS

EPIDEMIOLOGY

Invasive molds, particularly Aspergillus species, are a common complication of intensive cancer chemotherapy required for hematologic malignancies, and prolonged immunosuppression following hematopoietic and solid organ transplantation. Four species are commonly associated with invasive infection: Aspergillus fumigatus, Aspergillus flavus, Aspergillus terreus, and Aspergillus niger. Of these four species, A. fumigatus accounts for most of human infections. However, identification of Aspergillus mold in culture to the species level is still essential because the incidence of amphotericin B–resistant Aspergillus terreus and Aspergillus flavus have increased in some centers over the last 10 years. Additionally, less common mold infections such as fusariosis and mucormycosis often present with similar clinical features aspergillosis, but require different treatment approaches due to their inherent resistance to many antifungal agents. Early and accurate diagnosis of invasive aspergillosis (IA) improves the outcome of infection, reducing mortality rates by 30% to 50% with the timely administration of effective antifungal therapy.\(^{34}\)

CLINICAL PRESENTATION AND DIAGNOSIS

The pathogenesis of IA is defined largely by the underlying immune dysfunction of the host. The most common route of acquisition for Aspergillus is through the respiratory tract. Conidia dispersed in air currents are continuously inhaled through the sinuses and mouth and penetrate down to distal alveolar spaces (see Figure 84–4). Most conidia are rapidly phagocytosed and removed by resident macrophages and neutrophils in the upper and lower respiratory tract.\(^6\) However, macrophage function may be suppressed following transplantation, cytotoxic chemotherapy, or in patients who have received high-dose corticosteroid therapy. Conidia that escaped phagocytosis begin to germinate into hyphal forms that invade blood vessels or contiguous tissues or bone (in sinuses), resulting in hemorrhage and/or infarction and coagulative necrosis. Once in the bloodstream, viable hyphal fragments can break off and disseminate to distal organs including the brain. Control of the infection at this stage requires development of an adaptive TH1 or TH17 response to enhance the fungicidal activity of professional effector cells (ie, neutrophils) against hyphal elements.\(^6\)
Patients with dysregulated, suppressed T-cell–mediated immunity or prolonged neutropenia are unable to control fungal growth and are at high risk for dissemination of the infection. Without early diagnosis and antifungal therapy, IA in persistently immunosuppressed patients is uniformly fatal.

Signs and symptoms of IA are predictably muted in the immunocompromised host. Fever is common but nonspecific for infection and may be accompanied by pleuritic chest pain, cough, hemoptysis, and/or friction rub.14 Neurologic signs, including seizures, hemiparesis, and stupor, may be present in patients with dissemination to the brain. Cutaneous plaques or papules characterized by a central necrotic ulcer or eschar occur in up to 10% of patients with disseminated disease; however, concomitant blood cultures are often negative. Chest radiographs cannot detect early forms of disease and may remain negative in up to 10% of patients within 1 week of death. Nodular lesions detected by high-resolution computed tomography (HRCT) scans, along with fever, are often the first indication of invasive pulmonary aspergillosis in severely immunocompromised patients. Typically these radiographs reveal wedge-shaped or nodular lesions, surrounded by intermediate attenuation called the “halo sign” (Figure 84–5). These early lesions on CT scans represent hemorrhage and edema surrounding an infarcted blood vessel. Despite “effective” antifungal therapy, lesions on CT scan may continue to increase in size in neutropenic patients until neutrophil counts recover, at which time they begin to cavitate, forming the “air-crescent sign” on chest radiographs, indicative of resolving infection. Immunosuppressed patients on fluconazole with progressive sinus or pulmonary disease by radiography should be considered to have a possible mold infection and receive empiric antifungal therapy directed (at minimum) against Aspergillus species.40

LABORATORY DIAGNOSIS

Like other invasive mycoses, definitive diagnosis of aspergillosis requires histopathologic evidence of hyphal invasion in tissue (see Figure 84–3). However, procedures needed to establish a definitive diagnosis by sampling of suspicious lesions (eg, fine-needle aspiration or thoracoscopic lung biopsy) are not feasible in many patients with underlying thrombocytopenia secondary to hematologic malignancies or chemotherapy. Even if hyphae are observed in tissue, histopathology alone cannot distinguish Aspergillus from other angioinvasive septate molds, such as Fusarium, which have different patterns of antifungal susceptibility (see Table 84–1). Therefore, respiratory and/or wound cultures (if cutaneous or sinus/hard palate lesions are present) are important factors in the modification of empiric antifungal therapy.

Respiratory cultures, including sputum, bronchial washings, or bronchoalveolar lavage have a low sensitivity for diagnosis of IA but a high positive predictive value in immunocompromised patients. Therefore, a negative bronchoalveolar lavage culture does not rule out invasive pulmonary aspergillosis, but a positive culture in a high-risk patient (eg, allogeneic hematopoietic cell transplant patients) indicates pulmonary aspergillosis in at least 60% of such patients. Blood cultures have little diagnostic value for IA, but may reflect true disease with A. terreus. Patients with limited lung involvement or on prophylactic or empiric antifungal therapy may continue to be culture-negative for Aspergillus species, despite the appearance of progressing disease.14 Therefore, negative cultures are never the sole indication for stopping antifungal therapy in patients with suspected or proven aspergillosis.

In the past, antifungal susceptibility testing was not routinely recommended for Aspergillus spp. in treatment guidelines because of limited data to support the recommendation. Aspergillus terreus and A. flavus were considered to be the major concerns because of their intrinsic resistance to amphotericin B. Multitriazole-resistant Aspergillus fumigatus spp. have been reported in China, Canada, the United States, and several European countries, with especially high levels in the Netherlands and United Kingdom. These trends suggest that MIC testing (when isolates can be grown from patient) may be increasingly necessary to confirm susceptibility to first-line antifungal treatments.

Considerable effort has been focused in the last decade to develop non–culture-based laboratory methods (antigen detection, polymerase chain reaction [PCR], and antigen detection).
for the diagnosis of IA. The hope is that these surrogate tests could detect early evidence of *Aspergillus* infection before significant target organ damage eventually detected by CT scans occurs. Currently, most centers use an ELISA–based assay for the detection of a polysaccharide component of the *Aspergillus* cell wall called galactomannan. Although several large prospective studies have found that the sensitivity and specificity of the assay exceed 90% in neutropenic patients with hematologic malignancies, the median time span between galactomannan detection and clinical signs and symptoms of IA averages less than 6 days. The sensitivity of the galactomannan may be enhanced if the test is performed on bronchial lavage fluid. Other factors such as patient immune status (neutropenia vs graft-versus-host disease), antibacterial therapy, antifungal prophylaxis, and diet may affect the sensitivity and specificity of the galactomannan test. For example, false-positive results have been reported to be higher in the pediatric population, patients receiving piperacillin-tazobactam for neutropenic fever, and following the ingestion of certain cereals, pastas, nutritional supplements, or soy sauce. Accumulating clinical data suggest that rising galactomannan levels are a harbinger of breakthrough infection, and declining galactomannan concentrations are an early indicator of response to treatment. However, antifungal therapy is rarely stopped in patients once the serum galactomannan becomes negative, especially in persistently immunosuppressed patients. Hence, the galactomannan test and other non–culture-based strategies, such as serum β-glucan, which can also be detected during *Aspergillus* infection, serve as complementary methods to confirm results from microbiologic, histopathologic, and radiographic investigations directed toward diagnosing IA.

**TREATMENT**

Four comparative randomized controlled clinical trials have evaluated antifungal therapies for the treatment of diagnosis-proven IA. Voriconazole is considered by many experts and consensus treatment guidelines to be the preferred antifungal for IA (see Table 84–2). However, patients who are intolerant to voriconazole, have ongoing hepatotoxicity issues, or have received voriconazole prophylaxis in the recent past may initially be treated with a liposomal amphotericin B formulation. Lipid amphotericin B formulations are recommended over other antifungal classes because of their better coverage of Mucorales molds, which are intrinsically resistant to voriconazole, but often present as a breakthrough infection indistinguishable from IA. Once the infection has stabilized and diagnosis is clarified, patients can be transitioned back to an intravenous or oral triazole for the completion of their therapy.

Isavuconazole is a newer triazole unique from other agents because it is administered as a prodrug, isavuconazonium, which is rapidly cleaved in vivo to the active drug (isavuconazole) and an inactive prodrug cleavage product (BAL8728). In a phase 3 trial, patients with proven or probable aspergillosis treated with isavuconazole achieved similar clinical response rates as a standard voriconazole regimen, but with significantly fewer hepatic, skin, and visual adverse effects. Therefore, isavuconazole appears to be a promising alternative to voriconazole for the treatment of IA.

Echinocandins are clinically active against *Aspergillus* spp. and have demonstrated efficacy in the treatment of probable or proven aspergillosis. However, their lack of fungicidal activity and possibly lower response rates reported with monotherapy regimens in noncomparative studies makes them less appealing as a frontline treatment regimen for documented infections, despite their excellent safety profile.

Multiple studies in vitro and in animal models, as well small clinical studies have suggested that administration of an echinocandin with a triazole such as voriconazole may be synergistic and improve survival in IA over monotherapy, but prospective clinical studies, until recently, have been lacking. A multicenter, randomized clinical trial comparing voriconazole-aniulafugin combination therapy to voriconazole monotherapy for proven or probable aspergillosis reported a trend in improved 6-week survival for patients randomized to combination therapy, that was significant among a post-hoc analyzed group of patients whose disease was diagnosed with galactomannan antigen but not culture (reflecting patients with earlier-diagnosed disease). Nevertheless, the failure of the study to meet its primary endpoint objective raises lingering questions about the efficacy of combination therapy, and many clinicians reserve the use of combination regimens for patients with extensive disease (ie, multifocal or bilateral pneumonia, disseminated infection) or in cases of suspected breakthrough infection.

**PROPHYLAXIS**

Although published guidelines for preventing opportunistic infections in hematopoietic cell transplant recipients do not provide concrete recommendations for antifungal prophylaxis against *Aspergillus*, prophylaxis should be considered in certain high-risk subgroups with rates of IA exceeding 10%. These groups include (a) patients with prolonged pre-engraftment periods (eg, cord-blood transplant recipients), (b) patients with a history of IA prior to transplantation, (c) patients receiving transplants with a high risk of graft-versus-host disease (eg, haploidentical allogeneic transplant) or infection (eg, T-cell-depleted transplant), any patient with graft-versus-host disease on high-dose corticosteroid therapy (greater than 1 mg/kg prednisone equivalent) with or without antithymocyte globulin or tumor necrosis factor blockade (ie, infliximab), and (d) any transplant recipient with active cytomegalovirus disease, which is associated with an increased risk of subsequent mold infections due to the immunosuppressive effects of the virus. Posaconazole was shown in two prospective randomized trials to reduce *Aspergillus*-associated death in patients with acute high-risk leukemia and reduce mold infections in patients with graft-versus-host disease following hematopoietic stem cell transplantation. Similar data are available for voriconazole, for HSCT but less benefit was observed versus standard fluconazole prophylaxis plus intensive galactomannan monitoring in the hematopoietic stem cell transplant patients. Prophylactic approaches, however, are often individualized to institution and patient-specific risk factors.

**OUTCOME EVALUATION**

Response to antifungal therapy in invasive molds is slow and difficult to judge by clinical signs alone. Resolution of fever and eventual clearing of CT scans (in the case of lung infections) are indications of response to antifungal therapy. Toxicity associated with antifungal therapy is similar in these patients as in those described earlier. Patients who develop breakthrough infections on voriconazole should also undergo a careful clinical workup for other invasive mold pathogens such as mucormycosis (see Table 84–1), which are not susceptible to voriconazole. In most cases, antifungal therapy may be continued until immunosuppression has resolved.
Abbreviations Introduced in This Chapter

AIDS: Acquired immunodeficiency syndrome
ARDS: Acute respiratory distress syndrome
CNS: Central nervous system
CrCl: Estimated creatinine clearance
CSF: Cerebrospinal fluid
CT: Computed tomography
CYP: Cytochrome P-450 isoenzyme
ELISA: Enzyme-linked immunosorbent assay
FISH: Fluorescent in situ hybridization
HAART: Highly active antiretroviral therapy
HRCT: High-resolution computed tomography
IA: Invasive aspergillosis
ICU: Intensive care unit
IRIS: Immune reconstitution inflammatory syndrome
IV: Intravenous
MALDI-TOF: Matrix-assisted laser desorption/ionization time of flight
NIAID: National Institute of Allergy and Infectious Diseases
PCP: Pneumocystis jiroveci (carinii) pneumonia
PCR: Polymerase chain reaction
PMN: Polymorphonuclear cell

Antimicrobial Prophylaxis in Surgery

Mary A. Ullman and John C. Rotschafer

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the impact of surgical site infections (SSIs) on patient outcomes and health care costs.
2. Name and differentiate the four different types of wound classifications.
3. Recognize at least three risk factors for postoperative SSIs.
4. Identify likely pathogens associated with different surgical operations.
5. Compare and contrast antimicrobials used for surgical prophylaxis and identify potential advantage and disadvantages for each antimicrobial.
6. Discuss the importance of β-lactam allergy screening and how this could impact resistance and health care costs.
7. Identify nonantimicrobial methods that can reduce the risk of postoperative infection.
8. Discuss the importance of antimicrobial timing, duration, and redosing in relation to antimicrobial prophylaxis in surgery.
9. Recommend appropriate prophylactic antimicrobial(s) given a surgical operation.

INTRODUCTION

Surgical site infections (SSIs) are a significant cause of morbidity and mortality. Approximately 2% to 5% of patients undergoing clean extra-abdominal operations and 20% undergoing intra-abdominal operations will develop an SSI. SSIs have become the second most common cause of nosocomial infection, and these data are likely underestimated due to a large number of surgical procedures being performed on an outpatient basis.

SSIs negatively affect patient outcomes and increase health care costs. Patients who develop SSIs are five times more likely to be readmitted to the hospital and have twice the mortality of patients who do not develop an SSI. A patient with an SSI is also 60% more likely to be admitted to an ICU. SSIs lengthen hospital stays and increase costs. Deep SSIs, involving organs or spaces, result in longer durations of hospital stay and higher costs compared with incisional SSIs. Additionally, since 2008, Medicare and Medicaid Services no longer reimburses hospitals for any cost incurred from treating certain hospital-acquired infections, including SSIs.

SSIs are defined and reported according to Centers for Disease Control and Prevention (CDC) criteria. SSIs are classified as either incisional or organ/space. Incisional SSIs are further divided into superficial incisional SSI (skin or subcutaneous tissue) and deep incisional SSI (deeper soft tissues of the incision). Organ/space SSIs involve any anatomic site other than the incised areas (e.g., meningitis after brain tumor removal). An infection is considered an SSI if any of the above criteria is met and the infection occurs within 30 days of the operation. If a prosthesis is implanted during the operation, the timeline extends out to 1 year.

EPIDEMIOLOGY AND ETOIOLOGY

Risk factors for SSIs can be divided into two categories: patient and operative characteristics. Patient risk factors for SSI include age, comorbid disease states (especially chronic lung disease and diabetes), malnutrition, immunosuppression, nicotine or steroid use, and colonization of the nares with Staphylococcus aureus. Modifying risk factors prior to planned operations may decrease the threat of SSI.

Operative characteristics are based on the actions of both the patient and the operating staff. Shaving of the surgical site prior to operating can produce microscopic lacerations and increase the chance of SSI and is, therefore, not accepted as a method of hair removal. Maintaining aseptic technique and proper sterilization of medical equipment is effective in preventing SSI. Surgical staff should wash their hands thoroughly. In clean operations, most bacterial inoculums introduced postoperatively are generally small. However, subsequent patient contact between contaminated areas (such as the nares or rectum) and the surgical site can lead to SSI. Finally, the appropriate use of antimicrobial prophylaxis can have a significant impact on decreasing SSIs.

PATHOPHYSIOLOGY

Prophylaxis Versus Treatment

Properly identifying the site of an infection is important when using antimicrobial prophylaxis in surgery. Antimicrobial prophylaxis begins with the premise that no infection exists but that during the operation there can be a low-level inoculum of
bacteria introduced into the body. However, if sufficient antimicrobial concentrations are present, bacteria can be controlled without infection developing. This is the case when surgery is done under controlled conditions, there are no major breaks in sterile technique or spillage of GI contents, and perforation or damage to the surgical site is absent. An example would be an elective hysterectomy done with optimal surgical technique.

If an infection is already present, or presumed to be present, then antimicrobial use is for treatment, not prophylaxis, and the goal is to resolve the infection. This is the case when there is spillage of GI contents, gross damage or perforation is already present, or the tissue being operated on is actively infected (pus is present and cultures are positive). An example would be a patient undergoing surgery for a ruptured appendix with diffuse peritonitis.

![Key Concept]
The distinction between prophylaxis and treatment influences the choice of antimicrobial and duration of therapy. Appropriate antimicrobial selection, dosing, and duration of therapy differ significantly between these two situations. A regimen for antimicrobial prophylaxis ideally involves one agent and lasts less than 24 hours. Treatment regimens can involve multiple antimicrobials with durations lasting weeks to months depending on desired antimicrobial coverage and the surgical site.

**Types of Surgical Operations**

![Key Concept] Surgical operations are classified at the time of operation as clean, clean-contaminated, contaminated, or dirty. Antimicrobial prophylaxis is appropriate for clean, clean-contaminated, and contaminated operations. Dirty operations take place in situations of existing infection and antimicrobials are used for treatment, not prophylaxis (Table 85–1).

**Microbiology**

![Key Concept] Appropriate prophylactic antimicrobial selection relies on anticipating which organisms will be encountered during the operation. SSIs associated with extra-abdominal operations are the result of skin flora organisms in nearly all cases. These organisms include gram-positive cocci, with *Staphylococcus aureus* and *Staphylococcus epidermidis* being among the most frequently isolated SSI pathogens (Table 85–2). *Streptococcus* spp. may also be implicated.

Intra-abdominal operations involve a diverse flora with the potential for polymicrobial SSIs. *Escherichia coli* make up a large portion of bowel flora and are frequently isolated as pathogens. Other enteric gram-negative bacteria, as well as anaerobes (especially *Bacteroides* spp.), may be encountered during intra-abdominal operations.

*Candida albicans* continues to be an increasing cause of SSIs. Increased use of broad-spectrum antimicrobials and

*Data from Refs. 6 and 7.*
Choosing an Antibiotic

Ideal criteria for an antimicrobial in surgical prophylaxis include the following:

- Spectrum that covers expected pathogens
- Inexpensive
- Parenteral
- Easy to use
- Minimal adverse-event potential
- Longer half-life to minimize need for redosing during procedure

Operations can be separated into two basic categories: extra-abdominal and intra-abdominal. SSIs resulting from extra-abdominal operations are frequently caused by gram-positive aerobes. Thus an antimicrobial with strong gram-positive coverage is useful. Cefazolin provides a benign adverse-event profile, simple dosing, and low cost, making cefazolin the mainstay for surgical prophylaxis of extra-abdominal procedures. For patients with a β-lactam allergy, clindamycin or vancomycin can be used as an alternative.

Intra-abdominal operations necessitate broad-spectrum coverage of gram-negative organisms and anaerobes. Antianerobic cephalosporins, cefoxitin and cefotetan, are widely used. Fluoroquinolones or aminoglycosides, paired with clindamycin or metronidazole, should provide adequate coverage for intra-abdominal operations; these regimens are recommended as appropriate regimens for use in patients with β-lactam allergies.

Guidelines do not recommend routine use of vancomycin for surgical procedures. Vancomycin should be considered when a cluster of methicillin-resistant \( S.\) \( aureus \) (MRSA) or coagulase-negative staphylococci have been identified. Additionally, vancomycin is appropriate to use in patients with known MRSA colonization or at high risk for MRSA colonization. However, vancomycin use in institutions where MRSA rates are “high” may not translate into a lower incidence of SSI. The incidence of SSI for patients on cefazolin or vancomycin did not differ despite a high MRSA rate at the study institution. However, patients who received cefazolin were more likely to develop an SSI due to MRSA. The increasing prevalence of community-associated methicillin-resistant \( S.\) \( aureus \) (CA-MRSA) in patients admitted to the hospital creates an added concern, although this pathogen is often sensitive to clindamycin. Responsibility for determining appropriate use of vancomycin falls on each institution and interpretation of institutional resistance data.

Newer antimicrobials may be alternative agents for surgical prophylaxis, especially as drug shortages limit availability of routinely used antimicrobials. Ertapenem was superior to standard cefotetan in the prevention of SSIs after elective colorectal surgery. However, the ertapenem treatment group had a larger proportion of \( Clostridium\) \( difficile \) infections than those in the cefotetan treatment group. Ertapenem has been included as an approved antimicrobial for colon surgery. At this time, it is not considered appropriate to routinely use newer antimicrobials for surgical prophylaxis; overuse of these antimicrobials may contribute to collateral damage and the development of bacterial resistance.

β-Lactam Allergy

Allergy to β-lactam antimicrobials such as penicillin is one of the most common reported drug allergies. Concerns over cross-reactivity between antimicrobials may limit the use of β-lactams for surgical prophylaxis. A thorough drug allergy history should be taken to discern true allergy (eg, anaphylaxis) from medication intolerance (eg, upset stomach). Allergy testing may be helpful in confirming penicillin allergy and could spare vancomycin. However, practitioners should be aware that penicillin allergy testing may be difficult to perform due to the removal of a major component (penicilloyl-polylysine) of the testing from the commercial market. If a practitioner desires to perform allergy testing, the individual reagents required for penicillin allergy testing must be prepared at the health care facility, on a case-by-case basis. Cross-allergenicity between penicillins and cephalosporins is low. The increased risk of cephalosporin allergy in patients with a history of penicillin allergy may be as low as 0.4% for first-generation cephalosporins and nearly zero for second- and third-generation agents. Other studies also found the risk of cross-reactivity to be very low. However, in the case of severe penicillin allergy (anaphylaxis), cephalosporins should be avoided.

Alternative Methods to Decrease SSI

Several nonantimicrobial methods have been studied for reducing the risk of SSI. Supplemental warming of patients (36.7°C [98.0°F]) during the intraoperative period reduced infection rates compared with control patients (34.7°C [94.5°F]). Intensive glucose control (maintaining blood glucose to 80–110 mg/dL [4.4–6.1 mmol/L] versus conventional control (blood glucose < 220 mg/dL [12.2 mmol/L]) reduced operative site infections and improved outcomes in cardiac patients who received intensive insulin control in the ICU after surgery. Also, patients randomized to 80% (0.80) inspired oxygen had lower SSI rates compared with patients on 30% (0.30) oxygen after colorectal resection. Despite these findings, there are insufficient data to make definitive recommendations on the use of these approaches.

Alternative topical routes of antimicrobial prophylaxis such as antimicrobial-impregnated bone cement, implantable antimicrobial collage sponges, antimicrobial irrigations, and topical administration of antimicrobial powders have not been well studied. Studies demonstrating an advantage often lack rigorous design and only show superiority when compared to placebo. Irrigation with detergent solutions, rather than antimicrobials, appears to provide the same results but with less wound-healing problems encountered with antimicrobial irrigation. Con founding this issue is the lack of standards for topical administration routes. An array of drugs, from aminoglycosides to macrolides, is used in these preparations. Some bone cements are produced commercially, whereas others are made in the operating room. The long-term durability of impregnated cements is also unknown, as the addition of antimicrobials may reduce the tensile strength of bone cement. Irrigation solutions may be compounded in the surgical suites and result in variable concentrations. High concentrations can result in local irritation, systemic absorption, and toxicity. Alternatively, low concentrations can contribute to the development of resistant organisms may occur. Further study is required before topical administration is recommended for use in surgical prophylaxis.

With the increase of CA-MRSA, increased importance has been placed on screening for \( S.\) \( aureus \), especially MRSA and decolonization. Surgical patients with nasal colonization of
S. aureus have a higher risk of an SSI due to S. aureus, and decolonization leads to a lower incidence of SSIs. Guidelines endorse the use of mupirocin for S. aureus decolonization, especially in cardiac and orthopedic surgery. The most studied approach to eradication of methicillin-sensitive S. aureus (MSSA) and/or MRSA has been mupirocin applied to the anterior nares for 5 days prior to surgery. Additionally, skin decolonization with 4% chlorhexidine for 5 days prior to surgery has also been recommended. Although decolonization of the anterior nares is the most common and most studied, some controversy exists because patients may be colonized elsewhere (rectum, throat, vagina, etc) and often do not receive complete decolonization. Furthermore, decolonization usually does not lead to lifelong eradication. Other drugs, both topical and systemic, have been studied for decolonization/eradication of MRSA, but a review of randomized controlled trials for the eradication of MRSA found insufficient evidence for the use of any agent for eradication of MRSA. A significantly lower incidence of infections was demonstrated in surgical patients who were nasal colonized with S. aureus and completed a 5-day treatment of intranasal mupirocin twice daily and chlorhexidine wash daily. Although no MRSA infections were noted in the patients included in this study, the authors suggest that this treatment strategy would be beneficial in MRSA-colonized patients as long as those strains were susceptible to mupirocin. Although MRSA screening has gained more acceptance, less than 10% of centers screen for mupirocin and/or chlorhexidine resistance. Mupirocin resistance rates have varied from 1.9% to 5.6% of S. aureus isolates. Further studies are needed to elucidate this area of surgical prophylaxis, including cost-effectiveness.

**Principles of Antimicrobial Prophylaxis**

**Route of Administration**

IV antimicrobial administration is the most common delivery method for surgical prophylaxis. IV administration ensures complete bioavailability while minimizing the impact of patient-specific variables. Oral administration is also used in some bowel operations. Nonabsorbable compounds such as erythromycin base and neomycin are given during the 24 hours prior to surgery to reduce microbial concentrations in the bowel. Note that oral agents are used adjunctively and do not replace IV agents.

**Timing of First Dose**

For prevention of SSIs, correct timing of antimicrobial administration is imperative so as to allow the persistence of therapeutic concentrations in the blood and wound tissues during the entire course of the operation. The National Surgical Infection Prevention Project recommends infusing antimicrobials for surgical prophylaxis within 60 minutes of the first incision. Exceptions to this rule are fluoroquinolones and vancomycin, which can be infused 120 minutes prior to avoid infusion-related reactions. No consensus has been reached on whether the infusion should be complete prior to the first incision. However, if a proximal tourniquet is used, antimicrobial administration should be complete prior to inflation.

Administration of the intravenous antimicrobial should begin as close to the first incision as possible. This is important for antimicrobials with short half-lives so that therapeutic concentrations are maintained during the operation and reduce the need for redosing. Beginning the antimicrobial infusion after the first incision is of little value in preventing SSI. Administration of the antimicrobial after the first incision had SSI rates similar to patients who did not receive prophylaxis.

**Dosing and Redosing**

**The goal of antimicrobial dosing for surgical prophylaxis is to optimize the pharmacodynamic parameter of the selected agent against the suspected organism for the duration of the operation.** Dosing recommendations can vary between institutions and guidelines. Clinical judgment should be exercised regarding dose modifications for renal function, age, and especially weight. Obese patients often require higher antimicrobial doses than do nonobese patients. The newest guidelines recommended higher doses of cefazolin based on population pharmacokinetic/pharmacodynamics data: 2 g for all patients less than 120 kg; 3 g for patients more than or equal to 120 kg. Clindamycin should be given as a 900-mg preoperative intravenous dose. If an operation exceeds two half-lives of the selected antimicrobial, then another dose should be administered. Repeat dosing reduces rates of SSI. For example, cefazolin has a half-life of about 2 hours, thus another dose should be given if the operation exceeds 4 hours. The clinician should have extra doses of antimicrobial ready in case an operation lasts longer than planned.

**Duration**

The National Surgical Infection Prevention Project and published evidence suggest that the continuation of antimicrobial prophylaxis beyond wound closure is unnecessary. The duration of antimicrobial prophylaxis should not exceed 24 hours (48 hours for cardiac surgery); additional doses of antimicrobial past this time point do not demonstrate added benefits. Antimicrobial prophylaxis does not need to be continued until all drains and catheters have been removed. Longer durations of antimicrobial prophylaxis are advocated by some guidelines and will be discussed later.

**PROPHYLAXIS REGIMENS**

**Antimicrobial Prophylaxis in Specific Surgical Procedures**

**Gynecologic and Obstetric**

- Possible pathogens: enteric gram-negative bacilli, anaerobes, group B streptococci, enterococci
- Prophylaxis for hysterectomy: cefazolin, cefotetan, cefoxitin, ampicillin-sulbactam
- Alternatives for β-lactam allergy: clindamycin or vancomycin combined with aminoglycoside, aztreonam, or fluoroquinolone; metronidazole combined with aminoglycoside or fluoroquinolone
- Prophylaxis for Cesarean section: cefazolin
- Alternatives for β-lactam allergy: clindamycin and aminoglycoside

Cesarean sections are stratified into low- and high-risk groups. Patients who undergo emergency operations or have cesarean sections after the rupture of membranes and/or onset of labor are considered high risk. Prophylactic antimicrobials are most beneficial for high-risk patients but are used in both groups. Antimicrobials should not be administered until after the first incision and the umbilical cord has been clamped. This practice prevents potentially harmful antimicrobial concentrations from reaching the newborn.

**Orthopedic Surgery**
- Possible pathogens: gram-positive cocci, mostly staphylococci
- Prophylaxis for total joint arthroplasty (hip or knee): cefazolin
- Alternatives for β-lactam allergy: clindamycin, vancomycin

Antimicrobial-impregnated bone cement can be useful in lowering infection rates in orthopedic surgery but has not been approved for prophylaxis.

**Cardiothoracic and Vascular Surgery**
- Possible pathogens: gram-positive cocci, mostly staphylococci
- Prophylaxis for cardiac surgeries: cefazolin, cefuroxime
- Prophylaxis for noncardiac thoracic surgeries: cefazolin, ampicillin-sulbactam
- Prophylaxis for vascular surgeries: cefazolin
- For all cardiothoracic and vascular surgeries alternatives for β-lactam allergy: clindamycin, vancomycin

Debate exists on the duration of antimicrobial prophylaxis for cardiothoracic operations. SSIs are rare after cardiothoracic operations, but the potentially devastating consequences lead some clinicians to support longer periods of prophylaxis. The National Surgical Infection Prevention Project cites data that extending prophylaxis beyond 24 hours does not decrease SSI rates and may increase bacterial resistance. However, the Society of Thoracic Surgeons issued practice guidelines in 2006 to extend the duration of antimicrobials to 48 hours following cardiac surgeries. Duration of therapy should be based on patient factors and risk of development of an SSI.

**Colorectal Surgery**
- Possible pathogens: gram-positive, gram-negative, and anaerobic organisms

**Patient Encounter Part 1**

RP is a 61-year-old woman with a history of rectal bleeding and recent diagnosis of sigmoid colon cancer. She presents today for a colon resection (colorectal surgery). She has a history of nausea with cephalaxin. You have been asked for recommendation for surgical prophylaxis.

**VS:** BP 127/83 mm Hg, HR 63 beats/min, RR 21 breaths/min, T 98.6°F (37.0°C), Ht 62” (157 cm), Wt 186 lb (84.5 kg)

**Labs:** WBC 7 × 10^9/mm^3 (7 × 10^9/L), serum creatinine 0.7 mg/dL (62 μmol/L), glucose 95 mg/dL (5.3 mmol/L)

**What organisms are likely to be encountered for this operation and why?**

**What agents need to be avoided considering this patient’s previous reaction with cephalexin?**

**What drug would you choose for this operation and why?**

The surgeon agrees with your decision and wants to begin infusing the antimicrobial 3 hours prior to the first incision. Comment on this.

**What other interventions besides antimicrobial use could prove useful in lowering RP’s risk of SSI?**

---

**Patient Encounter Part 2**

RP is transferred to the oncology ward after completion of her surgery. In the procedure notes, the surgeon notes that part of the small bowel was nicked and possible intra-abdominal contamination may have occurred.

**Does this patient still require surgical site prophylaxis?**

**The surgeon asks for your opinion for which antimicrobial the patient should receive. Which antimicrobial do you recommend?**

**How long should this patient remain on antimicrobials?**

- Parenteral prophylaxis: cefazolin and metronidazole; cefoxitin; cefotetan; ampicillin-sulbactam; ceftriaxone and metronidazole; ertapenem
- Alternatives for β-lactam allergy: clindamycin combined with aminoglycoside, aztreonam, or fluoroquinolone; metronidazole combined with aminoglycoside or fluoroquinolone

Oral routes for prophylaxis include the combination of neomycin with either erythromycin or metronidazole and are administered at 19, 18, and 9 hours prior to surgery. These oral routes should be given with mechanical bowel preparation. For most patients, this oral regimen should be combined with a parenteral regimen.

Appendectomy is one of the most common intra-abdominal operations. Antimicrobial prophylaxis used for appendectomy is similar to that used for colorectal regimens. In the case of ruptured appendix, antimicrobials are used for treatment, not prophylaxis.

**OUTCOME EVALUATION**

The clinician should consistently follow up postoperative patients and screen for any sign of SSI. According to CDC criteria, SSIs may appear up to 30 days after an operation and up to 1 year if a prosthesis is implanted. This period often extends beyond hospitalization, so educate patients on warning signs of SSI and be encouraged to contact a clinician immediately if necessary. The presence of fever or leukocytosis in the immediate postoperative

**Patient Encounter Part 3**

RP was treated appropriately for her surgical complications based on your recommendations following her surgery. She presents to a 3-week follow-up appointment to the surgical clinic. She notes that her wound site has been increasing in redness over the past 1 to 2 days, accompanied by a slight discharge that started this morning prior to the clinic visit.

**VS:** BP 104/78 mm Hg, P 82 beats/min, RR 21 breaths/min, T 101.7°F (38.7°C)

**Labs:** WBC 19 × 10^9/mm^3 (19 × 10^9/L) serum creatinine 1.4 mg/dL (124 μmol/L)

**Based on the available data, does RP have an SSI?**

**What further steps should be taken in regard to this possible SSI?**
Conduct thorough medication history.
Monitor for signs and symptoms of postoperative infection
Obtain serum creatinine and weight.
Document allergies and the type of reaction.
Consider penicillin allergy testing in patients with unclear
documentation of penicillin allergy.
Document type of operation patient is to receive.
Start antimicrobials within 1 hour of surgical incision
Surgical site infection
Document type of operation patient is to receive.

Follow-Up Evaluation:
- Monitor for signs and symptoms of postoperative infection (30 days postoperation, up to 1 year if prosthesis involved).
- Draw cultures to further guide therapy if SSI suspected.

Follow-Up Evaluation:
- Monitor for signs of allergic reaction.
- Document any major breaks in surgical technique and adjust length of antimicrobial therapy if surgical classification changes.

Care Plan Development:
- Monitor patient for signs of allergic reaction.
- Document any major breaks in surgical technique and adjust length of antimicrobial therapy if surgical classification changes.

Therapy Evaluation:
- Consider penicillin allergy testing in patients with unclear documentation of penicillin allergy.
- Document type of operation patient is to receive.
- Start antimicrobials within 1 hour of surgical incision (2 hours for vancomycin, fluoroquinolones).

Patient Assessment:
- Conduct thorough medication history.
- Obtain serum creatinine and weight.
- Document allergies and the type of reaction.

Patient Care Process

period does not constitute SSI and should resolve with proper patient care. Distal infections, such as pneumonia, are not considered SSIs even if these infections occur in the 30-day period. Check the appearance of the surgical site regularly and document any changes (eg, erythema, drainage, or pus). The presence of pus or other signs suggestive of SSI must be treated accordingly. Any wound requiring incision and drainage is considered an SSI regardless of appearance. Collect prompt cultures and initiate appropriate antimicrobial therapy to reduce any chance of morbidity and mortality.
LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Define vaccination and immunization.
2. Recommend an immunization schedule for a child, including immunocompromised children.
3. Recommend an immunization schedule for an adult based on comorbid conditions and lifestyle choices.
4. Evaluate an adverse reaction and its probable association with a vaccine.

INTRODUCTION

The development and widespread use of vaccines is one of the greatest public health achievements of the 20th century. Other than safe drinking water, no other modality has had a greater impact on reducing mortality from infectious diseases. The first accounts of deliberate inoculation to prevent disease date back as far as the 10th century. However, it wasn’t until 1798 that Edward Jenner published his work on inoculation of natural cowpox as a means to prevent infection with smallpox that documented the first scientific attempt to prevent infection by inoculation. Since 1900, the widespread use of vaccines has resulted in the eradication of smallpox worldwide and wild-type poliovirus from the Western hemisphere. There have also been dramatic declines in the incidence of diphtheria, pertussis, tetanus, measles, mumps, rubella, and Haemophilus influenzae type b infections. In the United States, there are immunization recommendations against 17-vaccine preventable diseases affecting all age groups.

Vaccines have traditionally been preparations of killed or attenuated microorganisms that provide active immunity against a variety of viral and bacterial infections. Most vaccines are designed to prevent acute infections that can be rapidly controlled and cleared by the immune system. Successful immunization involves activation of antigen-presenting cells with processing of the antigen by lysosomal or cytoplasmic pathways. T and B lymphocytes will be activated to replicate and differentiate to form large pools of memory cells for protection against subsequent exposure to the antigen.

Vaccines against viral infections may be attenuated live viruses or inactivated viral particles. Attenuation may be accomplished by several methods to decrease the viruses’ virulence while retaining their immunogenicity. Bacterial vaccines utilize antigenic particles of the outer membrane to elicit an immune response. Outer membrane polysaccharides are poorly immunogenic in children younger than 2 years unless conjugated with a carrier protein. Also, bacterial toxins may undergo chemical treatment to render them nontoxic to form toxoids against infectious agents.

Often the terms vaccination and immunization are used interchangeably even though they are distinct concepts. Vaccination refers to the act of administering a vaccine, whereas immunization refers to the development of immunity to a pathogen. The delivery of a vaccine does not imply that the individual mounted an adequate immune response to the vaccine to elicit protection. However, immunization implies that the act of vaccination resulted in the development of protective immunity.

Herd immunity refers to high levels of immunization in one population, resulting in protection of another unvaccinated population. For example, concentrated vaccination of children with the pneumococcal conjugate vaccine resulted in decreased invasive Streptococcus pneumoniae infection not only in the vaccinated children, but also in elderly persons within the same community.

Cocoon immunization is a strategy used to immunize all persons surrounding another high-risk individual, such as vaccinating parents, siblings, and grandparents of a new infant who is too young to be vaccinated. This strategy is used to protect individuals who are not able to be vaccinated themselves.

THE ROUTINE VACCINES

Diphtheria, Tetanus, and Pertussis Vaccines

Diphtheria is a contagious bacterial respiratory infection characterized by membranous pharyngitis. The impact of diphtheria is not from the causative bacteria, Corynebacterium diphtheriae, but rather from complications attributed to its exotoxin, such as myocarditis and peripheral neuritis. Diphtheria is rarely reported in the United States since the introduction of vaccination with diphtheria toxoid; however, diphtheria continues to be a major problem in developing countries.

The tetanus vaccine differs from others in that it does not protect against a contagious disease such as diphtheria, but rather against an environmental pathogen. Clostridium tetani is widely found in the environment, especially in dirt and soils. Tetanus is rarely seen in developed countries.
Pertussis is a highly contagious respiratory tract infection caused by the bacteria Bordetella pertussis. Pertussis is characterized by a protracted severe cough with or without posttussive vomiting, whoop, difficulty breathing, difficulty sleeping, and rib fractures. It is often referred to as “whooping cough” or the 100-day cough.

### Use of Diphtheria, Tetanus, and Acellular Pertussis Vaccine

Diphtheria and tetanus toxoids and acellular pertussis vaccine should be administered in a five-shot series to all children beginning at 2 months of age. The shots are given at 2, 4, 6, and 15 to 18 months, and 4 to 6 years. Immunity to diphtheria, tetanus, and pertussis is achieved after the third vaccination.

### Use of Tetanus and Diphtheria Toxiod Vaccine

Immunity to tetanus and diphtheria wane with increasing age necessitating the need for booster doses every 10 years. The preferred agent to use in adults is tetanus and diphtheria toxoid in order to also give a booster for diphtheria. Tetanus immunization status should be assessed in the management of moderate and severe wounds or contaminated wounds in individuals seeking medical care. A tetanus booster should be administered if necessary.

### Use of Tetanus Toxoid, Reduced Diphtheria, and Acellular Pertussis Vaccine

Pertussis continues to be reported in adolescents and adults of all ages indicating a waning immunity following primary immunization. Additionally, adults with pertussis may infect young infants who have not received the first three doses of primary vaccination resulting in hospitalizations and death. A tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine is recommended for use in adolescents and adults.

Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine should be administered to adolescents 11 through 18 years as a single booster. Ideally it should be given at 11 to 12 years of age. Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine is also recommended for adults 19 years and older as a single booster dose in individuals who have not already received it. This may be given as a routine vaccination or for wound management.³

Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine is also used as part of cocoon immunization strategy to protect young infants. The vaccine should be administered to pregnant women during the third trimester (27–36 weeks preferred) of each pregnancy in order for transfer of maternal antibodies to the newborn infant. Additionally, individuals with close contact to infants less than 12 months of age, such as fathers, grandparents, health care workers, and child care workers, should also be vaccinated. Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine may be given at any interval following a tetanus vaccine.³

### Haemophilus Influenzae Type b Vaccine

H. influenzae is a bacterial respiratory pathogen that causes a wide spectrum of disease ranging from upper respiratory infections to bacterial meningitis. H. influenzae type b was the leading cause of invasive disease in children younger than 5 years. Approximately two-thirds of the cases were meningitis that resulted in a high degree of hearing loss among survivors.⁵ Since the introduction of the vaccine, invasive disease due to H. influenzae type b has been nearly eliminated.

The H. influenzae type b vaccine is a protein conjugate that elicits T-lymphocyte-dependent immunity. The T-dependent antigens induce an enhanced immune response in younger children including infants. H. influenzae type b conjugate vaccine is a recommended routine childhood vaccination beginning at 2 months of age. There are currently three licensed monovalent H. influenzae type b conjugate vaccines and three combination vaccines containing H. influenzae type b conjugate. Each vaccine has a different dosing schedule and age range for use. Vaccine providers need to be aware of the brand being used and related dosing schedule. The immune response to H. influenzae type b is similar among the different vaccines. The different brands are interchangeable without affecting the primary immune response or booster response.⁵

A booster dose of H. influenzae type b vaccine is also recommended in adolescents and adults at high risk for becoming infected with H. influenzae. The currently available vaccines are labeled for pediatric use, but can be used in adults when vaccination is indicated. H. influenzae type b and influenza vaccines have the potential for confusion and medication errors because of the similarity of the names. Care should be taken when ordering, dispensing, and administering these vaccines.

### Hepatitis A Vaccine

Hepatitis A virus continues to be a frequent cause of illness despite the availability of a highly effective vaccine. Frequently, children younger than 6 years are asymptomatic with primary infection and play a pivotal role in spreading disease to adults. The economic burden of hepatitis A is greater than $300 million annually in combined direct and indirect costs. Widespread use of the Hepatitis A vaccine significantly decreases the disease burden caused by hepatitis A infection.⁵

Hepatitis A vaccine was licensed in the United States in 1995. It is an inactivated whole virus vaccine that is administered in a two-dose series. More than 94% of children, adolescents, and adults will have protective antibodies 1 month after receiving the first dose and 100% following the second dose. The hepatitis A vaccine is recommended for all children following the first birthday, with the second dose administered 6 months later. Adults who are at high risk for hepatitis A should receive two doses at least 6 months apart. High-risk adults include persons with clotting disorders or chronic liver disease, men who have sex with men, illicit drug users, and international travelers going to areas with high to intermediate endemicity of hepatitis A, persons with anticipated close contact with an international adoptee, or any other person who wishes to become immune.⁴

### Hepatitis B Vaccine

Hepatitis B virus is transmitted following exposure to infected blood and body fluids. Individuals with chronic hepatitis B infection are at risk for cirrhosis, liver cancer, liver failure and death. Vaccination with hepatitis B vaccine is the most effective way to prevent hepatitis B infection.⁷

Hepatitis B vaccine is manufactured using recombinant DNA technology to express hepatitis B surface antigen (HBsAg) in yeast. Hepatitis B vaccine is available as a single component or in combination vaccines. Hepatitis B vaccine is recommended for routine use in infants and children in a three-dose series. The first dose should be given prior to discharge following birth. The remaining two doses should be administered with other routine infant vaccinations during the
first 6 months of life. The dosing schedule will depend on the use of single component or combination vaccines. Adolescents should receive the three-dose series if not previously vaccinated.7

Hepatitis B vaccine is recommended for adults at high risk for hepatitis B infection and those requesting protection from hepatitis B. The vaccine is administered in a three-dose series over 4 to 6 months.4 Frequently, individuals do not follow through with the complete three-dose series and questions arise about restarting the series. Hepatitis B vaccine produces an amnesic response; therefore, the series may be continued at any time in order to complete the three doses.

Following vaccination with hepatitis B vaccine, hepatitis B virus serologic markers will remain negative, with the exception of antibody to hepatitis B surface antigen (anti-HBs), which will be positive indicating immunity. Persons with anti-HBs concentration greater than 10 mIU/mL (10 IU/L) after vaccination will have complete protection against acute and chronic infection.6 There is no need for booster doses in immunocompetent individuals when anti-HBs concentrations fall below 10 mIU/mL (10 IU/L), since a good memory response will occur following exposure to hepatitis B virus. However, a booster dose may be warranted in immunocompromised individuals.

Human Papillomavirus Vaccine

Human papillomavirus (HPV) is the most common sexually transmitted virus and is associated with a wide range of diseases, including cervical cancer and genital warts. More than 150 HPVs have been identified and classified on their ability to cause malignant disease. HPV 16 and 18 are highly associated with causing cervical cancer, as well as anal, oropharyngeal, penile, vaginal, and vulval cancers. HPV 6 and 11 are associated with 90% of genital warts.

There are two HPV vaccines on the market. The bivalent vaccine is effective against HPV 16 and 18, while the quadravalent vaccine is effective against HPV 6, 11, 16, and 18. These vaccines are unique in that preventing infection by HPV will translate into prevention of cancer. Countries with high uptake of HPV vaccine have started to see declines in HPV infections and related diseases such as genital warts and high-grade cervical disease.7

HPV vaccination is recommended for females aged 11 or 12 in a three-dose series. Females aged 13 through 26 years should also be vaccinated if they have not previously received the full three-dose series. There is no preference to administering the bivalent or quadravalent vaccine in females.8

The HPV quadravalent vaccine is recommended for routine vaccination in males aged 11 or 12 years. Vaccination is also recommended for males 13 through 21 years who have not received the full three-dose series.8

The overall rate of HPV vaccination is low among 13 year olds, with 57% of girls and 34% of boys having initiated the HPV series in 2013. The main reasons cited for not vaccinating teens is related to knowledge gaps among clinicians and parents regarding recommendations for use and safety concerns. With over 68 million doses distributed, the adverse event profile is similar to other vaccines administered to adolescents.10

Influenza Vaccine

Influenza is a contagious viral respiratory infection that usually occurs during the winter months in the Northern Hemisphere and all year round in the Southern Hemisphere. All age groups are affected by influenza; however, children have the highest rate of infection. Serious illness and death due to influenza usually occurs in extremes of age, those older than 65 years or younger than 2 years.

Influenza A and B viruses are responsible for causing human disease. Both influenza A and B undergo frequent antigenic drift, creating new influenza variants. Immunity to the surface antigens decreases the likelihood of infection. Unfortunately, antibody to one influenza subgroup does not give complete protection against other influenza subtypes.

The best way to protect against seasonal influenza is through vaccination. The current trivalent influenza vaccine contains two A strains, 1 A(H1N1), 1 A(H3N2), and one B strain. The quadrivalent influenza vaccine contains the same components of the trivalent and an additional B strain. Inactivated influenza vaccine is available in both trivalent and quadrivalent presentations. The live attenuated vaccine is only quadrivalent.11

All individuals 6 months of age and older should receive yearly seasonal influenza vaccination. There is no preference for vaccine presentation when multiple types are available within an approved age range, except for the following groups. The live attenuated influenza vaccine should preferentially be administered to healthy children aged 2 through 8 years. Live attenuated influenza vaccine is more effective than inactivated influenza vaccine in this age group. However, in adults inactivated influenza vaccine is more effective than live attenuated influenza vaccine.12 In person 65 years and older, the high-dose trivalent-inactivated influenza vaccine produced increased immunity and protection against confirmed influenza when compared to regular dose influenza vaccine, and should be used for older adults.13 The recombinant influenza vaccine is used in persons with severe egg allergy.

Measles, Mumps, and Rubella Vaccine

Measles, mumps, and rubella are acute viral infections that can cause serious disease and complications. Aggressive vaccination programs have made these infections uncommon in the United States. Measles and rubella have been eliminated from the United States. Recent outbreaks have been caused from importation of infected persons from other parts of the world where measles are still circulating. Some outbreaks also occur in communities with high levels of unvaccinated individuals.

Measles, mumps, and rubella vaccine is a live attenuated vaccine. It causes a mild subclinical infection producing long-term immunity. Measles, mumps, and rubella vaccine is recommended for routine vaccination after the first birthday and a second dose administered at 4 through 6 years of age. Measles, mumps, and rubella vaccine is available in combination with varicella vaccine. This vaccine is not recommended for the first dose due to the increased risk of febrile seizures when compared to giving measles, mumps, and rubella and varicella separately at the same visit.14 Measles, mumps, and rubella vaccine should also be given to adults older than 18 years who are found to be nonimmune.

Measles, mumps, and rubella vaccine should be avoided in immunocompromised persons because of the risk of acquiring measles from the vaccine. However, HIV-infected persons, who are not severely immunocompromised, including those on antiretroviral therapy, can be vaccinated if not immune.14 Measles, mumps, and rubella vaccine is a safe vaccine and rarely associated with severe reactions. The most common reaction is fever which usually occurs more than a week after vaccination. Children with a personal or family history of febrile seizures or epilepsy are at increased risk for measles, mumps, and rubella vaccine associated febrile seizures.14
Meningococcal Vaccines

*Neisseria meningitidis* is a significant cause of meningitis and bacteremia. Invasive meningococcal disease is associated with a high morbidity and mortality rate. Morbidity in survivors is substantial, with approximately 20% having loss of limb or neurologic sequelae. The highest rates of meningococcal disease are among young children; however, rates have been increasing in adolescents and young adults. Thirteen meningococcal serogroups have been identified; however, five serogroups, A, B, C, Y, and W-135, are responsible for epidemic and endemic disease worldwide. Despite the availability of highly active antibacterial agents against *N. meningitidis*, there has been little impact on decreasing the morbidity and mortality due to invasive meningococcal disease.\(^15\)

The meningococcal vaccine is recommended for routine vaccination of adolescents. The first dose should be administered at 11 to 12 years with a booster dose at age 16 years. Meningococcal vaccine is also recommended for high-risk individuals older than 2 months.\(^15\) There are three quadravalent and a bivalent vaccine available for use. The quadravalent vaccines contain serogroups A, C, Y, and W-135. The bivalent contains serogroups C and Y, and is conjugated to *H. influenzae* type B vaccine. Each vaccine is approved for different age groups. The vaccine provider should be cognizant to use the appropriate vaccine for the age of the patient. The quadravalent conjugated vaccines should preferentially be used. The polysaccharide vaccine should be reserved for high-risk individuals older than 55 years.

Pneumococcal Vaccines

*S. pneumoniae* is the most common bacterial cause of community-acquired respiratory tract infections. *S. pneumoniae* causes approximately 3000 cases of meningitis, 50,000 cases of bacteremia, 500,000 cases of pneumonia, and more than 1 million cases of otitis media each year. The increasing prevalence of drug-resistant *S. pneumoniae* has highlighted the need to prevent infection through vaccination. Pneumococcal vaccines are highly effective in preventing disease from the common *S. pneumoniae* serotypes that cause human disease.

The 13-valent pneumococcal conjugate vaccine contains the serotypes that most commonly cause disease in children. The 23-valent pneumococcal polysaccharide vaccine contains 23 serotypes that are responsible for causing more than 80% of invasive *S. pneumoniae* infections in adults. The pneumococcal vaccines have demonstrated good immunogenicity and prevention of invasive pneumococcal disease.

The 13-valent pneumococcal vaccine is part of the routine childhood immunization schedule beginning at 2 months of age. Children older than 6 years who are at high risk of invasive pneumococcal disease should receive a single 23-valent pneumococcal polysaccharide vaccine, with a booster dose given in 5 years.\(^16\)

Both the 13-valent pneumococcal conjugate and 23-valent pneumococcal polysaccharide vaccines are recommended for routine use in all adults 65 years of age or older. The 13-valent vaccine should be administered first followed by the 23-valent vaccine 6 to 12 months later. If an individual has already received the 23-valent pneumococcal vaccine, the 13-valent vaccine should be administered at least 12 months after the 23-valent vaccine. Adults 19 through 64 years who are at increased risk for invasive pneumococcal disease are recommended to receive a single vaccination with the 13-valent pneumococcal conjugate vaccine. This is followed in 8 weeks with a 23-valent pneumococcal polysaccharide vaccine, and a booster dose in 5 years.\(^17\)

Revaccination with the 23-valent pneumococcal polysaccharide vaccine is recommended for adults older than 65 years if the first dose was administered when they were younger than 65 years and at least 5 years have passed. A dose of the 13-valent pneumococcal vaccine should be administered prior to receiving the 23-valent vaccine.\(^17\)

Poliovirus Vaccine

Poliomyelitis is a highly contagious disease that is often asymptomatic; however, approximately 1 in every 100 to 1000 cases will develop a rapidly progressive paralytic disease. Polio is caused by poliovirus. Since the introduction of the first poliovirus vaccine, there has been a significant reduction in the number of polio cases. Today, polio caused by wild-type poliovirus has been eradicated from the Western hemisphere with the goal of eradicating it from the world.\(^18\)

The oral poliovirus vaccine has been routinely used in the United States. Unfortunately, the oral poliovirus vaccine has the risk of vaccine-associated paralytic poliomyelitis occurring in approximately 1 case of every 2.4 million doses distributed. The risk with the first dose of oral poliovirus vaccine is 1 case in 750,000 doses.\(^18\)

The last reported case of indigenous wild-type poliovirus in the United States was in 1979; subsequent cases were all vaccine associated. In 1997, a transition period to the inactivated poliovirus vaccine was begun to reduce the risk of vaccine-associated paralytic poliomyelitis. By January 2000, the oral vaccine was no longer recommended for routine use. Currently, the inactivated poliovirus vaccine is recommended for routine use in the United States. It is available as a single component or in combination vaccines. A booster dose should be given after age 4 years, no matter how many doses were given in the infant vaccination series.\(^19\)

Rotavirus Vaccine

Rotavirus is the most common cause of severe diarrheal disease in children younger than 5 years. It is a major cause of diarrhea hospitalizations for dehydration worldwide. Rotavirus G1 is the most prevalent strain found in the United States. However, in any given year, other strains (G2, G3, G4, and G9) may predominate.

There are two rotavirus vaccines available for use. They are a pentavalent human–bovine reassortant vaccine that contains outer capsid proteins for G1, G2, G3, G4, and P1, and a monovalent, G1 vaccine. The exact mechanism by which these vaccines produce an immune response is unknown; however, these live virus vaccines replicate in the small intestine and induce immunity.

The rotavirus vaccine is administered in either a two-dose or a three-dose series that is orally administered. The first dose is
given to infants between 6 and 12 weeks of age. The impact of the rotavirus vaccine has been dramatic with a significant decrease in rotavirus hospitalizations and all-cause diarrhea hospitalizations in children younger than 5 years. The vaccine has also offered protection to children too old to receive the vaccine and young adults. The most severe adverse events associated with rotavirus vaccine is intrussusception, a telescoping of the intestines on to itself. Post-licensure monitoring has shown a minimal risk of the vaccine with 1 to 5 excess cases of intrussusception per 100,000 vaccinated children.

Varicella Vaccine

Varicella zoster virus is a highly contagious herpes virus. Primary infection with varicella zoster causes chickenpox and was one of the most common childhood diseases in the prevaccine era. Following primary infection, varicella becomes latent in cranial nerve, dorsal routes, and autonomic ganglia where it may reactivate to cause shingles (Zoster) in older adults. Since the introduction of the varicella vaccine virus in 1995, there has been a 90% reduction in varicella infections and hospitalization in all age groups.

The varicella vaccine is a live attenuated vaccine. Children younger than 12 years will have a 97% seroconversion rate following a single vaccination. Adolescents and adults older than 13 years will only have 78% seroconversion after a single inoculation, but will have 99% conversion following a second dose. Therefore, varicella vaccine is recommended to be administered in a two-dose series. The first dose should be administered after 12 months of age and a second dose at 4 years of age. Adolescents and adults without evidence of immunity to varicella zoster should receive two doses of varicella vaccine given 4 to 8 weeks apart. Antibody titers appear to persist for at least 20 years following immunization.

Varicella vaccine is well tolerated with tenderness at the injection site and mild rash the most common adverse events. Rashes due to the vaccine strain typically occur more than 20 days following vaccination. A few cases of secondary transmission to household contacts have been reported.

Zoster Vaccine

Later in life, approximately 15% of the population will develop herpes zoster (shingles). Zoster is the reactivation of latent varicella zoster virus in the sensory ganglia. Zoster most frequently occurs in the elderly and immunocompromised individuals who have decreased circulating antibodies to varicella zoster virus.

Zoster vaccine is a more concentrated form of the varicella vaccine. It is FDA approved for use in individuals 50 years and older. However, ACIP recommends its use in individuals 60 years and older even with a previous episode of shingles. Use of the zoster vaccine has shown a reduction in the incidence of zoster and postherpetic neuralgia.

Patient Encounter 2

A 65-year-old patient presents to the pharmacy to pick-up his prescription for blood pressure medication. The pharmacist asks the patient if he would like to receive his vaccines, and the patient accepts.

What vaccines should the patient receive?
What warnings should be given to the patient?

VACCINE ADMINISTRATION SCHEDULES

Most vaccines are administered in two- to four-shot series in order to elicit the best protection. Childhood and adult immunization schedules are revised frequently and published annually by the CDC Advisory Committee on Immunization Practices (ACIP). Current immunization schedules can be found at www.cdc.gov/vaccines/. Recommendations will be published throughout the year in the Morbidity and Mortality Weekly Report (MMWR) as new vaccines are licensed or new information necessitates a change in previous recommendations. See Table 86-1 for vaccine dosing.

The childhood immunization schedule is complex and requires a large number of injections. In small infants, the number of injections can be intolerable to the infant, parent, and health care provider. Limiting the number of injections at each visit can lead to missed vaccinations and increased expense for return visits.

Use of combination vaccines decreases the number of injections and increases the likelihood that the immunization schedule will be completed. Using combination vaccine does not adversely affect the immunity or increase adverse effects. Vaccine administration should not be delayed for mild to moderate respiratory tract illnesses or fevers.

VACCINE SAFETY

Vaccination is one of the most powerful tools used to prevent disease. As with all drugs, most vaccines have been reported to cause adverse reactions. The reactions are either acute or are related to the risk of developing another disease. Health care professionals should discuss the risks versus benefits of vaccines with individuals or caregivers prior to vaccination. Vaccine information sheets (VIS) provide written information about each vaccine and are required to be given individuals prior to vaccination.

Vaccine safety is monitored by the FDA and CDC through a passive reporting system that allows anyone, health professionals or lay public, to report any event through the Vaccine Adverse Event Reporting System (VAERS). Health care professionals are mandated to report certain events through VAERS. Additionally, any serious, life-threatening or unusual reactions should also be reported.

The VAERS database is continually monitored to determine whether the prevalence of reactions is changing and to identify previously unreported reactions to a particular vaccine. Large epidemiologic safety studies are conducted through the Vaccine Safety Datalink; a partnership between the CDC and 9 large health care organizations.

Pain at the injection site is one of the most commonly reported adverse effects of vaccination. The reaction is usually mild, with complaints of pain and tenderness at the injection site that may or may not be accompanied by erythema. Local reactions tend to be more frequent with repeated doses or booster doses of vaccine. Tetanus-containing vaccines are well known for causing localized reactions.

Fever is the most frequently reported adverse effect in children. Elevated temperature is usually self-limiting and resolves in a few days. Rarely febrile seizures may occur following vaccination with measles, mumps, and rubella vaccine.

Reports of syncope following vaccination have been increasing since the approval of human papillomavirus and tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines. Syncope most commonly occurs in adolescent girls and young adults. Health care professionals should implement measures to mitigate secondary injuries when vaccinating this age group.

### Autism

Thimerosal is a preservative used in vaccines that has been purported to cause autism in children. The assumption is that thimerosal, also known as ethyl mercury, causes similar effects as methyl mercury, which has neurotoxic and nephrotoxic effects at high doses. Numerous epidemiologic studies have not shown a higher rate of autism among children receiving thimerosal-containing vaccines when compared with the normal background rate of autism. Additionally, the mercury exposure with vaccination is much lower than through many other environmental exposures.²⁴

### Guillain-Barré Syndrome

Guillain-Barré syndrome is a transient neurologic disorder causing flaccid paralysis. It is thought to be caused from the development of autoimmune antibodies that cause damage to the peripheral nerves. Guillain-Barré syndrome has been temporally associated with several bacterial and viral infections as well as vaccinations.

The association with vaccination and Guillain-Barré syndrome was first recognized with the Swine flu vaccine of 1976. Since that time a clear association of influenza vaccination and Guillain-Barré syndrome has not been clearly established. Caution is still recommended with influenza vaccines since the influenza strains contained in the vaccine has the potential to change each year.²⁵

Several large epidemiologic studies have sought to establish a temporal association of Guillain-Barré syndrome and other routine vaccines. The evidence is inconclusive in determining a cause-and-effect relationship. Overall the risk of Guillain-Barré syndrome following vaccination is minimal with 1 to 2 cases per 100,000 vaccines administered. The benefits of vaccination far outweigh the risk of Guillain-Barré syndrome.²⁵
SPECIAL POPULATIONS

Immunocompromised Host

The number of immunocompromised persons is continually increasing as advances are made in medicine. The life expectancy for persons with cancer, HIV infection, and solid organ or bone marrow transplantation is increasing. Vaccination provides one tool to prevent infection in the immunocompromised host. However, the individual’s immunosuppressed state will alter the response to the vaccine. In general, all vaccinations should be updated prior to the person becoming immunosuppressed. **KEY CONCEPT** Once a person becomes significantly immunosuppressed, live virus vaccines should be avoided.

Infants, children, and adults with HIV should receive all routine vaccinations according to the recommended immunization schedule as long as T-lymphocyte CD4 count is more than 200 cells/mm³ (200 × 10⁹/L). Live vaccines should be used with caution when T-lymphocyte CD4 counts are less than 200 cells/mm³ (200 × 10⁹/L). All HIV-infected persons should receive yearly inactivated influenza vaccination.

Following hematopoietic stem-cell transplantation, the patient will need most routine vaccines to be administered 6 to 12 months following transplantation. Diphtheria, tetanus, acellular pertussis, H. influenzae type b, hepatitis B, meningococcal, pneumococcal, and inactivated poliovirus should be given. Inactivated influenza vaccine is given yearly, starting 6 months after transplant. Measles, mumps, and rubella can be given 2 years after transplant and varicella and zoster vaccines are contraindicated.

Solid organ transplant recipients have a blunted immune response to vaccines because the immunosuppressive regimens used to prevent organ rejection inhibit both T- and B-cell proliferation. Prior to transplant, children should complete primary immunization schedules if possible. Otherwise primary immunization schedule with inactivated vaccines may continue 2 months following transplantation. Adults should have all vaccinations updated prior to transplantation. Yearly seasonal inactivated influenza vaccine may be given 6 months following transplantation.

Household contacts of immunocompromised persons should have all routine vaccines as scheduled, including yearly influenza vaccination. Children in the household may receive live virus vaccines without special precautions; however, if a rash develops following varicella vaccination, contact should be avoided with the immunocompromised host until the rash resolves.

Pregnancy

Vaccination during pregnancy has the ability to protect not only the mother but also the newborn infant. A fully immunized mother is less likely to infect their infant with critical diseases such as influenza, tetanus, and pertussis. Mothers who are vaccinated in the second half of the pregnancy will have maternal transfer of antibodies through the placenta giving protection to the newborn infant. Pregnant women should be vaccinated with inactivated influenza and tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines during each pregnancy. Ideally the vaccines should be administered after 20-week gestation, but can be administered at any time during the pregnancy.

Live virus vaccines should be avoided during pregnancy due to the theoretical concern of the virus being transported across the placenta and infecting the fetus. Women found to be nonimmune to rubella or varicella may be vaccinated soon after delivery, but not during the pregnancy. The live attenuated influenza vaccine should also be avoided.

Health Care Professionals

Health care professionals are in a unique position to protect themselves and their patients by receiving immunizations against vaccine preventable diseases. Health care professionals should have documented immunity to measles, mumps, rubella, and varicella. The vaccine series should be administered if found nonimmune. Health care professionals with direct patient contact should also receive the Hepatitis B vaccine series and have proven immunity following the series. As concerns regarding the rise of pertussis among adults, it is now recommended that all health care professionals receive at least one dose of tetanus, reduced diphtheria, and acellular pertussis vaccine to protect against pertussis. This dose may be administered at any interval following a tetanus booster.

The Centers for Diseases Control recommends all health care professionals receive yearly influenza vaccination; there is no preference to the type of influenza vaccine that is given. Many health care facilities are now mandating that employees receive yearly influenza vaccination or wear masks during influenza season.

OUTCOME MEASURES

**KEY CONCEPT** Vaccines are a cost-effective means for disease prevention. From a societal perspective, for every dollar spent on routine childhood vaccines, there will be a $10 savings in direct and indirect costs. The rates of vaccination for young children are 90% or more for most recommended vaccines. This has been attributed to the requirements for proof of vaccination by States for enrollment into daycare centers and school. For vaccines not required by schools, the rate of vaccination is lower.

Adolescents present a unique challenge for vaccinating because they do not have as many encounters with health care professionals as young children do. However, the constantly changing immunization schedules makes this population vulnerable to missing newly approved vaccines and catch-up doses of vaccines that were not recommended when they were younger. Every encounter with a health care establishment should be viewed as an opportunity to evaluate and vaccinate if necessary. Adolescents may also have incomplete medical records due to changes in health care providers. Therefore, it is important for health professionals to regularly utilize universal State immunization databases that document pediatric and adult vaccinations. This eliminates the problems of lost immunization records if a child changes health care providers.

The vaccination rate in adults is much lower than that in children. Only 50% to 60% of adults who meet criteria have received pneumococcal vaccination, and less than 40% have received seasonal influenza vaccine. Comprehensive initiatives need to be implemented to increase the adult vaccination rate.
Some proven concepts are providing reminders to patients that vaccines are due and implementation of standing orders for vaccines. This latter concept allows nurses and pharmacists to screen patients to determine whether pneumococcal, influenza, or other vaccines are needed and to vaccinate without a direct physician’s order.

- **ACIP**: Advisory Committee on Immunization Practices
- **anti-HBs**: Antibody to hepatitis B surface antigen
- **CDC**: Centers for Disease Control and Prevention
- **HBsAg**: Hepatitis B surface antigen
- **VAERS**: Vaccine Adverse Event Reporting System
- **VIS**: Vaccine information sheets

### REFERENCES

INTRODUCTION

Human immunodeficiency virus type is the major cause of AIDS. HIV primarily targets CD4⁺ lymphocytes, which are critical to proper immune system function. If left untreated, patients experience a prolonged asymptomatic period followed by rapid, progressive immunodeficiency. Therefore, most complications experienced by patients with AIDS involve opportunistic infections and cancers. AIDS occurs when a patient with HIV has a CD4 cell count below 200 cells/mm³ (200 × 10⁶/L), a CD4 cell percentage of total lymphocytes less than 14% (0.14), or one of the Centers for Disease Control (CDC) AIDS defining conditions.¹

EPIDEMIOLOGY AND ETIOLOGY

HIV is primarily transmitted by sexual contact, by contact with blood or blood products, and from mother to child during gestation, delivery, or breast-feeding. Although the global incidence of HIV has fallen 33% since 2001, HIV prevalence has increased, largely due to life-extending antiretroviral therapy. Combination antiretroviral therapy (cART) has increased both the length and quality of life for HIV-infected patients, however, to date, there are no treatments that eradicate HIV from the body.²

As of 2012, approximately 35.3 million people are infected with HIV worldwide. Approximately 70% of these cases are in Sub-Saharan Africa, with a prevalence of approximately 5%. Central Asia, Eastern Europe, North Africa, and the Middle East are also seeing rapidly rising infection rates.³

In 2012 alone, approximately 1.6 million people worldwide died from AIDS and 2.3 million people were newly infected with HIV. Most of these infections were acquired through heterosexual transmission. As of December 2012, women accounted for 45.6% of all people living with HIV worldwide. Young adults, aged 15 to 24 years, accounted for approximately 39% of new HIV infections worldwide.²

In the United States, at the end of 2011, an estimated 1.2 million persons (aged 13 years or older) were living with HIV/AIDS. Approximately 14% of these are undiagnosed and unaware of their HIV infection and could be unknowingly transmitting the virus to others.³

In 2010, HIV/AIDS rates for African American men were six times those for white men and twice that for Hispanic males, representing 44% and 21% of cases, respectively. Although HIV/AIDS rates in African American women dropped by 21% in 2010, incidence in this population is 20 times the rate for white females and five times the rate for Hispanic females.³

Risk factors for HIV/AIDS infection include men who have sex with men (MSM), history of or current IV drug use (needle or equipment sharing), unprotected sexual intercourse with high-risk individuals, the presence of other sexually transmitted infections (eg, Chlamydia trachomatis or Neisseria gonorrhoeae), persons with coagulation/hemophilia disorders, and previous blood product recipients.

PATHOPHYSIOLOGY

HIV-1 is a retrovirus and member of the genus Lentivirus. There are two molecularly and serologically distinct but related types of HIV: HIV-1 and HIV-2. These viruses have a prolonged latency period. HIV-2 is a less common cause of the epidemic and is found primarily in West Africa. HIV-1 is categorized by phylogenetic lineages into three groups (M [main or major], N [new], and O [outlier]). HIV-1 group M can be further categorized into nine subtypes: A through D, F through H, and J and K. HIV-1 subtype B is primarily responsible for the North American and Western European epidemic.

HIV infection occurs through three primary modes of transmission: sexual, parenteral, and perinatal. The most common method for transmission is receptive anal and vaginal
intercourse, with the probability of transmission highest, 138 infections per 10,000 exposures, with receptive anal intercourse. The probability of transmission increases when the infected partner has a high level of viral replication (which occurs at the beginning of infection or late in disease) or when the uninfected partner has ulcerative disease or compromised mucosal surfaces or (in the case of men) has not been circumcised.

Parenteral transmission of HIV primarily occurs through injection drug use by sharing contaminated needles or injection-related supplies. Less than 1% of all cases of HIV infection occur as a result of transfusions of contaminated blood or blood products, or infected transplant organs. Health care workers have a 0.3% estimated risk of acquiring HIV infection through percutaneous needlestick injury.

Perinatal infection (also known as vertical transmission or mother-to-child transmission [MTCT]) can occur during gestation, at or near delivery, and during breast-feeding. In the absence of specific intervention including medications, the risk of MTCT up to and including delivery is approximately 25%, whereas the risk of transmission during breast-feeding is approximately 15% to 20% within the first 6 months of life. Because a high rate of HIV replication in the blood is a significant risk factor for transmission of HIV, it is important to treat women for their HIV infection during pregnancy. After delivery, mothers are strongly recommended not to breast-feed if safe alternatives are available.

Understanding the life cycle of the virus is important to know how antiretroviral drugs are combined for optimal therapy (Figure 87–1). Once HIV enters the body, an outer glycoprotein called gp120 binds to CD4 receptors found on the surface of dendritic cells, T lymphocytes, monocytes, and macrophages. This allows further binding to other chemokine receptors on the cell surface called CCR5 and/or CXCR4. Greater than 95% of newly infected patients have viruses that preferentially use CCR5 to enter the cell, and most patients with advanced disease have viruses that preferentially use CXCR4 to enter the cell.

After the virus has attached to CD4 and chemokine receptors, another viral glycoprotein (gp41) assists with viral fusion to the cell and internalization of the viral contents. The viral contents include single-stranded RNA, an RNA-dependent DNA polymerase (also known as reverse transcriptase), and other enzymes. Using the single-stranded viral RNA as a template, reverse transcriptase synthesizes a complementary strand of DNA. The single-stranded viral RNA is removed from the newly formed DNA strand by ribonuclease H, and reverse transcriptase completes the synthesis of double-stranded DNA. The viral reverse transcriptase enzyme is highly error-prone, and many mutations occur in the conversion of RNA to DNA. This inefficient reverse transcription activity is responsible for HIV’s ability to rapidly mutate and develop drug resistance.

A chronic infection is established when the double-stranded DNA migrates to the host cell nucleus and is integrated into the host cell chromosome by an HIV enzyme called integrase. Once the cell becomes activated by antigens or cytokines, HIV replication starts: Host DNA polymerase transcribes viral DNA into messenger RNA, and messenger RNA is translated into viral...

proteins. These proteins assemble beneath the bilayer of the host cell, a nucleocapsid forms containing these proteins, and the virus buds from the cell. After budding, the virus matures when an HIV protease enzyme cleaves large polypeptides into smaller functional proteins. Without this process, the virus is unable to infect other cells.

During the early stages of infection, approximately 10 billion virions can be produced each day. Most of the cells containing these viruses will be lysed as a result of budding virions, cytotoxic T-lymphocytes, or undergoing apoptosis. However, HIV will be protected within some cells (macrophages, T cells in lymph nodes), which can stay dormant for years.

The initial immune response against HIV is relatively effective, but it is unable to completely clear the infection, and the patient enters a latent, asymptomatic, or mildly symptomatic stage lasting 5 to 15 years. During this time, a high rate of viral replication can be seen in the lymph nodes. Eventually immune deficiency occurs when the body is no longer able to replenish helper T cells at a rate equal to that at which HIV is destroying them.

**KEY CONCEPT** The goal of therapy is to maximally and durably suppress HIV replication to restore and preserve immune system function and minimize morbidity and mortality. Because HIV replication has been found in all areas of the body, it is important to use potent combination drug therapy that can achieve adequate concentrations in all tissues, including protected sites such as the brain and genital tract.

### CLINICAL PRESENTATION AND DIAGNOSIS

Patients who are acutely infected with HIV may be asymptomatic or present with signs and symptoms associated with any viral infection, such as fever, myalgias, lymphadenopathy, pharyngitis, or rash. Taken together, these are the “acute retroviral syndrome,” and 40% to 90% of acutely infected individuals will have symptoms. Providers should consider the possibility of HIV infection in any patient with these findings and inquire about recent high-risk sexual encounters or other modes of high-risk exposures. In the United States, 1 in 6 HIV-infected individuals are not aware of their status, thus identifying acutely infected patients and providing referral into HIV care is critical for preventing HIV transmission.

During acute infection, HIV RNA concentrations in blood and the genital tract are very high, increasing the risk of transmission to others. Increased infectiousness coupled with undiagnosed HIV infection in these patients may account for a substantial proportion of sexual HIV transmission.

If patients are not identified during acute infection, they may later present with nonspecific symptoms such as myalgias, fatigue, weight loss, thrush, or symptoms associated with opportunistic infections. The U.S. CDC recommends that patients aged 13 to 64 years in all health care settings undergo opt-out HIV testing, meaning that a separate consent form for testing is not needed after the patient has been informed that testing will be performed. For those patients in the high-risk groups mentioned above, HIV testing should be performed on an annual basis, and pregnant women should be tested with each pregnancy.

Diagnosis of HIV is made either by a positive HIV enzyme-linked immunosorbent assay (ELISA) or rapid test (these tests may be positive as soon as 3–6 weeks after infection) and then confirmed by a positive test, usually the HIV western blot (WB) (Table 87–1). At-home HIV-1 test kits (Home Access Systems, OraQuick), allows patients to self-collect blood or oral swab samples, and obtain confidential results in the privacy of their home. Positive results require confirmation by WB.

If the WB is the gold standard confirmatory test and is commonly used. The WB is considered reactive if two of the three major bands (p24, gp41, and/or gp120/160) change color. The test is nonreactive if no viral bands are visible. If the test is indeterminate (one band visible), patients are retested in 2 to

Clinical Presentation and Diagnosis of HIV

Patients with acute HIV infection may display symptoms described as acute retroviral syndrome. Patients with chronic HIV infection may present with these same nonspecific symptoms and/or opportunistic infections.

Acute Retroviral Syndrome

The majority of patients may present with fever, lymphadenopathy, pharyngitis, and/or rash. Other symptoms include the following:

- Myalgia or arthralgia
- Diarrhea
- Headache
- Nausea and vomiting
- Hepatosplenomegaly
- Weight loss
- Thrush
- Neurologic symptoms (meningoencephalitis, aseptic meningitis, peripheral neuropathy, facial palsy, or cognitive impairment or psychosis)

Opportunistic Infections

Depending on the severity of immunosuppression (the CD4+ count), patients may present with the following opportunistic infections (grouped by CD4+ count):

- Any CD4+ count
  - Mycobacterium tuberculosis disease
  - Bacterial pneumonia (commonly Streptococcus pneumoniae, Haemophilus influenzae, Pseudomonas aeruginosa, and Staphylococcus aureus)

- CD4+ count < 200 cells/mm³
- CD4+ count < 150 cells/mm³
  - Herpes simplex virus disease
  - Varicella zoster virus disease
  - Bacterial enteric disease (most commonly Salmonella, Campylobacter, and Shigella)
  - Syphilis
  - Bartonellosis
  - Mycobacterium avium
  - Pneumocystis jiroveci (formerly carinii) pneumonia (PCP or PJP)
  - Oropharyngeal and esophageal candidiasis
  - Kaposi sarcoma or human herpesvirus-8 disease
  - Toxoplasma gondii encephalitis
  - Cryptosporidiosis
  - Microsporidiosis
  - Less than 50 cells/mm³ (50 × 10⁶/L)
  - Disseminated Mycobacterium avium complex disease
  - Cytomegalovirus disease (CMV)
  - Cryptococcosis, aspergillosis

3 months. This is most likely if a recent (ie, less than 3–6 weeks) infection has occurred, and HIV antibodies have not yet been fully formed. In this case, a plasma HIV RNA concentration (reverse transcriptase polymerase chain reaction [RT-PCR]) should be evaluated. Patients with acute infection will generally have HIV RNA concentrations greater than 10⁶ copies/mL (10⁵ copies/L). HIV treatment response and disease progression is determined by following: (a) the CD4+ lymphocyte count (CD4+ count) and percentage and (b) HIV RNA (viral load). The CD4+ percentage is followed because the absolute count may fluctuate and does not necessarily indicate a change in the patient’s condition.

TREATMENT

The goals of treatment are to maximally and durably suppress viral replication, avoid the development of drug resistance, restore and preserve immune function, prevent opportunistic infections, minimize drug adverse effects, and prevent disease transmission. Elimination or cure of HIV is not possible with currently available therapies. Instead, maximal suppression of viral replication (defined as HIV RNA concentrations undetectable by the most sensitive assay available) is desired. After the initiation of antiretroviral therapy, a rapid decline to undetectable HIV RNA in 16 to 24 weeks is a predictor of improved clinical outcomes.

Degree of immune function preservation is also correlated with decreased viral replication and is measured by CD4+ T-cell counts. CD4+ measures are the best predictor of progression to AIDS and help clinicians determine when to initiate treatment. At CD4+ T-cell counts of 200 cells/mm³ (200 × 10⁹/L) and lower, patients require drug prophylaxis for opportunistic infections. Table 87-2 details the monitoring points of HIV treatment for HIV RNA and CD4+ T-cell counts. In addition to these parameters, basic blood chemistry tests, liver function tests, complete blood counts, and lipid profiles should be monitored every 3 to 6 months in patients receiving antiretroviral therapy.

Six classes of drugs are available to treat HIV infection: nucleoside (NRTI)/nucleotide (NtRTI) reverse transcriptase inhibitor, protease inhibitor (PI), nonnucleoside reverse transcriptase inhibitor (NNRTI), fusion inhibitors, CCR5 inhibitors, and integrase strand transfer inhibitors (INSTI). Currently, combination antiretroviral drug therapy with three or more active drugs is the standard of care, which increases the durability of viral suppression and decreases the potential for the development of resistance. Two nucleoside (nucleotide) reverse transcriptase inhibitors AND an NNRTI OR a ritonavir-boosted PI OR an INSTI are the mainstay regimens of combination therapy in initial treatment. Combination regimens decrease HIV RNA to less than 50 copies/mL (50 × 10⁶ copies/L) in 80% to 90% of patients in clinical trials. Therefore, monotherapy with any agent or the use of NRTIs without another drug class are not recommended.
### Table 87–2

| Monitoring End Points for CD4+ T-Cell Counts and HIV RNA |
|-----------------|-----------------|-----------------|
| **CD4+ T Cell Counts** | **Goal** | **HIV RNA Concentration** |
| **When to Monitor?** | **Why?** | **When to Monitor?** | **Why?** | **Goal** |
| **Initial diagnosis** | Assess immune function | Start therapy in appropriate patients | Initial diagnosis/evaluation | Establish baseline | Start ART in appropriate patients |
| **Assess need for OI chemoprophylaxis** | Start prophylaxis when counts < 200 cells/mm^3 (200 × 10^3/L) | 2–8 weeks after starting or changing ART^a | Early assessment of regimen efficacy | Undetectable concentrations |
| **Every 3–6 months** | Receiving ART: monitor success of treatment^b | Average increase of 100–150 cells/mm^3/year (100 × 10^3–150 × 10^3/L/year) | Every 3–6 months | Receiving ART: assess success and durability of virologic suppression and adherence with current regimen | Steadily decreasing and/or consistently undetectable concentrations |
| **Not receiving ART: assess urgency to begin therapy** | Start ART in appropriate patients | Optional^c | Not receiving ART: monitor changes in viral load | Start therapy in appropriate patients |
| **Assess need for OI chemoprophylaxis** | Start prophylaxis when counts < 200 cells/mm^3 (200 × 10^3/L) | | | |

ART, antiretroviral therapy; OI, opportunistic infection.

^a If viral load is detectable, repeat every 4 to 8 weeks until less than 200 copies/mL (200 × 10^3/L), then resume every 3- to 6-month schedule.

^b In clinically stable patients with viral loads less than 50 copies/mL (50 × 10^3/L) for more than 2 years, monitoring can be extended to every 6 to 12 months.

^c For patients who choose to delay therapy, repeat viral load testing while not on therapy is optional. HIV RNA concentration should be determined prior to initiating therapy.

---

### Patient Encounter 1, Part 1: Treatment Initiation

A 32-year-old white man presents to the clinic requesting to be tested for HIV. He reports having unprotected receptive anal intercourse with multiple male partners in the past year. Last week, he presented to the urgent care clinic with complaints of fever, malaise, and pharyngitis. He was prescribed azithromycin for a presumed bacterial infection.

**PMH:** Seizure disorder, Allergic rhinitis, obesity

**FH:** Mother—HTN, CAD; father—Type II DM, dyslipidemia, prostate cancer

**SH:** Financial advisor; reports multiple sexual partners in the past 12 months with condom use about 50% of the time. He denies illicit drugs, but drinks about 10 alcoholic drinks weekly

**Meds:** Carbamazepine 200 mg by mouth twice daily; azithromycin 500 mg by mouth on day 1, 250 mg by mouth days 2 to 5 (completed 2 days ago); fexofenadine by mouth once daily; multivitamin by mouth once daily

**All:** Penicillin (anaphylaxis)

**ROS:** Negative for weight loss, decreased appetite, shortness of breath, and cough, chest pain, nausea, vomiting, diarrhea

**PE:**

Within normal limits

**VS:** BP 124/84 mm Hg, P 73 beats/min, RR 18 breaths/min, T 39.3°C

**HEENT:** Within normal limits

**CV:** RRR, normal S1, S2; no murmurs, rubs, gallops

**Abd:** Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly

**Rectal:** Deferred

**Labs:** Sodium 135 mEq/L (135 mmol/L), potassium 3.6 mEq/L (3.6 mmol/L), chloride 100 mEq/L (100 mmol/L), bicarbonate 24 mEq/L (24 mmol/L), blood urea nitrogen 14 mg/dL (5 mmol/L), creatinine 1.0 mg/dL (88 μmol/L), WBC 5.2 × 10^9/mm^3 (5.2 × 10^9/L), hemoglobin 11.5 g/dL (115 g/L or 7.14 mmol/L), hematocrit 34.1% (0.341), platelets 151 × 10^9/mm^3 (151 × 10^9/L), neutrophils 58% (0.58), bands 9% (0.09), lymphocytes 32% (0.32), monocytes 1% (0.01), eosinophils 0% (0.00), basophils 0% (0.00)

treatment options. Fusion inhibitors are only FDA approved for use in treatment experienced patients with drug resistance to NRTIs, NNRTIs, and/or PIs. Figure 87–1 details the mechanisms of action of the drug classes within the life cycle of HIV.

**Nonpharmacologic Interventions**

**KEY CONCEPT** *Patient adherence is a key component in treatment success.* Drug therapy is required for a lifetime, as the virus begins to replicate at high levels when medications are stopped. HIV combination therapy used in the past was exceedingly complicated for patients, with multiple daily doses, varying food restrictions, and large pill burdens. Advances in delivery and formulations now make possible once- or twice-daily dosing with fewer pills per day. Currently, two combination tablets providing one pill, once daily NNRTI-containing regimens are available: tenofovir + emtricitabine + efavirenz (Atripla) and tenofovir + emtricitabine + rilpivirine (Compera). Additionally, two fixed dose INSTI-containing combination tablets are available: elvitegravir + cobicistat + tenofovir + emtricitabine (Stribalib) and dolutegravir + abacavir + lamivudine (Triumeq), both once daily regimens. The use of low-dose ritonavir or cobicistat to enhance the concentrations of other PIs or elvitegravir, respectively (known as pharmacokinetic enhancement, or “boosting” agents) allows for significantly fewer daily doses and lower pill burdens. Cobicistat, unlike ritonavir, does not exert antiviral activity. Atazanavir or darunavir with ritonavir boosting are potent, once-daily PI options; once-daily lopinavir/ritonavir may be used in selected treatment-naive patients. These advances, however, do not replace the need for patient counseling by a trained pharmacist and a multidisciplinary approach to promoting adherence.

All patients should be counselled initially and repeatedly on ways to prevent viral transmission. Preventing the spread of resistant virus is particularly important. Patients receiving antiretroviral therapy can still transmit virus to sexual partners and to those with whom they share needles or other drug equipment. Where both partners are HIV-positive, safe sex and needle practices reduce the risk of superinfection with differing strains of HIV and the transmission of other sexually transmitted diseases. General guidelines for preventing viral transmission include using condoms with a water-based lubricant for vaginal or anal intercourse, using condoms without lubricant or dental dams for oral sex, and not sharing equipment used to prepare, inject, or inhale drugs. Treating other sexually transmitted infections (STIs), particularly genital herpes, in HIV-infected patients may help to prevent HIV transmission. The presence of STIs increases genital tract HIV viral load and, correspondingly, the risk of HIV transmission to sexual partners.

**KEY CONCEPT** Nutrition and dietary counseling should also be included in the care of the HIV patient, as poor nutrition leads to poorer outcomes and complicates treatment. Antiretroviral therapy itself introduces a host of nutritional issues, including drug–food interactions, GI adverse effects that may affect appetite and limit dietary intake, lipid abnormalities, and fat redistribution. The American Dietetics Association currently recommends assessing HIV-infected patients for their level of nutritional risk and involving a registered dietitian as part of the clinical team for optimal nutrition care.

**Pharmacologic Therapy for Antiretroviral-Naive Patients**

Two expert panels publish guidelines for the treatment of HIV-infected individuals. Although the recommendations are quite similar, slight differences do exist between the Department of Health and Human Services (DHHS) Guidelines and the International AIDS Society–USA (IAS-USA) Panel Recommendations. The DHHS Guidelines are updated frequently, and current and archived versions are available online at www.aidsinfo.nih.gov. Due to the intense research and constant modifications to therapeutic approaches in the treatment of HIV, the majority of the treatment algorithms and recommendations presented herein follow the most up-to-date information found in the May 2014 DHHS recommendations.

**KEY CONCEPT** The decision of when to begin antiretroviral therapy is complex. Initiating highly active antiretroviral therapy should be considered in all HIV-infected individuals willing to adhere to lifelong therapy. The strength of this recommendation is based on the CD4+ T-cell count and other comorbid conditions. Other factors to consider include the patient’s viral load, decline in CD4+ counts over time, hepatitis C status, risk for cardiovascular disease, risk of transmission to sex partners, willingness to begin therapy and maintain medication adherence, and the risk versus benefit of treating an asymptomatic patient. The DHHS guidelines recommend initiating antiretroviral therapy in all HIV-infected individuals to reduce the risk of disease progression. The strength and evidence to support this recommendation depends on pretreatment CD4+ T lymphocyte count. The clinical evidence is strongest for beginning treatment at CD4+ counts less than 350 cells/μm3 (350 × 10^3/L), but more recent evidence from long-term studies and the availability of potent drugs with improved tolerability support earlier treatment at higher CD4+ counts. Once the decision is made to initiate treatment, the regimen is selected based on patient-specific factors. All recommended regimens for initial treatment contain an NNRTI, a ritonavir-boosted PI, or an INSTI in combination with two NRTI (tenofovir + emtricitabine or abacavir + lamivudine). The recommended agents are shown in Table 87–3.

|Raltegravir + tenofovir + emtricitabine | |
The decision to choose an NNRTI-, PI-, or INSTI-based regimen as initial therapy is based on many patient- and clinician-specific factors. Drug resistance testing should be performed at diagnosis and again prior to initiating treatment if time has elapsed between diagnosis and treatment (see Pharmacologic Therapy for Antiretroviral-Experienced Patients for further discussion of drug resistance testing). The results of resistance testing may dictate which drug class is preferred; a minimum of 10% to 17% of newly diagnosed patients will have drug-resistant virus.1 This initial resistance pattern often involves the NNRTIs, but may involve other drug classes. NNRTI-based regimens have low pill burdens and may have decreased incidences of long-term adverse effects (eg, dyslipidemia) in comparison with some PI-based regimens. However, this class also has a low threshold for drug resistance (the K103N mutation causes high level cross-class resistance), and patient adherence is a critical consideration. In pregnant women, or women with the potential to become pregnant, a PI-based regimen is preferred due to the potential teratogenicity of efavirenz in early pregnancy (Pregnancy Category D). INSTI-based regimens have the advantage of avoiding many complex drug–drug interactions and toxicities seen with NNRTIs and PIs. However, raltegravir must be dosed twice daily, elvitegravir must be coadministered with cobicistat which is associated with many cytochrome (CYP)-450-mediated drug interactions and should not be initiated in patients with a creatinine clearance less than 70 mL/min (1.17 mL/s). Transmitted INSTI resistance is not yet a major clinical concern, but may develop as integrase inhibitors come into wider use. If transmitted INSTI resistance is a concern, integrates resistance testing must be ordered separately from standard HIV genotyping, which only includes the protease and reverse transcriptase genes.

In patients who cannot tolerate the preferred first-line therapies, or have a compelling reason to choose a different agent, the following alternative regimens are recommended.8

1. PI based:
   a. Darunavir/ritonavir + abacavir/lamivudine
   b. Lopinavir/ritonavir (dosed once or twice daily) + either tenofovir/emtricitabine or abacavir/lamivudine

2. INSTI:
   a. Raltegravir + abacavir/lamivudine

If abacavir is included in a regimen, patients should undergo human leukocyte antigen (HLA)-B*5701 testing prior to initiation to assess the risk of abacavir hypersensitivity. Patients who test positive for the allele are at high risk (approximately 50%–67%) of developing this reaction and should not be given abacavir.9 An abacavir allergy should also be documented in the patient’s medical record to prevent future administration. Those patients with a negative test may receive abacavir, but should still be counseled and monitored for the development of hypersensitivity.

Regimens with demonstrated efficacy but less desirable, including the CCR5 antagonist maraviroc, the NNRTI nevirapine, unboosted atazanavir, and boosted saquinavir are no longer recommended as first-line therapy for treatment-naïve patients. One of these regimens should only be selected if a first-line regimen is intolerable or the patient has a compelling reason to avoid drugs in a first-line regimen. If maraviroc is under consideration, viral tropism testing should be performed to ensure CCR5-tropic virus for optimal efficacy.

Therapies not recommended for initial treatment due to poor potency or significant toxicity include triple-NRTI regimens, delavirdine, nevirapine in patients with moderate to high CD4+ T-cell counts, indinavir ± ritonavir, darunavir, saquinavir or fosamprenavir used without ritonavir (“unboosted”), ritonavir used without another PI, nelfinavir, tipranavir/ritonavir, and tenofovir, lamivudine, or emtricitabine with didanosine. Because of limited data in antiretroviral naïve patients, etravirine is not recommended in the DHHS Guidelines at this time. Drugs that should not be combined due to overlapping toxicities include atazanavir plus indinavir (due to enhanced hyperbilirubinemia), two NNRTIs, and didanosine plus stavudine. Emtricitabine and lamivudine should not be combined because of their similar chemical structures, and antagonism can result when stavudine is combined with zidovudine.

### Pharmacologic Therapy for Antiretroviral-Experienced Patients

**Key Concept** Ongoing viral replication, whether at low levels in the face of adequate drug concentrations or at higher levels due to inconsistent systemic concentrations (or low concentrations in sanctuary sites, eg, male and female genital fluids, cerebrospinal fluid, or lymph nodes), will eventually lead to resistance to the prescribed medications. To avoid further progression of resistant mutations, a failing regimen should be discontinued as soon as possible. Virologic failure is defined as the inability to obtain or maintain an HIV RNA less than 200 copies/mL (200 × 10^3 copies/L), whereas incomplete virologic suppression is defined as two consecutive HIV RNA greater than 200 copies/mL (200 × 10^3 copies/L) after 24 weeks of therapy.8 Immunologic failure is defined as the failure to achieve and/or maintain an adequate CD4+ count in the setting of virologic suppression. A typical CD4+ count should increase at least 150 cells/mm^3 (150 × 10^3/L) over the first year of therapy. The goal of therapy for patients with antiretroviral resistance is to reestablish virologic suppression or HIV RNA lower than the limit of detection of the assay (typically less than 40 copies/mL [40 × 10^3 copies/L]).

Treatment considerations for antiretroviral-experienced patients are much more complex than for patients who are naïve to therapy. Prior to changing therapy, the reasons for treatment failure should be identified. A comprehensive review of the patient’s severity of disease, antiretroviral treatment history, adherence to therapy, intolerance or toxicity, concomitant drug...
describes the drug interaction potential of each regimen, these drugs can be recycled into future regimens. However, direct resistance testing can better identify the resistance and susceptibility patterns of the major viral strains. Because HIV may be susceptible to certain components of the failing antiretroviral regimen, these drugs can be recycled into future regimens.

Resistance testing should be used when all patients enter into care, in patients with virologic failure on an antiretroviral regimen, or with suboptimal suppression after initiation of antiretroviral therapy. Testing is generally preferred for antiretroviral-naive patients. For resistance testing to be useful, the patient should have a plasma HIV RNA of at least 1000 copies/mL (1 × 10^6 copies/L) and should be currently taking their antiretroviral medications (or be within 4 weeks of discontinuing antiretroviral therapy). This viral concentration is necessary to yield reliable amplification of the virus, and the antiretroviral medications are needed because the dominant viral species reverts to wild-type within 4 to 6 weeks after medications are stopped.

Two types of HIV resistance testing are available, an HIV genotype and an HIV phenotype. Genotyping involves detecting mutations by genetically sequencing the virus, whereas phenotyping determines the ability of the virus to replicate in the presence of varying antiretroviral concentrations. Genotyping is more rapid and less costly than phenotyping, but results in a list of mutations that may be more difficult to interpret than phenotyping. An HIV virtual phenotype report may also be obtained when genotypes are ordered. This compares the patient’s viral sequence to a database of matched genotypes and drug susceptibilities. Web-based tools are available to assist with interpretation of resistance mutations (eg, Stanford University’s HIV Drug Resistance Database; http://hivdb.stanford.edu/index.html). However, expert interpretation of genotype and phenotype reports is recommended.

Management of antiretroviral-experienced patients is complex, and expert opinion is advised before selecting therapy. As with antiretroviral-naive patients, three or more active drugs should be prescribed. Since considerable cross-resistance can occur between medications within an antiretroviral class, simply using drugs to which the patient has not been exposed may be insufficient. Complete cross-resistance occurs within the first generation of NNRTIs, whereas the NRTIs and PIs have variable overlapping resistance patterns. For this reason, HIV resistance assays are important tools for choosing subsequent effective therapies. The use of antiretrovirals with unique mechanisms of action like enfuvirtide (fusion inhibitor) or maraviroc (CCR5 antagonist) may be warranted as salvage therapy.

If patients fail therapy with resistance to only one drug, one or two active agents may be substituted for this drug while retaining the remaining drugs in the regimen. If patients fail therapy with resistance to more than one drug, changing classes of antiretrovirals and/or adding new active drugs is warranted. New NRTIs should be selected from resistance testing. If this is not available, the assumption should be made that resistance has developed to all NRTIs used in the failing regimen. In general, HIV that is resistant solely to lamivudine and/or emtricitabine will be susceptible to other NRTIs. If HIV develops resistance solely to tenofovir, then it may have reduced susceptibility to didanosine and likely abacavir but should remain susceptible to zidovudine, stavudine, lamivudine, and emtricitabine. Cross-resistance occurs between zidovudine and stavudine.

If a patient appears to fail an antiretroviral regimen without detectable HIV resistance, adherence should be investigated, and the adequacy of the plasma HIV RNA concentration in the resistance sample confirmed. Options include continuing the current regimen or starting a new regimen and repeating the resistance test 2 to 4 weeks after adherence is verified. The availability of new potent antiretrovirals has resulted in a decrease in the number of patients with multiclass drug resistance. Although rare, such patients have very limited treatment options, making it impossible to construct a regimen with two to three active agents.

Adapted from the DHHS Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents, May 1, 2014.
For these patients, continuing the current regimen may be beneficial because drug-resistant virus may have a compromised replication capacity. Other strategies may be considered for this type of patient, including pharmacokinetic enhancement with ritonavir, retreatment with prior antiretroviral agents, treatment with multidrug regimens (four or more antiretroviral drugs), and the use of new agents through expanded access programs or clinical trials.

**Treatment Considerations in Special Populations**

- **Acute HIV Infection**
  Diagnosis of acute HIV infection is difficult, since many patients are asymptomatic or have nonspecific clinical symptoms similar to other common respiratory infections. If acute HIV infection is suspected, HIV antibody tests and a plasma HIV RNA concentration should be obtained. A clear diagnosis is made when an HIV antibody test is negative and the plasma HIV RNA concentration is detected or p24 antigen is present.
  There is limited outcome data for treating acutely infected patients. Treatment of acute infection can decrease the severity of acute disease and decrease the viral set point; this may decrease progression rates and reduce the rate of viral transmission. Limitations include an increased risk of chronic drug-induced toxicities and the development of viral resistance. Resistance testing should be performed prior to initiation of therapy due to an increase in resistance of antiretroviral naive patients.

- **Adolescent and Young Adult Patients**
  As a result of similar modes of HIV transmission, adolescents infected after puberty are treated as adults. In this population, dosing of antiretroviral drugs should not be based on age, but on the Tanner stage (which considers external primary and secondary sexual characteristics). Adolescents in early puberty should be dosed according to pediatric guidelines, whereas those in late puberty should be dosed as adults. During growth spurs, adolescents should be monitored closely for drug efficacy and toxicity, since rapid changes in weight can lead to altered drug concentrations. Adherence is of concern in this population due to denial of the disease, misinformation, distrust of health care professionals, low self-esteem, and lack of family and/or social support. Additionally, asymptomatic patients this age find it more difficult to adhere to therapy while feeling well.

- **Pediatric Patients**
  There are unique considerations in the treatment of HIV-infected children. Specific treatment guidelines exist, but a thorough review is outside the scope of this chapter. Most children acquire HIV infection through perinatal transmission either in utero, intrapartum, or postpartum through breast-feeding, although antiretroviral interventions have dramatically reduced transmission rates. Antiretroviral therapy research is limited in pediatric patients, as some drugs have no dosing recommendations for this population or are not available in a formulation that can be easily administered to children. Additionally, drug exposures can change dramatically during early childhood development due to altered drug-metabolizing enzyme and drug transporter activities.

- **Pregnancy and Women of Reproductive Potential**
  The goals of antiretroviral therapy for women of reproductive age and pregnant women are the same as for other adult patients. Specific guidelines for HIV-infected pregnant women are available. If a woman is already virally suppressed on an antiretroviral regimen at the time she becomes pregnant, it is recommended that she remain on that regimen unless it contains efavirenz, which is pregnancy category D. However, because the risk of neural tube defects with efavirenz is highest during the first 5 to 6 weeks of pregnancy, and pregnancy is often not detected before 4 to 6 weeks, it is reasonable for women virologically suppressed on an efavirenz-containing regimen to continue that regimen rather than switch regimens and risk viral rebound. If not already on antiretroviral therapy, recommended therapies in pregnancy include zidovudine, lamivudine, lopinavir/ritonavir, atazanavir/ritonavir, and, if greater than 8 weeks of gestation, efavirenz. Nevirapine may be considered an alternative NNRTI for ARV-naïve pregnant women if the CD4 count is less than 250 cells/mm$^3$ ($250 \times 10^3\text{cells}/\text{mm}^3$). Although data on the use of raltegravir in pregnancy is limited, it may be considered as an alternative agent if first-line therapies are to be avoided. A dual nucleoside reverse transcriptase inhibitor (NRTI) backbone that includes one or more NRTIs with high levels of transplacental passage, if possible, is recommended. Drugs to be avoided include efavirenz (in the first 8 weeks of pregnancy due to potential teratogenicity), the combination of didanosine and stavudine (due to a high incidence of lactic acidosis), and nevirapine in patients with a CD4 count greater than 250 cells/mm$^3$ ($250 \times 10^3\text{cells}/\text{mm}^3$) (due to an increased risk of hepatotoxicity). The goal of therapy is to reduce plasma HIV RNA below detectable levels and prevent MTCT of HIV. Limited data are available on antiretroviral pharmacokinetics in pregnancy, and standard doses of antiretroviral drugs are currently recommended, with close HIV RNA and CD4$^+$ monitoring in the third trimester of pregnancy.
  Women of reproductive potential prescribed efavirenz should be counseled on its potentially teratogenic effects and the importance of birth control. Additionally, efavirenz, nevirapine, ritonavir, atazanavir/ritonavir, lopinavir/ritonavir, and tipranavir/ritonavir, darunavir/ritonavir, fosamprenavir/ritonavir, and saquinavir-ritonavir decrease the concentrations of different estrogens and/or progestins in oral contraceptives, which could lead to failure. For patients prescribed these drugs, barrier forms of contraception are preferred to prevent pregnancy. Atazanavir may be taken with oral contraceptives with extreme caution, as it can increase or decrease the exposure to estrogen and progesterone, depending on whether it is used in combination with ritonavir. Depo-Provera is likely the safest alternative, as studies have shown no significant interactions between depot medroxyprogesterone acetate and antiretrovirals. Maraviroc, raltegravir, elvitegravir/cobicistat, and dolutegravir have not shown clinically significant effects when used with oral contraceptives and are safe to use in combination.

- **Hepatitis B Coinfection**
  HIV-infected patients coinfected with hepatitis B virus (HBV) have higher concentrations of DNA and hepatitis B early antigen (HBeAg) and higher rates of HBV-associated liver disease. Indications to initiate therapy for HBV/HIV coinfected patients are the same as in HIV-negative patients and is based on the HBV DNA level, serum ALT, and severity of liver disease. Options include interferon-α 2a or 2b and nucleoside/tide analogs. Nucleoside/tide analogs that treat HBV but not HIV are adeovir and entecavir. Entecavir, however, exhibits minimal antiviral activity against HIV, and should never be administered to coinfected patients who are not concurrently receiving fully suppressive HIV therapy. If given without suppressive antiretrovirals, entecavir can select for M184 resistance, leading to HIV resistance to...
Data from these trials has led to the FDA approval of Truvada treatment of STI, etc.), reduce the rate of HIV transmission. Particularly tenofovir + emtricitabine, in combination with risk for acquiring HIV have demonstrated that antiretrovirals, particularly tenofovir should be continued for treatment of HBV in addition to the new HIV regimen. Abrupt discontinuation of these antiretrovirals may result in significant hepatic injury due to the exacerbation of hepatitis B.

Vaccination against HBV can effectively prevent transmission. Currently in the United States, all infants should get their first HBV vaccination at birth. If there is no record of vaccination, or immunization history is unknown, HIV-infected patients and adults with high-risk sexual behavior or occupational exposure to HBV should be vaccinated.

**Hepatitis C Coinfection**

All HIV-infected patients should be screened for hepatitis C infection. Patients coinfected with hepatitis C virus (HCV) and HIV have an increased rate of progression to cirrhosis, decompensated liver disease, hepatocellular carcinoma, and death compared with monoinfected HCV alone. All HCV/HIV coinfected patients should be considered for therapy, taking into consideration the HCV genotype, stage of liver disease, as well as patient specific factors that may contraindicate therapy (eg, nonadherence, depression, substance abuse). The goal of HCV treatment is to achieve sustained virologic response (absence of detectable viremia greater than or equal to 3 months after discontinuation of treatment) and to decrease the progression of liver injury and likelihood of end-stage liver disease. Comprehensive treatment guidelines for HIV/HCV-coinfected patients are available and have recently been updated to reflect the rapidly evolving treatment options for HCV. Recommended treatment regimens for HCV consist of pegylated interferon-α 2a or 2b, ribavirin, sofosbuvir, and simeprevir, with the combinations and duration of treatment determined by HCV genotype. Sofosbuvir and simeprevir are novel direct acting antivirals that exhibit potent antiviral activity and minimal toxicity. However, simeprevir, an HCV protease inhibitor, is metabolized primarily by CYP3A4 and is a substrate for the drug transporter P-glycoprotein (P-gp) and organic anion transporting polypeptide 1B1. Due to the potential for significant drug interactions, simeprevir is not recommended for use with HIV protease inhibitors, cobicistat, or the non-nucleoside reverse transcriptase inhibitors efavirenz, nevirapine, and etravirine. Coadministration of ribavirin with didanosine, and stavudine (due to increased risk of pancreatitis and/or lactic acidosis) and ribavirin with zidovudine (due to increased risk of anemia) should also be avoided. The first-generation protease inhibitors, telepravir and boceprevir, are associated with relatively increased toxicities and extensive drug-drug interactions, and are no longer recommended by the guidelines. With many potent direct-acting antivirals in the HCV pipeline, the landscape of HCV treatment is rapidly evolving, with the hope of multiple curative, interferon-free, regimens to come in the near future.

**Preexposure Prophylaxis (PrEP)**

Multiple large-scale clinical trials in populations at highest risk for acquiring HIV have demonstrated that antiretrovirals, particularly tenofovir + emtricitabine, in combination with effective risk-reduction services (counseling, access to condoms, treatment of STI, etc.), reduce the rate of HIV transmission. Data from these trials has led to the FDA approval of Truvada (fixed-dose combination of tenofovir disoproxil fumarate 300 mg and emtricitabine 200 mg), as preexposure prophylaxis (PrEP) to reduce the risk of HIV-1 in adult homosexual men who have sex with men, heterosexually active men and women, and injection drug users who are at substantial risk of HIV acquisition. The use of daily Truvada as PrEP should be in combination with effective risk-reduction interventions, as well as very close follow-up and monitoring. Patients must be tested for HIV at baseline, and minimally every 3 months while taking PrEP. Additionally, due to the potential toxicities associated with tenofovir, renal function must be assessed at baseline and at 6-month intervals in patients taking Truvada as PrEP. Patient counseling, stressing the importance of medication adherence, should be routinely provided, as medication adherence has been linked to PrEP efficacy.

**OUTCOME EVALUATION**

- **Key Concept** The success of antiretroviral therapy is measured by the degree to which the therapy (a) restores and preserves immunologic function, (b) maximally and durably suppresses HIV RNA, (c) improves quality of life, (d) reduces HIV-related morbidity and mortality.

**Patient Encounter 2**

A 29-year-old African American man presents to your clinic requesting medication to prevent the transmission of HIV. He had heard from his HIV-infected partner that the FDA approved a prescription medication for the prevention of HIV and he wanted to learn more about it. He reports engaging in MSM with an HIV-infected partner and uses condoms about 75% of the time.

- **What additional information do you need to know before creating a treatment plan for this patient?**
- **What laboratory tests do you recommend?**
- **What pharmacologic and nonpharmacologic options are available for this patient to protect himself from acquiring HIV?**
- **What monitoring assessments and follow-up would you recommend?**

**Patient Encounter 3**

A 43-year-old woman presents to your clinic with complaints that she has noticed yellowing of the whites of her eyes. Four months ago, she initiated a regimen consisting of emtricitabine, tenofovir, and atazanavir/ritonavir. She is very upset because colleagues from work have noticed and as a result she would like to switch therapy.

- **Which medication is responsible for this adverse event?**
- **What laboratory tests do you recommend?**
- **What additional information do you need to know before creating a treatment plan for this patient?**
- **What monitoring assessments and follow-up would you recommend?**

The Patient Care Process: Newly Diagnosed

**Patient Assessment:**
- Confirm HIV infection (see Table 87–1), screen for additional sexually transmitted infections, and assess the risk for opportunistic infections and need for prophylaxis.
- Create a safe and comfortable environment to obtain a thorough medical and medication history (prescription, nonprescription, and natural drug product use). Review and update patient allergies.
- Acquire baseline laboratory data (see Table 87–2) to stage HIV disease and to assist in the selection of ARV drug regimens (genotypic resistance testing, HLA-B*5701).
- Assess patient’s readiness for initiating ART.

**Therapy Evaluation:**
- Evaluate comorbid conditions (eg, mental illness, substance abuse) and social issues (economic stability, lack of social support, insurance coverage) that may impair medication adherence.
- Utilize results of genotype in conjunction with patient specific factors to construct a recommended ART regimen.

**Care Plan Development:**
- Provide patient with basic information regarding HIV infection, progression of HIV/prognosis, treatment options, and support services available.
- Inform patient of the benefits of initiating ART, stressing the importance of strict medication adherence.
- Educate patient on regimen-specific administration and the common adverse drug effects (see Table 87–4). Warn patient of the key signs and symptoms of severe toxicity (ie, jaundice and abacavir hypersensitivity reaction).
- Provide risk reduction counseling on effective strategies to prevent HIV transmission and disclosure to sexual and/or needle-sharing partners.

**Follow-up Evaluation:**
- Assess response to ARV therapy by drawing plasma HIV RNA within 2 to 4 weeks (no later than 8 weeks) after initiation of ART and every 4 to 8 weeks until viral load is suppressed.
- Monitor immune reconstitution by measuring CD4+ count 3 months after initiation of ART.
- Evaluate tolerability of regimen by assessing for adverse events and medication adherence.
other drugs in the regimen for up to 4 weeks or (b) substituting the NNRTI with a PI and continuing the PI with dual NRTIs for up to 4 weeks. In this situation, therapeutic drug monitoring of the long half-life drug can be useful in determining when to stop the NRTI ± PI coverage.8

**Abbreviations Introduced in This Chapter**

AIDS | Acquired immunodeficiency syndrome
---|---
ALT | Alanine aminotransferase
ART | Antiretroviral therapy
AST | Aspartate aminotransferase
CPK | Creatine phosphokinase
CVD | Cardiovascular disease
CYP | Cytochrome P-450 isoenzyme
D/C | Discontinue
DEXA | Dual-energy x-ray absorptiometry
DHHS | Department of Health and Human Services
ELISA | Enzyme-linked immunosorbent assay
GERD | Gastroesophageal reflux disease
gp | Glycoprotein
HAART | Highly active antiretroviral therapy
HBeAg | Hepatitis B e antigen
HBV | Hepatitis B virus
HCV | Hepatitis C virus
HDL | High-density lipoprotein
HIV | Human immunodeficiency virus
HLA | Human leukocyte antigen
HSR | Hypersensitivity reaction
HTN | Hypertension
IAS-USA | International AIDS Society–USA
ICH | Intracranial hemorrhage
IFA | Indirect immunofluorescence assay
LDL | Low-density lipoprotein
LFT | Liver function tests
MSM | Men who have sex with men
MTCT | Mother-to-child transmission
NNRTI | Nonnucleoside reverse transcriptase inhibitor
NRTI | Nucleoside reverse transcriptase inhibitor
NVP | Nucleoside reverse transcriptase inhibitor
P-gp | P-glycoprotein
PCP | Pneumocystis jiroveci (formerly carinii) pneumonia
PI | Protease inhibitor
PrEP | Pre-Exposure Prophylaxis
PT | Prothrombin time
RT-PCR | Reverse transcriptase polymerase chain reaction
SIV | Simian immunodeficiency virus
STI | Sexually transmitted infection
TBili | Total bilirubin
TDF | Tenofovir disoproxil fumarate
TG | Triglyceride
ULN | Upper limit of normal
WB | Western blot

**REFERENCES**

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the etiology of cancer.
2. Define the tumor, nodes, metastases (TNM) system of cancer staging.
3. Classify each drug used in the treatment of cancer and compare and contrast the mechanisms of action, uses, and adverse effects.
4. Outline actions for all health professionals to prevent medication errors with cancer treatments.
5. Discuss the impact that increased use of oral chemotherapy agents may have on oncology practice.
6. Describe what cancer survivorship means and how this impacts future health care needs of an individual.
7. Describe the role of health professionals in the care of cancer patients.

INTRODUCTION

The word cancer covers a diverse array of tumor types that affect a significant number of Americans and individuals worldwide and are a major cause of mortality. The term cancer actually refers to more than 100 different diseases. What is common to all cancers is that the cancerous cell is uncontrollably growing and has the potential for invading local tissue and spreading to other parts of the body, a process called metastases. Cancer is now the leading cause of death in Americans younger than 85 years. In 2015, it was projected that just over 1.6 million Americans will be diagnosed with cancer, and that an estimated 589,430 Americans will die from the cancer. Figure 88–1 describes cancers by gender, new cases, and deaths.

Although cancer in children and adolescents is less common when compared to older adults, it is estimated that about 1 in 285 children in America will be diagnosed before age 20. It is the second leading cause of death in children ages 5 to 14.

Once diagnosed, a cancer patient may encounter many different health professionals. All health professionals need to collaborate to ensure safe and appropriate prescribing, preparation, administration, and monitoring of anticancer agents; management of toxicities; resolution of reimbursement issues; and participation in clinical trials.

As a result of advances in research and technology, available cancer treatments have increased dramatically in the last couple of decades. The fields of radiation therapy, surgery, and drug development have made enormous progress over the years; therefore, patients may not only be receiving less toxic treatments but also treatments that have better outcomes than in the past. Supportive care therapies have improved, and patients now may be at less risk for toxicity and have a better quality of life than patients in the past. Twenty years ago, most patients received chemotherapy in the hospital because of side effects. Today, most patients are able to receive chemotherapy in the outpatient clinics and/or take oral anticancer agents at home.

Cancer Prevention

Because most cancers are not curable in advanced stages, cancer prevention is an important and active area of research. Both lifestyle modifications and chemoprevention agents may significantly reduce the risk of developing cancer. Although still an active area of investigation, the Food and Drug Administration (FDA) has approved three vaccines that can help prevent cancer. There are two approved vaccines that prevent infection with human papillomavirus, which can cause cancers of the cervix, vulva, vagina, and anus. Another approved vaccine prevents infection with hepatitis B virus, which can cause liver cancer. In addition to vaccines, there are other medications that can be taken orally for cancer prevention. An example is the selective estrogen receptor modulator (SERM) tamoxifen, which reduces the risk of breast cancer in premenopausal women. Another SERM, raloxifene and the aromatase inhibitor exemestane both have shown a reduction in breast cancer in high-risk postmenopausal women. Because these agents will have adverse effects and possible long-term complications (eg, an increased risk of endometrial cancer with the use of tamoxifen), benefits versus risks needs to be weighed when making a recommendation.

Tobacco

Tobacco smoking increases the risk of developing not only lung cancer but also many other types of cancer, including cancer of the bladder, mouth, pharynx, larynx, and esophagus as well as renal cell cancer. Smoking cessation is associated with a gradual decrease in the risk of cancer, but more than 5 years is needed before a major decline in risk is detected. In addition, most
studies have found that passive smoking (ie, secondhand smoke) also increases a person’s risk of developing lung cancer.4

Ultraviolet Radiation
Ultraviolet light (sunlight or tanning booths and lamps) and increased skin exposure may increase the risk of melanoma and other skin cancers, especially in individuals who have a positive family history, fair skin, light-colored eyes, high degrees of freckling, and a tendency to burn instead of tan. Practitioners can counsel patients on proper sun protection, including minimizing sun exposure, using sunscreens with a sun protection factor (SPF) of 15 or greater on exposed areas, wearing protective clothing and sunglasses, avoiding tanning beds and sun lamps, and the importance of early detection.

CARCINOGENESIS
The exact cause of cancer remains unknown and is probably very diverse given the vast array of diseases called cancer. It is thought that cancer develops from a single cell in which the normal mechanisms for control of growth and proliferation are altered. Current evidence indicates that there are four stages in the cancer development process. The first step, initiation, occurs when a carcinogenic substance encounters a normal cell to produce genetic damage and results in a mutated cell. The environment is altered by carcinogens that, through some genetic alteration caused by carcinogens, results in a mutated cell. The genetic damage may either be chromosomal rearrangement, or an increase in gene function, converting a protooncogene into oncogene. Protooncogenes are present in all normal cells and regulate cell function and replication. Genetic damage of the protooncogene may occur through point mutation, chromosomal rearrangement, or an increase in gene function, resulting in the oncogene.

Cancer Genetics
Because the human genome has been sequenced and with the great improvements in genetic technology, there is growing knowledge regarding the genetic changes of cancer. There are two major classes of genes involved in carcinogenesis, oncogenes and tumor suppressor genes. Protooncogenes are normal genes that, through some genetic alteration caused by carcinogens, change into oncogenes. Protooncogenes are present in all normal cells and regulate cell function and replication. Genetic damage of the protooncogene may occur through point mutation, chromosomal rearrangement, or an increase in gene function, resulting in the oncogene. The genetic damage may either be inherited from an individual’s parents (germline mutations) or by way of carcinogenic agents (eg, smoking). The oncogene produces abnormal or excessive gene product that disrupts normal cell growth and proliferation.3 As a result, this may cause the cell to have a distinct growth advantage, increasing its likelihood of becoming cancerous. Table 88–1 provides examples of oncogenes by their cellular function and associated cancer.

Tumor suppressor genes inhibit inappropriate cellular growth and proliferation by gene loss or mutation. This results in loss
of control over normal cell growth. The \( p53 \) gene is one of the most common tumor suppressor genes, and mutations of \( p53 \) may occur in up to 50% of all malignancies. This gene stops the cell cycle to enable “repairs” of the cell. If \( p53 \) is inactivated, then the cell allows the mutations to occur. Although mutations of the \( p53 \) gene are found in many tumors, such as breast, colon, and lung cancer, it is also associated with drug resistance of cancer cells. DNA repair genes fix errors in DNA that occur because of environmental factors or errors in replication and can be classified as tumor suppressor genes. Mutations in DNA repair genes have been reported in hereditary nonpolyposis colon cancer and in some breast cancer syndromes.

**Number of cellular changes occur in the genetic material of the cancer cell so that programmed cell death, or apoptosis, does not occur. Proliferation of cancer cells goes unregulated.** If mutations persist and cells are not repaired or suppressed, cancer may develop. Apoptosis, or programmed cell death, may prevent the mutated cell from becoming cancerous. Loss of \( p53 \) and overexpression of \( bcl-2 \) are two examples of changes within the cell that occur to result in enhanced cell survival. Cellular senescence refers to cell death that occurs after a preset number of cell doublings. Telomeres are DNA segments at the ends of chromosomes that shorten with each replication to the point where senescence is triggered.

Identification of genes involved in cancer may be conducted for various reasons, including cancer screening to determine if an individual is at an increased risk of cancer, to develop new anticancer agents, to aid in diagnosis, and to predict response and/or the toxicity of the agents used in individual patients.

**Principles of Tumor Growth**

It takes about \( 10^9 \) cancer cells to be clinically detectable by palpation or radiography. Figure 88–2 demonstrates the classic Gompertzian kinetics tumor growth cycle. From the diagram, one can see that malignant cell growth occurs many times before a mass may be detected. The number of malignant cells may decrease drastically because of surgery or in decreasing steps by each administration of chemotherapy. One dosing round, or cycle, of

</table>

Chemotherapy does not eliminate all malignant cells; therefore, repeated cycles of chemotherapy are administered to eliminate tumor cell burden. The cell kill hypothesis states that a fixed percentage of tumor cells will be killed with each cycle of chemotherapy. According to this hypothesis, the number of tumor cells will never reach zero. This theory assumes that all cancers are equally responsive and that anticancer drug resistance and metastases do not occur, which is not the case.

Metastases
A metastasis is a growth of the same cancer cell found at some distance from the primary tumor site. The metastasis may be large, or it may be just a few cells that may be detected through polymerase chain reaction (PCR); however, the presence of metastasis at staging usually is associated with a poorer prognosis than the patient with no known metastatic disease. As the technology to detect malignant cells evolves, the dilemma exists on how to treat patients based on current guidelines that were not based on cellular detection technology.

Cancers spread usually by two pathways: hematogenous (through the bloodstream) or through the lymphatics (drainage through adjacent lymph nodes). The malignant cells that split from the primary tumor find a suitable environment for growth. It is believed that malignant cells secrete mediators that stimulate the formation of blood vessels for growth and oxygen, the process of angiogenesis. The usual metastatic sites for solid tumors are the brain, bone, lung, and liver.

PATHOPHYSIOLOGY
Tumor Origin
Tumors may arise from the four basic tissue types: epithelial, connective (ie, muscle, bone, and cartilage), lymphoid, or nerve tissue. The suffix -oma is added to the name of the cell type if the tumor cells are benign. A lipoma is a benign growth that resembles fat tissue.

Precancerous cells have cellular changes that are abnormal but not yet malignant and may be described as hyperplastic or dysplastic. Hyperplasia occurs when a stimulus is introduced and reverses when the stimulus is removed. Dysplasia is an abnormal change in the size, shape, or organization of cells or tissues.

Malignant cells are divided into categories based on the cells of origin. Carcinomas arise from epithelial cells, whereas sarcomas arise from muscle or connective tissue. Adenocarcinomas arise from glandular tissue. Carcinoma in situ refers to cells limited to epithelial origin that have not yet invaded the basement membrane. Malignancies of the bone marrow or lymphoid tissue, such as leukemias or lymphomas, are named differently.

Tumor Characteristics
Tumors are either benign or malignant. Benign tumors often are encapsulated, localized, and indolent; they seldom metastasize; and they rarely recur once removed. Histologically, the cells resemble the cells from which they developed. Malignant tumors are invasive and spread to other locations even if the primary tumor is removed. The cells no longer perform their usual functions, and their cellular architecture changes. This loss of structure and function is called anaplasia. Despite improvements in screening procedures, many patients have metastatic disease at the time of diagnosis. Usually, once distant metastases have occurred, the cancer is considered incurable.

DIAGNOSIS OF CANCER
Cancer can present as a number of different signs and symptoms. Unfortunately, many people fear a diagnosis of cancer and may not seek medical attention at the first warning signs.
when the disease is at its most treatable stage. After the initial visit with the clinician, a variety of tests will be performed, which are somewhat dependent on the initial differential diagnoses. Appropriate laboratory tests, radiologic scans, and tissue samples are necessary. The sample of tissue may be obtained by a biopsy, fine-needle aspiration, or exfoliative cytology. No treatment of cancer should be initiated without a pathologic diagnosis of cancer. During the pathologic workup, genetic analysis may be done. Depending on the type of cancer, the genetic analysis can provide the additional information on prognosis of the malignancy and whether certain therapies may be appropriate.

Once the pathology of cancer is established, then staging of the disease is done before treatment is initiated. **KEY CONCEPT** Cancer staging is usually done according to the primary tumor size, extent of lymph node involvement, and the presence or absence of metastases, also referred to as the tumor, nodes, metastases (TNM) system (Table 88–2). The stage of the disease is a compilation of the primary tumor size, the nodal involvement, and metastases and is usually referred to as stages I, II, III, or IV. Not all cancers can be staged according to this system, but many of the solid tumors are.

Staging of the disease is an important part of determining the prognosis of the cancer. Staging also allows comparison of

patient groups when examining data from clinical trials; staging reflects the extent of disease. Finally, the clinician uses it as a guide to treatment and may use restaging after treatment to guide further treatment.

Some cancers produce substances (eg, proteins) that are detected by a blood test, that may be useful in following response to therapy or detecting a recurrence; these are referred to as tumor markers. An example of a clinically used tumor marker is the prostate-specific antigen (PSA). The PSA serum level is used to monitor response to treatment. Unfortunately, some tumor markers are nonspecific and may be elevated from nonmalignant causes. In the case of PSA, nonmalignant causes such as prostatitis, trauma, surgery, ejaculation, some medications, benign prostatic hypertrophy, or riding on an exercise bicycle can all cause increased PSA levels. Some tumors may express a marker in some patients and not in others. The full role of tumor markers has not been fully elucidated.

**TREATMENT**

**Desired Outcome**

Surgery may be able to remove all macroscopic disease; however, microscopic cells may still be present near the surgical site or may have traveled to other parts of the body. When malignant cells have traveled to other parts of the body and become established there and are able to grow in this new environment, they are called metastatic cancer cells. Thus, for chemotherapy-sensitive diseases, systemic therapies may be administered after surgery to destroy these microscopic malignant cells; this is called adjuvant chemotherapy. The goals of adjuvant chemotherapy are to decrease the recurrence of the cancer and to prolong survival. Chemotherapy may also be given before surgical resection of the tumor; this is referred to as neoadjuvant chemotherapy. Chemotherapy given before surgery should decrease the tumor burden to be removed (which may result in a shorter surgical procedure or less physical disfigurement to the patient) and make the surgery easier to perform because the tumor has shrunk away from vital organs or vessels. Neoadjuvant chemotherapy also gives the clinician an idea of the responsiveness of the tumor to that particular chemotherapy.

Chemotherapy may be given to cure cancers that are curable, or it may be given to help control the symptoms of an incurable cancer, which is referred to as palliative therapy.

**Response**

The responses to chemotherapy may be referred to as complete response (CR), partial response (PR), stable disease (SD), or disease progression. A cure in oncology implies that the cancer is completely gone, and the patient will have the same life expectancy as a patient without cancer. The Response Evaluation Criteria in Solid Tumors (RECIST) was developed in 2000 and revised in 2009 and is considered to be the standard criteria to evaluate a response to therapy (Table 88–3). The term overall objective response rate refers to the combination of PR and CR. Some cancers, such as leukemia, cannot be measured by size, so biopsy of the bone marrow provides a cellular indication of the absence or presence of disease.

Anticancer treatments can be thought of as being analogous to antinfectives treatments. Cancer cells may be sensitive to certain chemotherapy agents, but then with repeated exposure, the cells may become resistant to treatment. The resistant cells then may grow and multiply. A number of genetic mutations, including EGFR, KRAS, and BRAF, predict sensitivity to chemotherapy agents that target these mutations. These mutations will be discussed in depth in the following cancer-specific chapters.

**Nonpharmacologic Therapy**

The four primary treatment modalities of cancer are surgery, radiation, biotherapy, and pharmacologic therapy. Surgery is useful to gain tissue for diagnosis of cancer and for treatment, especially those cancers with limited disease. Radiation plays a key role not only in the treatment and possible cure of cancer but also in palliative therapy. Together, surgery and radiation therapy may provide local control of symptoms of the disease. However, when cancer is widespread, surgery may play little or no role, but radiation therapy localized to specific areas may palliate symptoms.

**Pharmacologic Therapy**

Chemotherapy of cancer started in the early 1940s when nitrogen mustard was first administered to patients with lymphoma. Since then, numerous agents have been developed for the treatment of different cancers.

**Dosing of Chemotherapy**

Chemotherapeutic agents typically have a very narrow therapeutic index. If too much is administered, the patient may suffer from fatal toxicities. If too little is given, the desired effect on cancer cells may not be achieved. Many chemotherapy agents have significant organ toxicities that preclude using steadily increasing doses to treat the cancer. The doses of chemotherapy must be given at a frequency that allows the patient to recover from the toxicity of the chemotherapy; each period of chemotherapy dosing is referred to as a cycle. Each cycle of chemotherapy may have the same dosages; the dosages may be modified based on toxicity; or a chemotherapy regimen may alternate from one set of drugs given during the first, third, and fifth cycles to another set of different drugs given during the second, fourth, and sixth cycles. The dose density of chemotherapy refers to shortening of the period between cycles of chemotherapy. This can accomplish two things: First, the tumor has less time between cycles of chemotherapy to grow, and second, patients receive the total

Clinical Presentation and Diagnosis: Cancer Chemotherapy and Treatment

Signs and Symptoms
The seven warning signs of cancer are:
- Change in bowel or bladder habits
- A sore that does not heal
- Unusual bleeding or discharge
- Thickening or lump in breast or elsewhere
- Indigestion or difficulty in swallowing
- Obvious change in a wart or mole
- Nagging cough or hoarseness

The eight warning signs of cancer in children are:
- Continued, unexplained weight loss
- Headaches with vomiting in the morning
- Increased swelling or persistent pain in bones or joints
- Lump or mass in abdomen, neck, or elsewhere
- Development of a whitish appearance in the pupil of the eye
- Recurrent fevers not caused by infections
- Excessive bruising or bleeding
- Noticeable paleness or prolonged tiredness

Diagnostic Procedures
- Laboratory tests: CBC, lactate dehydrogenase (LDH), renal function, and liver function tests
- Radiologic scans: x-rays, CT scans, MRI, position emission tomography (PET)
- Biopsy of tissue or bone marrow with pathologic evaluation
- Cytogenetics
- Tumor markers

The eight warning signs of cancer in children are:
- Changes in the way the child looks or acts, such as irritability or loss of appetite
- A new lump or mass
- Any change in organ size, such as a liver that is harder than normal
- A sore that does not heal
- Unusual bleeding or discharge
- Any change in the way the child breathes or moves
- Loss of bowel or bladder control
- Any change in appetite or weight loss

The seven warning signs of cancer are:
- Unusual bleeding or bruising
- Changes in the skin, such as a lump or change in color or texture
- Changes in the way the body moves, such as pain or weakness
- Persistent or unexplained fever
- Frequent or persistent cough
- Difficulty with swallowing
- Any change in the way the child talks or sounds

Diagnostic Procedures
- Laboratory tests: CBC, lactate dehydrogenase (LDH), renal function, and liver function tests
- Radiologic scans: x-rays, CT scans, MRI, position emission tomography (PET)
- Biopsy of tissue or bone marrow with pathologic evaluation
- Cytogenetics
- Tumor markers

Staging determination of the primary tumor size, extent of lymph node involvement, and the presence or absence of metastases, referred to as the TNM system (see Table 88–2). Most solid tumors are staged according to the TNM classification system. The size of the primary tumor, extent of nodal involvement, and presence of metastases are used to determine the stage. Metastases are cancer cells that have spread to sites distant from the primary tumor site and have started to grow. The most frequently occurring sites of metastases of solid tumors are the brain, bone, liver, and lungs.

Another important consideration for treatment of cancers is reimbursement by third-party payers for compendia off-label use. Off-label use is when a medication is used to treat a cancer that is not an FDA-labeled indication. Because of rapid advancements in oncology, it is estimated that up to 75% of chemotherapy agents are prescribed “off-label.” Drugs used according to FDA-approved indications are usually reimbursed. If sufficient supportive literature exists and the use is supported by one of the Medicare-approved compendia (eg, AHFS-DI, Clinical Pharmacology, DRUGDEX, NCCN, others), an insurer should cover the cost of the anticancer treatment that does not have an FDA indication.

During the time of chemotherapy administration, patients will likely experience various toxicities. The National Cancer Institute (NCI) has provided a standardized system for evaluating and grading the toxicity from chemotherapy to provide uniform grading of toxicity and evaluation of new agents and new regimens (Table 88–5).

Combination Chemotherapy
The underlying principles of using combination therapy are to use (1) agents with different pharmacologic actions, (2) agents with different organ toxicities, (3) agents that are active against the tumor and ideally synergistic when used together, and (4) agents that do not result in significant drug interactions (although these can be studied carefully and the interactions addressed). When two or more agents are used together, the risk of development of resistance may be lessened, but toxicity may be increased.

Key Concept: Traditional chemotherapy agents have some similar side effects, usually manifested on the most rapidly proliferating cells of the body. However, there are unique toxicities of various pharmacologic categories of antineoplastic agents. Anthracyclines (eg, doxorubicin) have the potential to cause cardiac toxicity, which is related to the cumulative dose. Microtubule-targeting agents (eg, vincristine) are associated with various forms of...

neurotoxicity. Alkylation agents (e.g., melphalan) are associated with secondary malignancies.

Currently, anticancer agents are categorized by the mechanism of action. As depicted in Figure 88–3, different agents work in different parts of the cell.

Antimetabolites: Pyrimidine Analogues

**Fluorouracil**

5-Fluorouracil (5-FU) is a fluorinated analogue of the pyrimidine uracil. Once administered, this prodrug is metabolized by dihydropyrimidine dehydrogenase. 5-FU ultimately is metabolized to fluorodeoxyuridine monophosphate (FdUMP), which interferes with the function of thymidylate synthase (TS), which is required for synthesis of thymidine. The triphosphate metabolite of 5-FU is incorporated into RNA to produce the second cytotoxic effect of 5-FU. Inhibition of thymidylate synthesis occurs with the continuous infusion regimens, whereas the triphosphate form is associated with bolus administration. Patients with a low activity of dihydropyrimidine dehydrogenase appear to be at risk for life-threatening toxicities. Folates increase the stability of FdUMP–TS inhibition, which enhances the activity of the drug in certain cancers. 5-FU is metabolized extensively by the liver, but up to 15% of a dose may be found unchanged in the urine.
Age does not appear to alter the pharmacokinetics. 5-FU has shown clinical activity in several solid tumors, and is frequently used to treat both breast and colon cancer. Adverse effects may include stomatitis, diarrhea, esophagitis, gastric ulcercations, cardiac abnormalities, and rarely reported cerebellar toxicities. Some alopecia may occur, but hair regrowth may occur with subsequent doses. Cryotherapy (using ice chips in the mouth) for 30 minutes while receiving bolus 5-FU may decrease the severity of mucositis. Neurotoxicity may consist of headaches, visual disturbances, and cerebellar ataxia. Cardiac toxicity may consist of ST-segment elevation, which appears to be more common in patients with a history of coronary artery disease.

▶ **Capecitabine**

Capecitabine is an orally active prodrug of 5-FU and has shown to be active in tumors of the colon, rectum, and breast. It not only shares the same mechanism but the toxicity profile is also similar to that of 5-FU. There appears to be a higher level of thymidine phosphorylase intracellularly, which is the enzyme responsible for converting capecitabine into 5-FU. This is believed to make the agent more selective against malignant cells. Toxicities include diarrhea, mucositis, palmar-plantar erythrodysesthesia, nausea, and myelosuppression. Palmar-plantar erythrodysesthesia, also called hand-foot syndrome, refers to redness, itching, and blistering of the palms of the hands and soles of the feet. Patients should be counseled to notify the prescriber when this adverse effect occurs. Significant increases in international normalization ratio (INR) and prothrombin time may occur within several days when capecitabine is initiated in patients concomitantly receiving warfarin. The INR should be monitored closely or the patient may be switched to a low-molecular-weight heparin. Phenytoin levels may become elevated related to possible CYP2C9 inhibition by capecitabine; therefore, plasma levels of phenytoin should be monitored. Patients should be instructed to take capecitabine within 30 minutes of a meal to increase absorption of the drug.

▶ **Cytarabine**

Cytarabine is a structural analogue of cytosine and is phosphorylated intracellularly to the active triphosphate form, which inhibits DNA polymerase. The triphosphate form also may be incorporated into DNA to result in inhibition of DNA synthesis and cell death. The most common adverse effects are hematologic toxicities, neutropenic fever, headaches, and gastrointestinal toxicities. Severe neurologic toxicities, including mental status change, convulsions, peripheral neuropathies, and effects similar to Guillain–Barré syndrome, have been reported.

▶ **Gemcitabine**

Gemcitabine is a deoxycytidine analogue that is structurally related to cytarabine. Gemcitabine inhibits DNA polymerase activity and ribonucleotide reductase to result in DNA chain elongation. Gemcitabine has shown activity in several solid tumors and some lymphomas. The toxicities include myelosuppression; flu-like syndrome with fevers during the first 24 hours after administration; rash that appears 48 to 72 hours after administration; and hemolytic uremic syndrome, a rare but life-threatening adverse effect. Patients should be counseled to use acetaminophen to treat the fevers during the first 24 hours; however, fevers occurring 7 to 10 days after gemcitabine are likely to be febrile neutropenias and need prompt treatment with broad-spectrum antibiotics.

▶ **Azacitidine and Decitabine**

Azacitidine and decitabine are nucleoside analogues approved for the treatment of patients with myelodysplastic syndrome, a hematopoietic disorder that can transform into acute myeloid leukemia (AML). Both of these agents cause cytoxicity by directly incorporating in the DNA and inhibiting DNA methyltransferase, which causes hypomethylation of DNA. Hypomethylation of DNA appears to normalize the function of the genes that control cell differentiation and proliferation to promote normal cell maturation. The major side effects reported are myelosuppression and infections.

▶ **Nelarabine**

Nelarabine is indicated for the treatment of patients with T-cell acute lymphoblastic leukemia and T-cell lymphoblastic lymphoma, whose disease has been already treated with at least two other chemotherapy regimens. Nelarabine is a produg that accumulates as the active 5’-triphosphate form in leukemic blasts to result in inhibition of DNA synthesis and cell death. The most common adverse effects are hematologic toxicities, neutropenic fever, headaches, and gastrointestinal toxicities.

▶ **Antimetabolites: Purine Analogues**

▶ **Mercaptopurine and Thioguanine**

6-Mercaptopurine (6-MP) and thioguanine are oral purine analogues that are converted to ribonucleotides that inhibit purine synthesis. Mercaptopurine is converted into thiopurine.
Fludarabine is an analogue of the purine adenine. It interferes with DNA polymerase to cause chain termination and inhibits transcription by its incorporation into RNA. Fludarabine is dephosphorylated rapidly and converted to 2-fluoro-Ara-AMP (2-FLAA), which enters the cells and is phosphorylated to 2-fluoro-Ara-ATP, which is cytotoxic. Fludarabine is used in the treatment of chronic lymphocytic leukemia (CLL), some lymphomas, and refractory AML. This drug is given intravenously (IV) usually daily for 5 days every 4 weeks. Significant and prolonged myelosuppression may occur, along with immunosuppression, so patients are susceptible to opportunistic infections. Prophylactic antibiotics and antivirals are recommended until CD4 counts return to normal. Mild nausea and vomiting and diarrhea have been observed. Rarely, interstitial pneumonitis has occurred.

Cladribine is a purine nucleoside that is a prodrug. It is activated via phosphorylation to a 5′-triphosphate derivative, which is incorporated into DNA, resulting in inhibition of DNA synthesis and chain termination. It may be administered as a continuous 7-day IV infusion or as a 2-hour infusion daily for 5 days; both regimens deliver the same total dose of drug. The primary indication for cladribine is hairy cell leukemia. Although fairly well tolerated, patients may experience myelosuppression and opportunistic infections. Fever, which is thought to be as a result of cell lysis and endogenous pyrogens being released into the bloodstream, can prompt the clinician to consider initiation of antibiotics. Even though it is likely drug induced, it may be difficult to rule out an infectious cause. Rash occurs in approximately 50% of patients.

Clofarabine was developed based on the structures of fludarabine and cladribine with the hope it would be resistant to deamination by adenosine deaminase. Clofarabine has shown activity in myeloid leukemia and myelodysplastic syndrome. Side effects include bone marrow suppression, severe but transient liver dysfunction in 15% to 25% of patients, skin rashes, and hand–foot syndrome.

Pentostatin is an inhibitor of adenosine deaminase, an enzyme important in purine base metabolism. Pentostatin irreversibly inhibits adenosine deaminase, which blocks DNA synthesis through inhibition of RNA ribonucleotide reductase. Side effects include bone marrow suppression, myalgias, conjunctivitis, and rash.

**Antimetabolites: Folate Antagonists**

Folates carry one-carbon groups in transfer reactions required for purine and thymidylate acid synthesis. Dihydrofolate reductase is the enzyme responsible for supplying reduced folates intracellularly for thymidylate and purine synthesis.

**Methotrexate**

Methotrexate inhibits dihydrofolate reductase of both malignant and nonmalignant cells. When high doses of methotrexate are given, the “rescue drug” leucovorin, a reduced folate, is administered to bypass the methotrexate inhibition of dihydrofolate reductase of normal cells and is usually initiated 24 hours after methotrexate administration. This is done to prevent potentially fatal myelosuppression and mucositis. For safety purposes, the term folic acid, another term used for leucovorin, should not be used because of the potential for a medication error in which folic acid might be given instead. Methotrexate concentrations should be monitored to determine when to stop leucovorin administration. Generally, leucovorin administration may be stopped when methotrexate concentrations decrease to $5 \times 10^{-8}$ M, although this may vary by the chemotherapy regimen. High dosages of methotrexate may cause methotrexate to crystallize out in the kidney, which may result in acute renal failure and decreased methotrexate clearance. Administration of IV hydration with sodium bicarbonate to maintain urinary pH greater than or equal to 7 is necessary to prevent methotrexate-induced renal dysfunction. Methotrexate is eliminated by tubular secretion; therefore, concomitant drugs (eg, probenecid, salicylates, penicillin G, and ketoprofen) that may inhibit or compete for tubular secretion should be avoided. Methotrexate doses must be adjusted for renal dysfunction and close monitoring of methotrexate concentrations is advised. Side effects of methotrexate include myelosuppression, nausea and vomiting, and mucositis. Methotrexate also may be administered via the intrathecal route or via an Ommaya reservoir in very low doses as small as 12 mg, so it is crucial for the clinician to know the correct dose by the correct route in order to avoid substantial toxicity. The methotrexate used for intrathecal and intraventricular injection must be preservative-free to prevent CNS toxicity.

Pemetrexed inhibits four pathways in thymidine and purine synthesis. Pemetrexed has shown activity in the treatment of mesothelioma and non–small cell lung cancer (NSCLC). Side effects include myelosuppression, rash, diarrhea, and nausea and vomiting. Patients should receive folic acid and cyanocobalamin to reduce bone marrow toxicity and diarrhea. Doses of folic acid of at least 400 mcg/day starting 5 days before treatment and continuing throughout therapy, as well as for 21 days after the last pemetrexed dose, have been used. Cyanocobalamin 1000 mcg given intramuscularly the week before pemetrexed and then every three cycles thereafter. Dexamethasone 4 mg twice daily the day before, the day of, and the day after pemetrexed administration helps to decrease the incidence and severity of rash.

**Pralatrexate**

Pralatrexate is a folate analogue metabolic inhibitor that is transported into tumor cells via the reduced folate carrier (RFC-1) and competitively inhibits dihydrofolate reductase. It also competitively inhibits polyglutamylation by the enzyme folylpolyglutamyl
synthetase, resulting in the depletion of thymidine and other molecules. It is an intravenously administered agent indicated for the treatment of patients with refractory or relapsed peripheral T-cell lymphoma. Pralatrexate was approved based on overall response rates, not survival benefits. Common adverse reactions include mucositis, thrombocytopenia, nausea, and fatigue. In an effort to reduce the treatment-related mucositis and hematologic toxicity associated with pralatrexate, patients should be counseled to take low-dose oral folic acid on a daily basis and vitamin B<sub>12</sub> intramuscular injections every 8 to 10 weeks.

**Microtubule-Targeting Agents**

- **Vinca Alkaloids (Vincristine, Vinblastine, and Vinorelbine)**

The vinca alkaloids (vincristine, vinblastine, and vinorelbine) are derived from the periwinkle (vinca) plant and cause cytotoxicity by binding to tubulin, disrupting the normal balance between polymerization and depolymerization of microtubules, and inhibiting the assembly of microtubules, which interferes with the formation of the mitotic spindle. As a result, cells are arrested during the metaphase of mitosis. The vinca alkaloids are used in several malignancies, primarily hematologic. Even though these agents have similar structures, the incidence and severity of toxicities vary among the agents. The dose-limiting toxicity of vincristine is neurotoxicity, which can consist of depressed tendon reflexes, paresthesias of the fingers and toes, toxicity to the cranial nerves, or autonomic neuropathy (constipation or ileus, abdominal pain, and/or orthostatic hypotension.) In contrast, the dose-limiting toxicity associated with vinorelbine and vinblastine is myelosuppression. All of the vinca alkaloids are vesicants and can cause tissue damage; therefore, the clinician must take precautions to avoid extravasation injury. Biliary excretion accounts for a significant portion of elimination of vincristine and its metabolites, so doses need to be adjusted for obstructive liver disease.

Vincristine, vinblastine, and vinorelbine have similar sounding names, which is a potential cause of medication errors. As with all chemotherapy prescribing, dispensing, and administration, the clinician must be very careful with sound-alike, look-alike medications. Unfortunately, vincristine has been involved in numerous cases of fatal chemotherapy errors, including inadvertent intrathecal administration. Because the drug is a vesicant, intrathecal administration of the drug can cause widespread tissue damage in the brain and death. An example of a strategy that health systems can use to decrease the likelihood of an error such as this is for the pharmacy to only dispense vincristine in a minibag for IV administration. Many clinicians cap IV vincristine doses at 2 mg to prevent severe neuropathic side effects; however, if the intent of chemotherapy is curative, the vincristine dose may be dosed above the 2-mg cap.

- **Taxanes (Paclitaxel, Nanoparticle Albumin-Bound Paclitaxel, Docetaxel, and Cabazitaxel)**

Paclitaxel and docetaxel are taxane plant alkaloids that, similar to the vinca alkaloids, exhibit cytotoxicity during the M phase of the cell cycle by binding to tubulin. Unlike the vinca alkaloids, however, the taxanes do not interfere with tubulin assembly. Rather, the taxanes promote microtubule assembly and inhibit microtubule disassembly. Once the microtubules are polymerized, the taxanes stabilize against depolymerization.

Hepatic metabolism and biliary excretion account for the majority of paclitaxel’s elimination. Paclitaxel has demonstrated activity in several solid tumors. Considerable variability exists in paclitaxel dosing, from weekly 1-hour infusions to 24-hour infusions administered every 3 weeks. The diluent for paclitaxel, Cremophor EL, is composed of ethanol and castor oil. Infusions must be prepared and administered in non–polyvinyl chloride–containing bags and tubings, and solutions must be filtered. Patients receive dexamethasone, diphenhydramine, and an H<sub>2</sub> blocker to prevent hypersensitivity reactions caused by Cremophor EL. Patients also may have asymptomatic bradycardia during the infusion. Approximately 3 to 5 days after administration, patients may complain of myalgias and arthralgias that may last several days. Myelosuppression, flushing, neuropathy, ileus, and total-body alopecia are other common side effects. Because paclitaxel is a substrate for CYP 3A4, steady-state concentrations of paclitaxel were 30% lower in patients receiving phenytoin than in patients not receiving phenytoin. Paclitaxel clearance was decreased by 33% when it was administered after cisplatin, so paclitaxel is administered before cisplatin.

A nanoparticle albumin-bound nab-paclitaxel product is also available for the treatment of metastatic breast cancer resistant to conventional chemotherapy or progressing within 6 months of receiving a regimen containing an anthracycline. The nab-paclitaxel formulation uses nanotechnology to combine human albumin with paclitaxel allowing for the delivery of an insoluble drug in the form of nanoparticles. This unique formulation allows for an increased bioavailability and higher intracellular concentrations of the drug. It does not have the serious hypersensitivity reactions encountered with paclitaxel solubilized in Cremophor EL, so premedication with H<sub>1</sub> and H<sub>2</sub> blockers and steroids is not necessary. There is also a significantly lower incidence of severe neutropenia when compared to paclitaxel. The dose is infused over 30 minutes and does not require a special IV bag, tubing, or filter. The dosing of this product is different from that of the original paclitaxel, so practitioners need to be aware of which product is being prescribed. The pharmacokinetics of the albumin-bound paclitaxel displays a higher clearance and larger volume of distribution than paclitaxel. The drug is eliminated primarily via fecal excretion. Bone marrow suppression, neuropathy, ileus, arthralgias, and myalgias still occur.

Docetaxel has activity in the treatment of several solid tumors also. Dexamethasone, 8 mg twice daily for 3 days starting the day before treatment, is used to prevent the fluid-retention syndrome associated with docetaxel and possible hypersensitivity reactions. The fluid-retention syndrome is characterized by edema and weight gain that is unresponsive to diuretic therapy and is associated with cumulative doses greater than 800 mg/m<sup>2</sup>. Myelosuppression, alopecia, and neuropathy are other side effects associated with docetaxel treatment.

Cabazitaxel is a newer taxane used in combination with prednisone for the treatment of metastatic hormone-refractory prostate cancer in patients previously treated with a docetaxel-containing treatment regimen. Cabazitaxel has shown to have similar adverse effects as paclitaxel and docetaxel. Premedication with an antihistamine, corticosteroid, and H<sub>2</sub> antagonist to prevent hypersensitivity reactions is required.

- **Halichondrins**

Erubulin mesylate is a nontaxane microtubule dynamics inhibitor. It is a synthetic analogue of halichondrin B, which is a product isolated from the sea sponge *Halichondria okadai*. While taxanes inhibit cell division by stabilizing microtubules, erubulin arrests the cell cycle through inhibition of the growth phase of microtubules without interfering with microtubule
shortening. The cytotoxicity results from its effects via a tubulin-based antimitotic mechanism, resulting in G₂/M cell-cycle arrest and mitotic blockage. Apoptotic cell death results from prolonged mitotic blockage. Estramustine has shown activity in the treatment of cancers of the colon, rectum, cervix, and lung. Estramustine-induced diarrhea is a serious complication and may be life threatening. One form of diarrhea (acute) can occur during or immediately after the infusion. This is a result of a cholinergic process in which the patient may experience facial flushing, diaphoresis, and abdominal cramping. IV atropine should be administered to treat diarrhea that occurs during the first 24 hours of administration. Another form of diarrhea (chronic) can occur several days after administration and can result in severe dehydration. This adverse effect should be treated immediately with loperamide at a dosage of 2 mg every 2 hours or 4 mg every 4 hours until diarrhea has stopped for 12 hours. Other side effects include myelosuppression, fatigue, and alopecia. Individuals homozygous for UGT1A1*28 have an increased risk of febrile neutropenia and diarrhea and should be considered for an empiric dose reduction of one level; heterozygotes should receive closer monitoring, including more frequent complete blood counts (CBCs) to detect myelosuppression.

Topotecan has shown clinical activity in the treatment of ovarian and lung cancer, myelodysplastic syndromes, and AML. The IV infusion may be scheduled daily for 5 days or once weekly. Side effects include myelosuppression, mucositis, and diarrhea. Diarrhea is less common than with irinotecan.

**Anthracene Derivatives**

- **Daunorubicin, Doxorubicin, Idarubicin, and Epirubicin**

Anthracyclines (daunorubicin, doxorubicin, idarubicin, and epirubicin) are also referred to as antitumor antibiotics or topoiso-erase inhibitors when considering their mechanism of action. All of the anthracyclines contain a four-membered anthracene ring, a chromophore, with an attached sugar portion. Free radicals formed from the anthracyclines combine with oxygen to form superoxide, which can make hydrogen peroxide. These agents are able to insert between base pairs of DNA to cause structural changes in DNA. However, the primary mechanism of cytotoxicity appears to be the inhibition of topoisomerase II. These drugs are widely used in a variety of cancers.

Oxygen-free-radical formation is a cause of cardiac damage and extravasation injury, which is common with these drugs. The anthracyclines can cause cardiac toxicity as manifested by a congestive heart failure or cardiomyopathy symptomatology, alopecia, nausea or vomiting, mucositis, myelosuppression, and urinary discoloration. These drugs are vesicants. Dosage alterations should be made in the presence of biliary dysfunction.\(^\text{19}\)

To reduce the risk of cardiotoxicity associated with doxorubicin, the maximum lifetime cumulative dose is 550 mg/m\(^2\). Ven- tricular ejection fractions should be measured before therapy and periodically if therapy is continued. Therapy should be halted if there is a 10% to 20% decrease from baseline in ejection fraction. Patients at increased risk of cardiotoxicity include patients reaching the upper limit of cumulative lifetime dose; those taking concomitant or previous cardiotoxic drugs, concurrent paclitaxel, or bolus administration; patients with preexisting cardiac disease or mediastinal radiation; and the very young and elderly. Cardioprotectants (eg, dexrazoxane) have been used to decrease risk in some cases. Clinical guidelines exist recommending when cardioprotective agents are warranted.\(^\text{20}\)

Liposomal doxorubicin is an irritant, not a vesicant, and is dosed differently from doxorubicin, so clinicians need to be very careful when prescribing these two drugs. Liposomal doxorubicin has shown significant activity in the treatment of breast and
Alkylating Agents

Although still widely used for many malignancies, the alkylating agents are the oldest class of anticancer drugs. The agents cause cytotoxicity via transfer of their alkyl groups to nucleophilic groups of proteins and nucleic acids. The major site of alkylation within DNA is the N7 position of guanine, although alkylation does occur to a lesser degree at other bases. These interactions can either occur on a single strand of DNA (monofunctional agents) or on both strands of DNA through a cross-link (bifunctional agents), which leads to strand breaks. The major toxicities of the alkylating agents are myelosuppression, alopecia, nausea or vomiting, sterility or infertility, and secondary malignancies.

Nitrosoureas (Carmustine and Lomustine)

Carmustine (BCNU) and lomustine (CCNU) are nitrosoureas that are lipophilic in nature and therefore able to cross the blood–brain barrier. Carmustine, which is reconstituted with ethanol, crosses the blood–brain barrier when given IV. It also comes as a biodegradable wafer formulation that may be implanted to treat residual tumor tissue after surgical resection of brain tumors. Lomustine is available in an oral formulation. Carmustine has shown clinical activity in the treatment of lymphoma, melanoma, and brain tumors. Lomustine has shown clinical activity in the treatment of non-Hodgkin lymphoma and melanoma. Patients receiving high-dose lomustine should receive anticonvulsant prophylaxis. Toxicities associated with busulfan dosing along with a discussion on adverse effects can occur within 48 to 72 hours of administration and is usually reversible.

Patient Encounter 1, Part 3

The patient goes into complete remission (or a complete response), and now consolidation therapy with high-dose cytarabine (2 g/m2/dose IV every 12 hours for six doses) will be initiated.

What is the mechanism of action of cytarabine? How do the toxicities of high-dose cytarabine differ from those of conventional (low-dose) cytarabine? What are the risk factors, prophylaxis recommendations, and treatment recommendations for these toxicities?

to and inactivates acrolein in the bladder), frequent voiding, and monitoring in patients receiving ifosfamide and high-dose cyclophosphamide. Patients should be counseled to drink plenty of fluids; void frequently; and report any hematuria, irritation, or flank pain. Dosing regimens of MESNA range from an equal miligram dose to the ifosfamide mixed in the same IV bag to 20% of the dose before ifosfamide and 20% of the dose repeated at 4 and 8 hours after the dose. Chloroacetaldehyde, a metabolite of ifosfamide, can result in encephalopathy, especially in patients receiving ifosfamide that exhibit risk factors such as renal dysfunction or advanced age. This adverse effect can occur within 48 to 72 hours of administration and is usually reversible.

Busulfan

Busulfan is an alkylating agent that forms DNA–DNA and DNA–protein cross-links to inhibit DNA replication. Oral busulfan is well absorbed, has a terminal half-life of 2 to 2.5 hours, and is eliminated primarily by metabolism. It is also available in an IV formulation, which is useful when using the high doses required in blood and marrow transplantation. Busulfan has shown significant clinical activity in the treatment of AML and CML and has been used as a conditioning regimen prior to stem cell transplant. Side effects include bone marrow suppression; hyperpigmentation of skin creases; and rarely, pulmonary fibrosis. High doses used for bone marrow transplant preparatory regimens result in severe nausea and vomiting, tonic–clonic seizures, and sinusoidal obstruction syndrome. Patients receiving high-dose busulfan should receive anticonvulsant prophylaxis. Toxicities associated with busulfan dosing along with a discussion on adaptive dosing of busulfan can be found in Chapter 98.

Nitrosoureas (Carmustine and Lomustine)

Carmustine (BCNU) and lomustine (CCNU) are nitrosoureas that are lipophilic in nature and therefore able to cross the blood–brain barrier. Carmustine, which is reconstituted with ethanol, crosses the blood–brain barrier when given IV. It also comes as a biodegradable wafer formulation that may be implanted to treat residual tumor tissue after surgical resection of brain tumors. Carmustine is available in an oral formulation. Carmustine has shown clinical activity in the treatment of lymphoma, melanoma, and brain tumors. Lomustine has shown clinical activity in the treatment of non-Hodgkin lymphoma and melanoma. Patients should receive only enough lomustine for one cycle at a time to prevent confusion with their drug regimens and the prolonged neutropenia that can occur. Side effects include myelosuppression, severe nausea and vomiting, and pulmonary fibrosis with long-term therapy.

Patient Encounter 1, Part 2

The decision to treat the patient with a systemic chemotherapy regimen is made. He will be receiving the standard induction regimen of 7 + 3 (idarubicin 12 mg/m2/day IV every day for 3 days + cytarabine 100 mg/m2/day continuous IV infusion for 7 days).

Before initiating this chemotherapy regimen in the patient, what patient specific issues need to be addressed? What adverse effects will the patient likely experience with these two chemotherapy drugs?
**Nondclassic Alkylating Agents (Dacarbazine and Temozolomide)**

Although the exact mechanism of action remains unclear, dacarbazine and temozolomide appear to inhibit DNA, RNA, and protein synthesis. Dacarbazine has shown clinical benefit in the treatment of patients with melanoma, Hodgkin lymphoma, and soft tissue sarcomas. Side effects include myelosuppression, severe nausea and vomiting, and a flu-like syndrome that starts about 7 days after treatment and lasts 1 to 3 weeks. Temozolomide is an orally active agent that is well absorbed and crosses the blood–brain barrier. Temozolomide is converted via pH-dependent hydrolysis to the active metabolite 5-(3-methyltriazeno)-imidazole-4-carboxamide. Temozolomide may be used in the treatment of melanoma, refractory anaplastic astrocytoma, and glioblastoma multiforme. Nausea may be minimized by administering the drug at bedtime. Because patients receiving temozolomide may have confusion secondary to their brain tumors and because dosing can consist of multiple capsule sizes, care must be taken by all providers to simplify regimens to prevent chemotherapy overdose.

**Procarbazine**

Although the exact mechanism of action of procarbazine is unknown, it does inhibit DNA, RNA, and protein synthesis. Procarbazine is used most often in the treatment of lymphoma. Myelosuppression is the major side effect. Nausea, vomiting, and a flu-like syndrome occur initially with therapy. Patients must be counseled to avoid tyramine-rich foods because procarbazine is a monoamine oxidase inhibitor. Patients should be provided a list of foods and beverages to avoid a hypertensive crisis. A disulfiram-like reaction can occur with the ingestion of alcohol.

**Bendamustine**

Bendamustine has three chemically active groups: a 2-chlorethyl group, a butyric acid side chain, and a benzimidazole ring. Bendamustine has shown activity in chronic lymphocytic leukemia and non-Hodgkin lymphoma. It is usually given in combination with rituximab as first-line therapy. Side effects include nausea, vomiting, bone marrow suppression, headache and dyspnea.

**Thiotepa**

Thiotepa is an alkylating agent that reacts with DNA phosphate groups to produce chromosomal cross-linkage. Thiotepa has shown clinical activity in the treatment of breast, bladder, and ovarian cancer, along with carcinomatous meningitis and malignant effusions, and usually is administered IV or as an intravascular infusion. It also may be used intrathecally. Side effects include myelosuppression, nausea and vomiting, and venous irritation.

**Heavy Metal Compounds**

Platinum drugs form reactive platinum complexes that bind to cells, so the pharmacokinetics of the individual drug may be of the platinum, both free and bound, rather than of the parent drug.

**Cisplatin**

Cisplatin forms inter- and intrastrand DNA cross-links to inhibit DNA synthesis. Cisplatin has shown clinical activity in the treatment of numerous tumor types, from head and neck cancers to anal cancer, including many types of lymphoma and carcinoma of unknown primary. Cisplatin is highly emetogenic, even when low doses are given daily for 5 days, and causes delayed nausea and vomiting as well; patients require aggressive antiemetic regimens for both delayed and acute emesis. Significant nephrotoxicity and electrolyte abnormalities can occur if inadequate hydration occurs. Otoxicity, which manifests as a high-frequency hearing loss, and a glove-and-stocking neuropathy may limit therapy.

**Carboplatin**

Carboplatin has the same mechanism of action as cisplatin, however, its side effects are similar but less intense than those of cisplatin. Many chemotherapy regimens dose carboplatin based on an area under the curve (AUC), which is also called the Calvert equation. According to the Calvert equation, the dose in milligrams of carboplatin = (CrCl + 25) × AUC desired, where CrCl is expressed in mL/min. Carboplatin has shown clinical activity in the treatment of several solid tumors and lymphoma. Thrombocytopenia, nausea and vomiting, and hypersensitivity reactions are adverse effects.

**Oxaliplatin**

Oxaliplatin has shown clinical activity in the treatment of colorectal cancer. Oxaliplatin, although similar in action to cisplatin and carboplatin in terms of adverse effects, also, causes a cold-induced neuropathy. Patients should be counseled to avoid cold beverages, to use gloves to remove items from the freezer, and to wear protective clothing in cold climates for the first week after treatment. A glove-and-stocking neuropathy also occurs with long-term dosing. Hypersensitivity reactions and moderate nausea and vomiting are also adverse effects.

**mTOR Inhibitors**

**Temsirolimus and Everolimus**

The mammalian target of rapamycin (mTOR) is a downstream mediator in the phosphatidylinositol 3-kinase/Akt signaling pathway that controls translation of proteins that regulate cell growth and proliferation but also angiogenesis and cell survival. The mTOR is an intracellular component that stimulates protein synthesis by phosphorylating translation regulators, and contributes to protein degradation and angiogenesis.

Temsirolimus is approved for the treatment advanced renal cell carcinoma. Temsirolimus and its metabolite sirolimus are substrates of the cytochrome CYP3A4/5 isoenzyme system. The primary side effects of temsirolimus include mucositis, diarrhea, maculopapular rash, nausea, leucopenia, thrombocytopenia, and hyperglycemia.

Everolimus is an oral inhibitor of mTOR that is approved for the treatment of patients with advanced renal cell cancer after failure of treatment with sunitinib or sorafenib and most recently for the treatment of advanced pancreatic neuroendocrine tumors. Drug interactions and adverse reactions are similar to those of temsirolimus.

**Miscellaneous Agents**

**Altretamine**

Altretamine, formerly known as hexamethylmelamine, is similar in structure to alkylating agents but is known to have anticancer activity in cancer cells resistant to alkylating agents. Altretamine has shown activity in the treatment of ovarian and lung cancer. This orally administered drug has the dose-limiting side effects of anorexia, nausea, vomiting, diarrhea, and abdominal cramping. Other side effects include neuropathy, agitation, confusion, and depression.
Bleomycin is a mixture of peptides with drug activity expressed in units, where 1 unit equals to 1 mg. Bleomycin causes DNA strand breakage. Bleomycin has shown clinical activity in the treatment of patients with testicular cancer and malignant effusions, squamous cell carcinomas of the skin, and Kaposi sarcoma. Hypersensitivity reactions and fever may occur, so premedication with acetaminophen may be required. The most serious side effect is the pulmonary toxicity that presents as a pneumonitis with a dry cough, dyspnea, rales, and infiltrates. Pulmonary function studies show decreased carbon monoxide diffusing capacity and restrictive ventilatory changes. “Bleomycin lung” is associated with cumulative dosing greater than 400 units and occurs rarely with a total dose of 150 units. The pulmonary toxicity is potentiated by thoracic radiation and by hyperoxia. Additional side effects include fever with or without chills, mild to moderate alopecia, and nausea and vomiting. Bleomycin has been used to manage malignant plural effusions at doses of 15 to 60 units through installation into the affected area. The drainage tube of the effusion is clamped off for some period of time after administration of bleomycin and then the amount of drainage is monitored to determine efficacy of the treatment.

Hydroxyurea is an oral drug that inhibits ribonucleotide reductase, which converts ribonucleotides into the deoxyribonucleotides used in DNA synthesis and repair. Hydroxyurea has shown clinical activity in the treatment of CML, polycythemia vera, and thrombocytosis. The major side effects are myelosuppression, nausea and vomiting, diarrhea, and constipation. Rash, mucositis, and renal tubular dysfunction occur rarely.

L-Asparaginase is an enzyme that may be produced by Escherichia coli. Asparaginase hydrolyzes the reaction of asparagine to aspartic acid and ammonia to deplete lymphoid cells of asparagine, which inhibits protein synthesis. L-Asparaginase has shown clinical activity in the treatment of ALL and childhood AML. Severe allergic reactions may occur when the interval between doses is 7 days or greater, so while a skin test result may be negative, patients should be observed closely after asparaginase administration. Pancreatitis and fibrinogen depletion may also occur during therapy. Repletion of fibrinogen should be done to prevent disseminated intravascular coagulation and fatal bleeding. If the patient suffers an allergic reaction to L-asparaginase, pegaspargase, which is L-asparaginase modified through a linkage with polyethylene glycol, which extends the half-life and allows for lower doses and less frequent administration, may be given. Cost and limited availability are some reasons pegaspargase may not be used first.

Arsenic trioxide, which is approved for the treatment of acute promyelocytic leukemia (APL), induces the growth of cancer cells into mature, more normal cells and induces programmed cell death, or apoptosis. Arsenic trioxide causes QT-interval prolongation, so frequent electrocardiograms need to be done before each dose, and other drugs that may prolong the QT interval need to be avoided during therapy. Monitoring of potassium and magnesium should be performed and active replacement undertaken to prevent QT prolongation. Other side effects include dry skin with itching, nausea and vomiting, loss of appetite, and elevations of serum hepatic enzymes. A serious side effect is APL differentiation syndrome, which appears similar to pneumonia but is related to the arsenic therapy.

Mitomycin C forms cross-links with DNA to inhibit DNA and RNA synthesis. Mitomycin C has shown clinical activity in the treatment of several solid tumors. Side effects consist of myelosuppression and mucositis, and it is a vesicant.

Tretinoin, also referred to as ATRA, which stands for all-trans-retinoic acid, is a retinoic acid that is not cytotoxic but promotes the maturation of early promyelocytic cells and is specific to the t(15;17) cytogenetic marker. The most significant side effect is the APL differentiation syndrome, which may occur anywhere from the first couple of days of therapy until the end of therapy and consists of symptoms of fever, respiratory distress, and hypotension. Chest radiographs are consistent with a pneumonia-like process. The syndrome can be confused easily with pneumonia in a patient with possible neutropenia. The treatment for retinoic acid syndrome is dexamethasone 10 mg IV every 12 hours; the syndrome may resolve within 24 hours of the start of dexamethasone therapy. However, the use of steroids in a febrile neutropenic patient may further compromise the treatment of infection.

Immunomodulatory Agents (Thalidomide, Lenalidomide, and Pomalidomide) were introduced into the market in Europe on October 1, 1957, as a sedative–hypnotic, and when it was taken by pregnant women, it resulted in severe limb deformities (phocomelia) and its withdrawal from use. Thalidomide is an angiogenesis inhibitor, but the full mechanism of action is still unknown. Possible mechanisms of action include free radical oxidative damage to DNA, inhibiting tumor necrosis factor a production, altering the adhesion of cancer cells, and altering cytokines that affect the growth of cancer cells. Thalidomide has shown clinical activity in the treatment of multiple myeloma. Because of thalidomide’s potential to cause phocomelia, each patient must be enrolled in the STEPS program and counseled on the risks of thalidomide not only for the patient but also the patient’s reproductive partner. Clinicians must be registered to prescribe thalidomide. Common adverse effects include somnolence, constipation, peripheral neuropathy, and deep vein thrombosis (DVT). Recommendations for DVT prophylaxis include standard dose warfarin or low-molecular-weight heparins.

Lenalidomide is approved for the treatment of myelodysplastic syndrome when the 5q deletion is present and multiple myeloma. Because lenalidomide is an analogue of thalidomide, all of the same precautions must be taken to prevent phocomelia. However, lenalidomide has fewer adverse effects than thalidomide. Dosing adjustments are necessary for renal dysfunction. Lenalidomide is used in the treatment of myelodysplastic syndrome and multiple myeloma. Other side effects are neutropenia, thrombocytopenia, deep vein thrombosis (DVT), and pulmonary embolus.

Pomalidomide was approved for the treatment of refractory or progressive multiple myeloma in February 2013. Adverse effects include myelosuppression and infections. The use of
the immunomodulatory agents in the treatment of multiple myeloma is discussed thoroughly in Chapter 96.

**Bexarotene**

Bexarotene is a retinoid that selectively activates retinoid X receptors, which affects cellular differentiation and proliferation. Bexarotene is eliminated primarily by the hepatobiliary system. Bexarotene is indicated for the treatment of cutaneous manifestations of cutaneous T-cell lymphoma in patients who are refractory to other therapy. Side effects include hypercholesterolemia, elevations in triglycerides, pancreatitis, hypothyroidism, and leukopenia, headache, and dry skin.

**Proteasome Inhibitors (Bortezomib and Carfilzomib)**

The proteasome is an enzyme complex that exists in all cells and plays an important role in degrading proteins the control the cell cycle. When the proteasome is inhibited, the numerous pathways that are necessary for the growth and survival of cancer cells are disrupted. Bortezomib specifically inhibits the 26S proteasome, which is a large protein complex that degrades ubiquitinated proteins. This pathway plays an essential role in regulating the intracellular concentration of specific proteins, causing the cells to maintain homeostasis. Inhibition of the 26S proteasome prevents this to occur, ultimately causing a disruption in the homeostasis and cell death.

Bortezomib is approved for the treatment of multiple myeloma (MM), mantle cell lymphoma, and in some cases of relapsed/refractory AML. It is administered as an IV injection. The most commonly reported adverse effects are asthenia, gastrointestinal disturbances (nausea, diarrhea, decreased appetite, constipation, vomiting), thrombocytopenia, peripheral neuropathy, anemia, headache, insomnia, and edema. Prophylactic anti-coagulation is required to prevent this to occur, ultimately causing a disruption in the homeostasis and cell death.

Bortezomib is approved for the treatment of multiple myeloma (MM), mantle cell lymphoma, and in some cases of relapsed/refractory AML. It is administered as an IV injection. The most commonly reported adverse effects are asthenia, gastrointestinal disturbances (nausea, diarrhea, decreased appetite, constipation, vomiting), thrombocytopenia, peripheral neuropathy, anemia, headache, insomnia, and edema. Prophylactic anti-coagulation is not routinely required. Reactivation of varicella zoster infection is also common with bortezomib, and antiviral prophylaxis with acyclovir should be considered.

Carfilzomib is a newer second-generation proteasome inhibitor and is used in the treatment of refractory cases of MM.

**Omacetaxine Mepesuccinate**

Omacetaxine mepesuccinate, an alkaloid from *Cephalotaxus harringtonia*, was granted accelerated approval by the FDA in October 2012. The agent reversibly inhibits protein synthesis, causing cell death. It affects both malignant and nonmalignant cells. It is a subcutaneous injection and is indicated for the treatment of CML patients (including those patients with the T315I mutation) showing resistance and/or intolerance to two or more TKIs. The most common nonhematological adverse effects are gastrointestinal disruption, fatigue, and hyperglycemia. Rare but serious adverse reactions include febrile neutropenia, infections, and cerebral hemorrhage.

**Ziv-aflibercept**

Ziv-aflibercept is a recombinant fusion protein that consists of vascular endothelial growth factor (VEGF)-binding portions from the extracellular domains of human VEGF receptors 1 and 2 fused to the Fc portion of the human IgG1 immunoglobulin. It is an intravenously administered and approved for the treatment of metastatic colorectal cancer in combination with FOLFIRI after progression on an oxaliplatin-based regimen. Ziv-aflibercept has black-box warnings, which include hemorrhage, gastrointestinal perforation, and compromised wound healing. Other adverse effects include neutropenia, diarrhea, and a reversible posterior leukoencephalopathy syndrome.

**HDAC Inhibitors (Vorinostat and Romidepsin)**

Vorinostat is indicated for the treatment of cutaneous T-cell lymphoma in patients with progressive, persistent, or recurrent disease after treatment with two systemic therapies. Romidepsin is approved for the treatment of cutaneous or peripheral T-cell lymphoma in patients who have received at least one systemic therapy. These agents catalyze the removal of acetyl groups from acetylated lysine residues in histones, resulting in the modulation of gene expression. Vorinostat is an orally available agent, and romidepsin is only available in an IV formulation. These drugs are metabolized by CYP3A4, so caution should be exercised with monitoring for drug–drug interactions. Side effects include diarrhea, fatigue, nausea and anorexia, hypercholesterolemia, hypertriglyceridemia, and hyperglycemia. Despite anemia, thrombocytopenia, and neutropenia, patients have developed pulmonary embolism and DVT while on therapy.

**Immune Therapies**

**Interferons**

The categories of α, β, and γ interferons exist; the α-interferons are used in the treatment of cancer. Interferon enhances the immune system’s attack on cancer cells, can decrease new blood vessel formation, and can augment expression of antigen on tumor cell surfaces. Interferon has shown clinical activity in the treatment of melanoma, kidney cancer, Kaposi sarcoma, and CML and CLL. Unfortunately, interferon is not well tolerated by patients because it causes a flu-like syndrome that consists of fevers and chills; depression, malaise, and fatigue are other side effects. Premedication with acetaminophen helps alleviate the flu-like symptoms, which decrease with chronic administration.

**Aldesleukin**

Aldesleukin, which is a human recombinant interleukin-2 (IL-2), is a lymphokine that promotes B- and T-cell proliferation and triggers a cytokine cascade to attack the tumor. Aldesleukin has shown clinical activity in the treatment of kidney cancer and melanoma. Side effects of IL-2 vary by dose and route. IV high-dose IL-2 causes a drug-induced shock-like picture. Patients may develop hypotension despite aggressive IV hydration. Patients develop a red, itchy skin; liver and kidney function tests change; via immune complex formation in the kidneys, fluid and electrolyte imbalances occur; and high fevers occur while receiving scheduled acetaminophen and nonsteroidal anti-inflammatory agents. Severe rigors and chills may require symptom control. All the side effects reverse within 24 hours of stopping the drug. The

### Patient Encounter 2

A 48-year-old man is receiving doxorubicin and ifosfamide for a newly diagnosed osteosarcoma. While receiving chemotherapy, he begins to complain of flank pain and hematuria. His serum creatinine has risen from 0.8 mg/dL to 2.1 mg/dL (71 to 186 μmol/L) in the last 3 days.

**What is the likely diagnosis?**

**What medication should always be included as part of this regimen?**

**What should patients be counseled to do while receiving ifosfamide therapy?**
toxicity profile is much less with subcutaneous administration. However, with subcutaneous administration, nodules form at the injection site and may take months to resolve. Corticosteroids should not be administered to patients while they are receiving aldesleukin unless a life-threatening emergency occurs. Steroids reverse all the symptoms and the antitumor effect even with topical administration. The itching, red skin may be treated with topical creams and antihistamines.

**Denileukin Diftitox**

Denileukin diftitox is a combination of the active moieties of IL-2 and diphtheria toxin. It binds to high-affinity IL-2 receptors on the cancer cell (and other cells), and the toxin portion of the molecule inhibits protein synthesis to result in cell death. Denileukin diftitox is used for the treatment of persistent or recurrent cutaneous T-cell lymphoma whose cells express the CD25 receptor. Side effects include vascular leak syndrome, fevers or chills, hypersensitivity reactions, hypotension, anorexia, diarrhea, and nausea and vomiting.

**Peginterferon α-2b**

Sylatron is a covalent conjugate of recombinant α-2b interferon with monomethoxy polyethylene glycol (PEG). The mechanism of cytotoxicity in patients with melanoma is unknown. This agent is specifically indicated for the adjuvant treatment of melanoma with microscopic or gross nodal involvement up to 84 days after definitive surgical resection (including complete lymphadenectomy). Adverse effects include fatigue, increased liver enzymes, pyrexia, headache, anorexia, myalgia, nausea, chills, and pain at the injection site.

**Sipuleucel-T**

Sipuleucel-T is a novel autologous cellular immunotherapy approved for the treatment of asymptomatic or minimally symptomatic metastatic hormone refractory prostate cancer. Sipuleucel-T is designed to induce an immune response targeted at prostate acid phosphatase (PAP), which is an antigen expressed in greater than 95% of prostate cancers. Patients receiving sipuleucel-T undergo leukapheresis to collect their own antigen-presenting cells. These cells are then sent to a manufacturing facility and cultured with a recombinant antigen (PAP-GM-CSF, composed of PAP and GM-CSF, an immune cell activator). The cellular product, which is made specifically for each patient, is then delivered to the patient’s clinic and infused intravenously into the patient on day 3 or 4. Each course consists of three infusions of activated cells given at 2-week intervals. Adverse effects include chills, fatigue, fever, back pain, nausea, joint pain, and headache.

**Monoclonal Antibodies**

The cell surface contains molecules, which are referred to as CD, which stands for “cluster of differentiation.” The antibodies are produced against a specific antigen. When administered, usually by an IV injection, the antibody binds to the antigen, which may trigger the immune system to result in cell death through complement-mediated cellular toxicity, or the antigen–antibody cell complex may be internalized to the cancer cell, which results in cell death. Monoclonal antibodies also may carry radioactivity, sometimes referred to as hot antibodies, and are referred to as radioimmunotherapy, so the radioactivity is delivered to the cancer cell. Antibodies that contain no radioactivity are referred to as cold antibodies.

All monoclonal antibodies end in the suffix -mab. The syllable before -mab indicates the source of the monoclonal antibody (Table 88–6). When administering an antibody for the first time, one should consider the source. The less humanized an antibody, the greater the chance for the patient to have an allergic-type reaction to the antibody. The more humanized the antibody, the lower the risk of a reaction. The severity of the reactions may range from fever and chills to life-threatening allergic reactions. Premedication with acetaminophen and diphenhydramine is common before the first dose of any antibody. If a severe reaction occurs, the infusion should be stopped and the patient treated with antihistamines, corticosteroids, or other supportive measures.

**Bevacizumab**

Bevacizumab is a humanized monoclonal antibody that binds to vascular endothelial growth factor (VEGF), which prevents it from binding to its receptors, ultimately resulting in inhibition of angiogenesis. Bevacizumab has shown clinical activity in the treatment of colorectal, kidney, lung, breast, and head and neck cancer. Patients may develop hypertension requiring chronic medication during therapy. Impaired wound healing, thromboembolic events, proteinuria, bleeding, and bowel perforation are serious side effects that occur with this drug.

**Brentuximab**

Brentuximab vedotin is a CD30-directed antibody–drug conjugate (ADC) that consists of the antibody specific for CD30, a microtubule disrupting agent called monomethyl auristatin E (MMAE), and a protease-cleavable linker that covalently attaches MMAE to the antibody. It is reported that the cytotoxic activity is a result of the binding of the ADC to CD30-expressing cells followed by internalization of the ADC–CD30 complex, and then proteolytic cleavage and release of MMAE into the cell. Binding of MMAE to tubulin disrupts the microtubule network, resulting in cell cycle arrest and apoptosis. This IV agent is indicated for Hodgkin lymphoma patients after failure of autologous stem cell transplant (ASCT) or after failure of at least two multidrug regimens in patients who are not eligible for ASCT and for patients with systemic anaplastic large cell lymphoma who have failed at least one systemic chemotherapy regimen. In vitro data suggests that MMAE is a substrate and an inhibitor of CYP3A4/5; therefore, patients need to be monitored for drug–drug interactions. The most common adverse effects are neutropenia, peripheral neuropathy, fatigue, nausea and vomiting, diarrhea, anemia, thrombocytopenia, and upper respiratory infection. Dosing modifications guidelines for peripheral neuropathy can be found in the prescribing information.
Cetuximab

Cetuximab is a chimeric antibody that binds to the epidermal growth factor receptor (EGFR) to block its stimulation. Tumors that have KRAS mutations do not respond to treatment with cetuximab; therefore, tumors should be tested for KRAS mutations before initiating therapy. Cetuximab has shown clinical activity in the treatment of colorectal and head and neck cancers. An acne-like rash may appear on the face and upper torso 1 to 3 weeks after the start of therapy. Other side effects include hypersensitivity reactions, interstitial lung disease, fever, malaise, diarrhea, abdominal pain, and nausea and vomiting.

Iplimumab

Iplimumab is a recombinant, human monoclonal antibody that binds to the cytotoxic T lymphocytic–associated antigen 4 (CTLA-4), which is a molecule on T cells that causes a suppression of the immune response. CTLA-4 is a negative regulator of T-cell activation. Iplimumab binds to CTLA-4 and blocks the interaction of CTLA-4 with its ligands. This blockade has been reported to enhance T-cell activation and proliferation. Iplimumab is approved for patients with unresectable or metastatic melanoma. The antitumor effects appear to be T-cell–mediated immune responses. Iplimumab administration can result in severe and fatal immune-mediated adverse reactions, including enterocolitis, hepatitis, toxic epidermal necrolysis, neuropathy, and endocrine abnormalities. These symptoms can occur during treatment or weeks to months after discontinuation of the drug. Liver and thyroid function tests should be performed at baseline and before each dose. If this occurs, treatment should be initiated with systemic corticosteroids and the drug should be discontinued permanently. Progressive multifocal leukoencephalopathy has been reported. Additional less serious adverse effects include fatigue, diarrhea, pruritus, rash, and colitis.

Panitumumab

Panitumumab binds to the EGFR to prevent receptor autophosphorylation and activation of receptor-associated kinases, which results in inhibition of cell growth and induction of apoptosis. Panitumumab has demonstrated activity against tumors of the colon and rectum. However, panitumumab is not recommended for the treatment of colorectal cancer with KRAS mutations in codon 12 or 13. Retrospective subset analyses have not shown a treatment benefit for these mutations. Side effects include dermatitis, pruritus, exfoliative rash, infusion reactions, pulmonary fibrosis, diarrhea, hypomagnesemia, hypocalcemia, and photosensitivity.

Rituximab

Rituximab is a monoclonal antibody to the CD20 receptor expressed on the surface of B lymphocytes; the presence of the antibody is determined during flow cytometry of the tumor cells. Cell death results from antibody-dependent cellular cytoxicity. Rituximab has shown clinical activity in the treatment of B-cell lymphomas that are CD20 positive. Side effects include infusion-related reactions, hypotension, fever, chills, rash, headache, and mild nausea and vomiting. Premedication with diphenhydramine and acetaminophen is recommended to minimize the first-dose infusion reaction.

Tositumomab and Ibritumomab Tiuxetan

Tositumomab, a “hot antibody,” is linked to radioactive iodine and binds to the CD20 receptor present on B lymphocytes (see Rituximab). Tositumomab has shown activity in non-Hodgkin lymphoma. Hematologic toxicity occurs several weeks after administration and may persist for months. Because radioactive iodine may have adverse effects on the thyroid, all patients must receive thyroid-blocking agents.

Ibritumomab Tiuxetan, a “hot antibody,” is linked to yttrium and binds to the CD20 receptor of B lymphocytes. Similarly, hematologic toxicity may occur several weeks after administration and may take weeks to resolve.

Ofatumumab and Obinutuzumab

Ofatumumab and obinutuzumab are two newer monoclonal antibodies that are directed at the CD20 antigen in patients with chronic lymphocytic leukemia that is refractory to fludarabine and alemtuzumab therapy. Obinutuzumab was approved recently for the combination treatment with chlorambucil in patients that have previously untreated CLL. The most common adverse effects include infusion-related reactions, neutropenia, infections, pyrexia, anemia, diarrhea, and nausea. Serious adverse events, including fatal infections, progressive multifocal leukoencephalopathy, and reactivation of hepatitis B, have been reported.

Alemtuzumab

Alemtuzumab is an antibody to the CD52 receptor present on B and T lymphocytes. Alemtuzumab has shown clinical activity in the treatment of chronic lymphocytic leukemia. Severe and prolonged (6 months) immunosuppression may result, which necessitates pneumocystis carinii pneumonia (PCP) prophylaxis and antifungal and antiviral prophylaxis to prevent opportunistic infections. Infusion-related reactions typically occur with the first dose and can be severe. Premedication with antihistamines and acetaminophen is recommended. Subcutaneous administration will also alleviate the severity of infusion reactions.

Ramucirumab

Ramucirumab is a humanized monoclonal antibody that binds with high affinity to the extracellular domain of vascular endothelial growth factor receptor 2 (VEGFR2, preventing the binding of VEGF-A, VEGF-C, and VEGF-D. This agent was approved in 2014 for the treatment of advanced gastric cancer with disease progression after fluoropyrimidine- or platinum-containing chemotherapy. The most common grade 3 or 4 adverse effects are hypertension, most commonly occurring in patients with preexisting hypertension. There is also a risk of hemorrhage, and the drug should be permanently discontinued in patients experiencing a severe bleeding episode.

Trastuzumab

Trastuzumab is a humanized monoclonal antibody directed against human epidermal receptor 2 (HER-2), which is amplified or overexpressed by 15% to 20% of all breast cancers and is associated with aggressive disease and decreased survival. Breast cancer tissue must be tested for the presence of HER-2 because patients who do not express HER-2 do not respond to trastuzumab. It can be used as single agent or in combination with an anthracycline or taxane-based combination chemotherapy. Trastuzumab is also indicated for the treatment of gastric cancer. Severe congestive heart failure may occur with concurrent anthracycline administration. Cardiac toxicity may be seen when the drug is administered months after anthracycline administration, so patients must be counseled on the signs and symptoms of heart failure. A common side effect associated with trastuzumab
is a first-dose infusion-related reaction which includes chills. The patient may be given acetaminophen and diphenhydramine and/or the infusion may be slowed. Other side effects which are rare include hypersensitivity reactions and pulmonary reactions. A more detailed discussion of the use of trastuzumab in breast cancer can be found in Chapter 89.

» **Trastuzumab-DM1 (T-DM1, Trastuzumab Emtansine)**
Trastuzumab-DM1 or ado-trastuzumab emtansine was approved by the FDA in February 2013. In this compound, trastuzumab is used as a drug vehicle to deliver an anticancer agent known as emtansine (a maytansine derivative). Phase 3 clinical data evaluating the use in progressive HER-2-positive breast cancer patients will be discussed in Chapter 89. The most common serious adverse effect reported in clinical trials was thrombocytopenia. The platelet nadir usually occurred about 7 days after treatment and recovered within a week. Other adverse effects included abnormal liver function tests, fatigue, nausea, headache, and hypokalemia. Cardiac toxicity was not a reason for study withdrawal.

» **Pertuzumab**
The FDA approved the new HER-2-targeted pertuzumab in June 2012. When compared to trastuzumab, pertuzumab recognizes different extracellular epitopes, binds uniquely which causes structural changes and therefore interrupts receptor dimerization. These differences were thought to be able to provide greater inhibition of HER-2 when compared to trastuzumab. This has not been proven to be the case, but based on clinical studies is indicated for first-line treatment in combination with trastuzumab and docetaxel for HER-2-positive metastatic breast cancer. Adverse effects seen in clinical trials were diarrhea and a similar incidence of cardiac toxicity as trastuzumab. When used in combination with trastuzumab, it does not appear to increase the incidence of cardiac toxicity.

**Tyrosine Kinase Inhibitors**

There are more than 100 different types of tyrosine kinases present in the body. Tyrosine kinase inhibitors (TKIs) are also referred to as small-molecule inhibitors. Each of the following drugs was developed to block either several or a specific tyrosine kinase.

» **Imatinib**
Imatinib was the first FDA-approved TKI and is considered to be first-generation. Imatinib inhibits phosphorylation during cell proliferation. The drug was designed to block the breakpoint cluster region tyrosine kinase (BCR-ABL) produced by the Philadelphia chromosome associated with CML and ALL. Imatinib also has shown activity against gastrointestinal stromal tumors (GIST) that are positive for c-kit (CD117). Imatinib is usually well tolerated, but common adverse effects include myelosuppression, rash, GI upset, edema, fatigue, arthralgias, myalgias, and headaches. A cumulative cardiotoxicity is a serious but rare adverse effect therefore it is recommended to closely monitor patients with preexisting cardiac conditions. Numerous drug interactions have been reported for imatinib. CYP3A4 inducers, such as rifampicin and St. John’s wort, increase the clearance of imatinib. Ketoconazole, a CYP3A4 inhibitor, has been shown to decrease imatinib clearance by almost 30%. Imatinib also may increase the exposure of simvastatin, a CYP3A4 substrate. These are various examples of how drug-drug interactions can occur and how important monitoring for these reactions is for the health professionals.

» **Advanced-Generation BCR-ABL TKIs**
Advanced generation BCR-ABL TKIs were developed in an effort to overcome the resistance or intolerance to imatinib. These agents are more potent than imatinib and can overcome most BCR-ABL mutations that lead to imatinib resistance. Dasatinib and nilotinib are second-generation TKI that share the same binding site on the BCR-ABL cluster region as imatinib but maintains activity despite imatinib resistance, with higher potency than imatinib. Dasatinib also inhibits SRC kinases, which are tyrosine kinases that mediate cellular differentiation, proliferation, and survival. Dasatinib and nilotinib are used front line in the treatment of CML and in CML with resistance or intolerance to imatinib. Side effects of dasatinib and nilotinib are similar to imatinib and include myelosuppression, nausea and vomiting, headache, fluid retention, and hypocalcemia. Pleural effusions have been reported with dasatinib and imatinib but not with nilotinib. QT prolongation can occur with dasatinib and nilotinib. Abnormalities in indirect bilirubin have been reported with nilotinib.

Nilotinib is a competitive inhibitor of UGT1A1 in vitro, which could increase the concentrations of nilotinib. In a pharmacogenetic analysis, patients with (TA)7/(TA)7 genotype (UGT1A1*28) had a statistically significant increase in bilirubin over other genotypes. Nilotinib should be administered on an empty stomach or 2 hours after a meal.

Bosutinib is indicated for the second-line treatment of CML in cases of resistance or intolerance to prior TKI therapy. With the exception of T315I, Bosutinib overcomes most BCR-ABL domain mutations. Gastrointestinal disturbances and rash are common. Bosutinib appears to have a milder side effect profile than other TKIs.

Ponatinib is a third-generation multikinase inhibitor and the only advanced generation TKI that overcomes the T315I mutation. Serious adverse effects reported included thrombosis, hepatotoxicity (rare) and death (rare). These are included as black-box warnings. Less serious adverse effects include abdominal pain, dry skin, and rash.

» **Ibrutinib and Idelalisib**
Two small molecule inhibitors that target the B-cell receptor pathway have been recently approved. Ibrutinib inhibits Bruton tyrosine kinase and has shown activity in mantle cell lymphoma and CLL. Idelalisib, in combination with rituximab, is approved for relapsed CLL and targets phosphatidylinositol-3-kinase (PI3-K), an essential lipid kinase. Adverse effects associated with these agents are GI disturbances, rash, hematological side effects, fatigue and musculoskeletal pain. Idelalisib has hepatotoxicity, colitis, pneumonitis, and intestinal perforation as black-box warnings.

» **Epidermal Growth Factor Receptor Pathway Inhibitors (Erlotinib, Afatinib, and Lapatinib)**
Patients with malignancies (eg, non-small cell lung cancer or NSCLC) in which the tumors have mutations in exon 19 and/or 21 in the epidermal growth factor receptor (EGFR) pathway will likely respond to EGFR tyrosine kinase inhibitors such as erlotinib. These agents are believed to inhibit the intracellular phosphorylation of the EGFR. Erlotinib is about 60% absorbed after oral administration. Food increases bioavailability to almost 100%, but this is variable, and experts recommend administering erlotinib on an empty stomach. Erlotinib is eliminated predominately by CYP3A4. Smoking increases the clearance of erlotinib by 24%, which may result in treatment failure. Erlotinib is used...
in the treatment of NSCLC and cancer of the pancreas. Side effects include interstitial lung disease, rash, diarrhea, anorexia, pruritus, conjunctivitis, and dry skin. Again, significant drug interactions have been documented with CYP3A4 inducers and inhibitors.

Afatinib is an oral, selective EGFR-TKI approved for the treatment of metastatic NSCLC in patients with EGFR exon 19 deletions or exon 21 (L858R) substitution mutations. It is taken on an empty stomach at a dose of 40 mg orally once daily. Adverse effects are similar to those reported with erlotinib.

Lapatinib inhibits the intracellular kinase domains of both EGFR and HER-2 and has been shown to retain activity against breast cancer cells that have become resistant to trastuzumab. Lapatinib is indicated for the treatment of patients with breast cancer whose tumors overexpress HER-2. When used in combination with capecitabine, the adverse effects of lapatinib include decreased left ventricular ejection fraction and QT prolongation, diarrhea, dyspepsia, rash, and hepatotoxicity. When not used as a doublet with capecitabine, the cardiac events and adverse effects were not as common.

**Multikinase Inhibitors (Sorafenib, Sunitinib, Pazopanib)**

Sorafenib is a multikinase inhibitor that inhibits both intracellular and extracellular kinases to decrease renal cell cancer proliferation. Sorafenib is metabolized primarily by the liver by CYP3A4. Sorafenib is used for the treatment of renal cell cancer. The primary side effects of sorafenib include rash, hand–foot skin reaction, diarrhea, pruritus, and elevations in serum lipase.

Sunitinib blocks several tyrosine kinases, including platelet-derived growth factor, VEGF receptor, stem cell factor receptor, fms-like receptor growth factor, colony-stimulating growth factor receptor type 1, and glial cell line–derived neurotrophic factor receptor. The active metabolite of sunitinib blocks these same enzymes with similar potency. Significant side effects include left ventricular dysfunction, hemorrhage, asthenia, hypertension, nausea and vomiting, and diarrhea. Approximately one-third of patients may develop a yellow color of the skin along with dryness and cracking of the skin. Also, hair may become depigmented with doses of 50 mg/day or more; the depigmentation is reversible when therapy is stopped. Clinically significant drug interactions exist with inducers and inhibitors of CYP3A4; ketoconazole has been shown to increase concentrations of sunitinib, whereas rifampin has been shown to decrease concentrations of sunitinib.

Pazopanib is a vascular epidermal growth factor receptor (VEGFR) TKI that acts at VEGFR-1, VEGFR-2, and VEGFR-3. It is specifically indicated for the treatment of patients with advanced renal cell carcinoma. Pazopanib is metabolized through CYP3A4; therefore, drug–drug interactions should be monitored. Pazopanib is an orally administered agent that should be taken on an empty stomach. Common adverse effects include diarrhea, hypertension, hair color change, nausea and vomiting, fatigue, and anorexia. Serious toxicities that have been observed are increased in liver enzymes and bilirubin, including fatal hepatotoxicity, prolonged QT intervals and torsades de pointes, hemorrhagic events, arterial thrombotic events, gastrointestinal perforation, and proteinuria.

**Regorafenib**

Regorafenib is a small molecule inhibitor of multiple membrane-bound and intracellular kinases. It is approved for the treatment of metastatic colorectal cancer in patients who have been previously received fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy, anti-VEGF therapy, and an anti-EGFR therapy if KRAS wild-type. The proposed mechanism of action is through inhibition of vascular endothelial receptors involved in angiogenesis. It was recently approved for the treatment of gastrointestinal stromal tumor that had been previously treated with imatinib mesylate and sunitinib malate. GI effects, hypertension, mucositis, infection, rash, and fever are commonly occurring adverse effects. Hepatotoxicity is listed as a black-box warning; therefore hepatic function should be monitored closely. It is an orally administered agent given for the first 21 days per 28-day cycle and should be taken with a low-fat breakfast.

**Vemurafenib, Trametinib, Dabrafenib**

Vemurafenib is a potent inhibitor of mutated BRAF and is indicated for the treatment of unresectable or metastatic melanoma in patients with documented BRAFV600E mutation as determined by an FDA-approved test. Vemurafenib produced improved rates of overall and progression-free survival in a phase III trial when compared with dacarbazine. Vemurafenib is not indicated for patients with wild-type BRAF. The orally administered vemurafenib is dosed at 960 mg twice daily without regards to meals. Common adverse effects include arthralgia, rash, fatigue, alopecia, keratoacanthoma or squamous cell cancer, photosensitivity, nausea, and diarrhea. Approximately 40% of patients require dosage modifications because of adverse effects.41

Trametinib is a reversible inhibitor of mitogen-activated extracellular kinases (MEK)-1 and MEK-2 that is also active against BRAF V600-mutated forms of BRAF kinases in melanoma cells. It is indicated as monotherapy and in combination with dabrafenib for unresectable or metastatic malignant melanoma. It is not indicated in patients previously treated with a BRAF inhibitor. Rash, diarrhea, and lymphedema were commonly reported. Cardiomyopathy (defined as heart failure) and bleeding have also been reported.

Dabrafenib is a kinase inhibitor that has activity against BRAF kinases. It is indicated for the treatment of unresectable or metastatic malignant melanoma as monotherapy in patients with BRAF V600E mutation or in combination with trametinib in patients with BRAF V600E or V600K mutations. Adverse effects associated with this agent include arthralgias, alopecia, headache, palmar-plantar erythrodysesthesia syndrome, elevated liver enzymes, pyrexia, and papilloma.

**Crizotinib and Ceritinib**

Crizotinib is a small-molecule inhibitor of the anaplastic lymphoma kinase gene (ALK) and mesenchymal epithelial transition growth factor (c-MET). This orally available agent is approved for the treatment of locally advanced or metastatic NSCLC that is ALK positive (about 2%–7% of NSCLC patients) as detected by an FDA-approved test. Adverse effects reported include mild gastrointestinal symptoms, edema, and visual disturbances, which have been described as trails of light following objects as they move.42 Ceritinib is newly approved for ALK-positive NSCLC patients who have progressed on or are intolerant to crizotinib. Ceritinib, which has shown to be 20 times more potent than crizotinib in enzymatic assays, primarily targets ALK along with additional targets, including insulin-like growth factor 1 (IGF-1) receptor, insulin receptor (InsR), and ROS1. In comparison with crizotinib, ceritinib does not inhibit the kinase activity of c-MET. GI toxicities and elevated liver function tests
were the most common adverse reactions. Visual changes, pulmonary disease, and QT prolongation were also seen in clinical trials.

**Vandetanib**

Vandetanib is an orally available receptor TKI that blocks both the VEGF and EGF receptor kinase. This agent is indicated for the treatment of symptomatic or progressive medullary thyroid cancer in patients with unresectable locally advanced or metastatic disease. Common adverse effects include diarrhea, rash, acne, nausea, hypertension, headache, fatigue, decreased appetite, and abdominal pain.

**Hormonal Therapies**

A patient’s hormonal receptor status (eg, estrogen and progesterone receptor status) can be used clinically as a prognostic indicator and can help predict a response to hormonal therapy. Hormonal or endocrine therapies have shown activity in the treatment of cancers whose growth is affected by gonadal hormonal control. Hormonal treatments either block or decrease the production of endogenous hormones. You will learn more about these treatments and outcomes in chapters 89 and 91, including the breast and prostate cancer chapters.

**Antiandrogens: Bicalutamide, Flutamide, and Nilutamide**

The antiandrogens block androgen receptors to inhibit the action of testosterone and dihydrotestosterone in prostate cancer cells. Unfortunately, prostate cancer cells may become hormone refractory.

Side effects common to these agents are hot flashes, gynecomastia, and decreased libido. Flutamide tends to be associated with more diarrhea and requires three times daily administration, whereas bicalutamide is dosed once daily. Nilutamide may cause interstitial pneumonia and is associated with the visual disturbance of delayed adaptation to darkness.

**Pure Androgen Receptor Antagonist: Enzalutamide**

Enzalutamide is an androgen receptor (AR) antagonist that works by competitively inhibiting androgen binding to androgen receptors and by inhibiting androgen receptor nuclear translocation and coactivator recruitment of the ligand-receptor complex. This agent has shown to competitively inhibit androgen binding to androgen receptors and inhibit androgen receptor nuclear translocation and interaction with DNA. Enzalutamide is indicated for the treatment of metastatic castration-resistant prostate cancer. The oral dosage is 160 mg orally once daily. Adverse effects associated with the agents are musculoskeletal effects, hot flashes, diarrhea, peripheral edema, hypertension, infections, headache, spinal cord compression, and hematuria.

**Luteinizing Hormone–Releasing Hormone Agonists: Goserelin and Leuprolide**

Initially, luteinizing hormone–releasing hormone (LHRH) agonists increase levels of luteinizing hormone and follicle-stimulating hormone, but testosterone and estrogen levels are decreased because of continuous negative-feedback inhibition. Major side effects are testicular atrophy, decreased libido, gynecomastia, and hot flashes. Goserelin is injected as a pellet under the skin, whereas bicalutamide is dosed once daily. Nilutamide may cause interstitial pneumonia and is associated with more diarrhea and requires three times daily administration.

**Aromatase Inhibitors**

There are three aromatase inhibitors (AIs) currently available, anastrozole, letrozole, and exemestane. Anastrozole and letrozole are selective nonsteroidal aromatase inhibitor that lowers estrogen levels. Anastrozole is a standard adjuvant treatment of postmenopausal women with hormone-positive breast cancer. The length of therapy is usually 5 years; however, evidence exists that suggests a benefit of prolonged treatment in certain situations. Exemestane, a steroidal compound, is an irreversible aromatase inactivator that binds to the aromatase enzyme to block the production of estrogen from androgens. This difference in activity does not appear to translate into improved clinical outcomes when compared to other AI therapies. When compared to tamoxifen, there are less endometrial and uterine cancers, vaginal bleeding, and thrombosis with AI therapy. Common adverse effects associated with the AI therapy include hot flashes and arthralgias. Serious adverse effects include osteoporosis, skeletal-related events, and atherosclerotic cardiovascular disease. The AIs are used exclusively for postmenopausal women. More information on the pharmacology and clinical use of AI therapy can be found in Chapter 89.

**Antiestrogens**

Antiestrogens bind to estrogen receptors and block the effect of estrogen on tissue. There are two classes of antiestrogens: selective estrogen–receptor modulators (SERMs, tamoxifen, raloxifene) and selective estrogen–receptor downregulators (SERDs, Fulvestrant). SERDs were developed in an effort to eliminate the unwanted estrogenic side effects from the SERMs. Tamoxifen is used for the treatment of estrogen receptor (ER) positive premenopausal or postmenopausal metastatic hormone receptor–positive breast cancer, as adjuvant and primary treatment of
breast cancer, and in the prevention of breast cancer in high-risk women. It is associated with a significant decrease in disease recurrence and mortality. The agent has a beneficial effect on bone density and the lipid profile. Unwanted side effects include hot flashes, fluid retention, and mood swings. Thrombosis, endometrial and uterine cancer, corneal changes, and cataracts are harmful adverse effects that occur more frequently with this agent. Although uncommon, there is a disease/tumor flare which can occur during the initiation of therapy in metastatic breast cancer patients with bone metastases. Because tamoxifen is a substrate of CYP3A4, decreased tamoxifen levels have occurred with use of St. John’s wort and rifampin. Tamoxifen is also a substrate for CYP450 2D6, and evidence suggests that those who are CYP2D6 4/*4 may have a poorer response and more toxicity with tamoxifen. Routine pharmacogenomics screening of these patients is not currently recommended. Significant drug interactions exist and drug–drug interactions affecting this enzyme should be avoided if possible.

Raloxifene is another SERM and is used for the treatment of osteoporosis in postmenopausal women and is the chemopreventative agent of choice for the prevention of breast cancer in high-risk women. When compared head to head with tamoxifen for breast cancer prevention, it was demonstrated to have equal efficacy with less toxicity. Raloxifene was not studied in premenopausal women; therefore, tamoxifen is still the preventative agent of choice in these women. Hot flashes, arthralgias, and peripheral edema occur frequently with raloxifene, but thrombosis and endometrial cancer is less common than with tamoxifen.

Fulvestrant is used as second-line treatment in hormone receptor–positive metastatic breast cancer, postmenopausal women with disease progression following antiestrogen therapy. Fulvestrant is given as a monthly intramuscular injection, which might be a deterrent to some patients.

Other antiestrogen agents that are used in the treatment of breast cancer include toremifene (SERM) and megestrol acetate. Megestrol acetate can cause fluid retention, hot flashes, vaginal bleeding and spotting, breast tenderness, and thrombosis.

ADMINISTRATION ISSUES

Extravasation

One issue of chemotherapy safety is extravasation. Antineoplastic agents that cause severe tissue damage when they escape from the vasculature are called vesicants. The tissue damage may be severe, with tissue sloughing and loss of mobility, depending on the area of extravasation. Patients need to be educated to notify the nurse immediately if there is any pain on administration. If extravasation of a vesicant occurs, the injection should be stopped and any fluid aspirated out of the injection site. The prevention, risk factors, signs and symptoms, causative agents, and treatment will be discussed thoroughly in Chapter 99.

Hypersensitivity Reactions

Hypersensitivity reactions of cancer treatments is problematic because of cross-reactivity between agents and the desire to continue active therapies against the cancer. For documented immediate hypersensitivity reactions to a particular agent, further administration of the agent may be achieved through extensive premedication with H₂ and H₁ antihistamines and corticosteroids and through use of escalating doses of the offending agent given at doses of one-hundredth, one-tenth, and the balance of the dose (so the total dose administered is equivalent to the normally prescribed dose) administered over a much longer period of time. These treatments must be given in an environment where resuscitation is readily available in case of medical emergency.

Secondary Malignancies

Chemotherapy and radiation therapy treatments may cause cancers later in life; these are referred to as secondary cancers. The most common type of secondary cancer is myelodysplastic syndrome, or AML. The antineoplastic agents most commonly associated with secondary malignancies are alkylating agents, etoposide, teniposide, topoisomerase inhibitors, and anthracyclines. Although the risk for secondary cancers is extremely low, it must outweigh the risk of survival produced by treatment of the primary malignancy. Because secondary malignancies may not occur for several years after treatment, patients with relatively short-term survival owing to the primary malignancy should consider the more immediate benefits of chemotherapy. Radiation therapy rarely may cause solid tumors as secondary cancers decades after treatment. The most common example of radiation therapy–induced secondary malignancy is breast cancer, which rarely occurs after mantle field radiation therapy for Hodgkin disease.

CHEMOTHERAPY SAFETY

One of the first Institute of Medicine reports, the health arm of the National Academy of Sciences, starts out with a patient who died from an overdose of chemotherapy; the patient did not have an immediately life-threatening cancer, so her death was hastened by a medication error. Chemotherapy agents may cause harm to patients, health professionals, and the environment if not handled correctly.

Because of the risk of severe toxicities associated with many of the chemotherapy agents, safety precautions must be in place to prevent chemotherapy errors or accidental chemotherapy exposures of health professionals or patients. The Oncology Nursing Society and the American Society of Health-System Pharmacists have information to assist in the safe handling of chemotherapy agents. National, state, and local regulations regarding the safe disposal of chemotherapy agents and the equipment used to administer them need to be followed to protect the environment.

Each organization should have chemotherapy safety checks built into the prescribing, preparation and administration of chemotherapy. Dosing based on patient-specific information should be included on every order for chemotherapy, whether it is oral or parenteral. Many chemotherapy regimens are referred to by acronyms (eg, AC, which is doxorubicin cyclophosphamide); these should not be allowed as the only reference to drugs in the prescribing of chemotherapy. Also, abbreviations for the names of chemotherapy agents should be avoided because one abbreviation may stand for two different drug entities. For drugs such as doxorubicin and liposomal doxorubicin, the names should be written out fully, and in this case, the addition of the brand name may help to prevent a mistake.

The measured height and weight, along with the body surface area (BSA), if applicable, should be readily available, along with the dosage in milligrams per meter squared or kilogram, so that the dosage may be checked. If a chemotherapy regimen is a continuous infusion of 800 mg/m²/day for 4 days, an added safety feature would be to include the total dosage of 3200 mg in order to prevent any ambiguity. In cases where the clinician wants to decrease the dosage based on a laboratory value or side effect, it

*Monitor levels closely in all patients receiving high-dose therapy (eg, 150 mg/m² or greater).*

is recommended that the clinician include that information with the order so that everyone understands what the correct dosage is for that patient. Chemotherapy dosages should be checked for route and dose to determine that the dosages prescribed are correct according to the regimen and do not exceed dosing guidelines. Appropriate laboratory values should be checked to verify that dosages are correct for any organ dysfunction present, and drug interactions should be scrutinized closely (Tables 88–7 and 88–8). Health professionals administering chemotherapy should check the dosage calculation for the patient’s weight or BSA along with the five Rs of administering medication (ie, right patient, right medication, right dose, and right route, at the right time). If there is any question about the safe dosage or safe administration of a chemotherapy agent, the chemotherapy should not be administered until the question is resolved.

An area of controversy with chemotherapy dosing: What weight should be used for patients who are morbidly obese currently? Based on clinical practice guidelines published by the American Society of Clinical Oncology, it is recommended that clinicians routinely use an obese patient’s actual body weight, instead of an ideal body weight or other measurement.

**ORAL CHEMOTHERAPY**

*Over the past decade, self-administration of oral chemotherapy has increased because of the availability of oral, novel anticancer agents. Although oral chemotherapy has many advantages, such as convenience for the patient, potential increase in quality of life, and decreased treatment-associated costs, it also comes with an increased risk of medication errors, less monitoring of adverse effects and drug, dietary supplements, OTC medication and/or food interactions and accidental exposure to other individuals. Health professionals have an important role in ensuring safe handling of oral anticancer agents, and should be properly trained and perform competently within guidelines for the storage, handling, and disposal of oral agents. The health professionals are also expected to provide proper training and education on safe handling and proper administration (See Table 88–9) for the patient and caregivers.*

**CANCER SURVIVORSHIP**

*As early detection of cancers and effective therapies have improved over the last several years, the number of cancer survivors has increased. A cancer survivor by definition, according to the National Coalition for Cancer Survivorship, starts at the point of diagnosis. It is estimated that two out of every three people with cancer live at least 5 years after diagnosis. In 2005, the Institute of Medicine (IOM) released a report, “From Cancer Patient to Cancer Survivor: Lost in Transition,” which emphasized that a lack of definitive guidance in this area and identified that increased efforts were needed to raising awareness. In addition to facing a risk of a cancer recurrence, secondary malignancy, and an increased risk of developing other health.*

---

**Patient Encounter 3**

A 63-year-old woman with a stage IV NSCLC (adenocarcinoma) and a mutation in exon 19 of the EGFR gene presents to the clinic. She will be receiving a new prescription for afatanib 40 mg orally, once daily.

**What education and training should be provided to the patient to ensure their understanding of safe handling procedures as well as thorough knowledge of proper administration?**

**How should the patient be instructed to take this medication, in regards to meals or the time of day?**

**What adverse reactions would require that a holding treatment or a dose modification be made in therapy?**

---

Conditions, cancer survivors often face physical, emotional, financial, and social challenges as a result of the cancer diagnosis and treatment. Agencies such as the American Cancer Society (ACS), National Cancer Institute (NCI), Centers for Disease Control (CDC), and American Society of Clinical Oncology (ASCO) are implementing strategies to meet the needs of these individuals who experience the long-term effects of cancer and its treatment.

**OUTCOME EVALUATION**

Once a pathologic diagnosis of cancer is made, the patient may be evaluated by a radiation oncologist, a surgical oncologist, and a medical oncologist. Options for treatment are presented that may include surgery, radiation, chemotherapy, biotherapy, or some combination of these modalities. The goals of treatment vary by the cancer and the stage of disease. For example, the
patient who has metastatic kidney cancer could be presented with several options. They may have a possible cure with high-dose aldesleukin or receive palliative therapy with sorafenib or sunitinib, or the patient may decline any therapy because of fears of significant toxicity that would decrease quality of life. In this case, if the patient’s performance status is poor, such as an ECOG performance status 3, then the patient would not be a candidate for aldesleukin therapy because of significant toxicity or even death from treatment. The patient with the poor performance status will receive palliative therapy to control symptoms of the disease to improve the quality of life at the end of life. For the patient with a poor performance status and extensive metastatic disease, no treatment of the cancer may be appropriate, and the patient may be enrolled in a hospice program or provided comfort care.

### Patient Care Process

#### Patient Assessment:
- Based on workup, confirm cancer diagnosis and stage of disease before initiating anticancer treatment.
- Determine treatment goals (ie, cure) considering type of cancer, stage of disease, patient characteristics (eg, age, performance status, etc).
- Review the medical history. Does the patient have any special population precautions (eg, pregnancy, breastfeeding, dialysis, renal/hepatic dysfunction, pharmacogenomic information, etc) or specific concerns that would change your approach with standard of care treatments?
- Ensure that weight and height is accurate and recent. Calculate the BSA (if applicable). Determine if actual, ideal, or adjusted weights are to be used, based on treatment goals and discussion with health care team.
- Check patient laboratory values, physical assessment and any other work-up to ensure that the CBC and organ function studies are normal or within acceptable limits before administering chemotherapy. Does the patient need a measure of ejection fraction or a chest x-ray, for example? Does the patient need a central line (if receiving a vesicant)?
- Conduct a medication history (including prescriptions, OTC medications, herbs and dietary supplements) and nutrition history. Identify any possible drug–drug or drug–food interactions. Does the patient have any allergies or previous treatment with an anticancer agent? For example, has a patient received an anthracycline in the past?

#### Therapy Evaluation:
- Evaluate the chemotherapy regimen to ensure the correct dose and route of administration.
- If a patient has hematologic, renal or hepatic, or other toxicities, recommend adjustments in chemotherapy and/or doses if necessary.
- Ensure appropriate antiemetic therapy, hydration, and ancillary medications (antihistamines, steroids, folate, anti-infectives, etc) along with any rescue medications (leucovorin, mesna, etc) are ordered for patient.
- Assess the regimen to determine if primary prophylaxis with colony-stimulating factors is needed.

#### Care Plan Development:
- Counsel patient and caregivers on the treatment plan, short- and long-term adverse effects, precautions, supportive care plans.
- Use safe handling and disposal methods.
- For oral chemotherapy, provide specific recommendations to patients and caregivers to ensure their understanding of safe handling procedures as well as thorough knowledge of proper administration of the medication.

#### Follow-up Evaluation:
- Monitor CT scans or other imaging studies, and categorize patient with a CR, PR, SD, or progressive disease.
- Monitor CBC, renal function, liver function, and other laboratory or diagnostic tests as needed.
- Monitor patient for other known toxicities of the chemotherapy regimen and hold or modify the dose or discontinue the regimen if necessary.
- Ensure that cancer survivorship needs are being met.

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Explain the relative importance of various risk factors.
2. Summarize the features of the four intrinsic breast cancer subtypes.
3. Articulate some of the reasons for improved patient survival.
4. Recognize signs and symptoms related to early and late stages of the disease.
5. Distinguish between good and poor prognostic factors.
6. Describe the roles of hormone and HER2 receptors.
7. Determine treatment goals for early stage, locally advanced, and metastatic breast cancers.
8. State the rationale for inclusion of adjuvant and neoadjuvant therapies.
9. Discuss the benefits and risks associated with various endocrine therapies.
10. List relevant factors that guide management and treatment of early and metastatic breast cancers.

INTRODUCTION

Two breast cancer trends, the modest decline in new diagnoses and improvement of 5-year survival rates, have continued over the past decade. One factor that could be associated with both the former and latter findings is screening. The link to screening is plausible as detection of more patients with non-invasive (ie, in situ) disease could impact the number of new invasive breast cancer cases, while diagnosis of early-stage disease should translate to improved overall survival.

EPIDEMIOLOGY AND ETIOLOGY

Breast cancer is the most common type of cancer and second only to lung cancer as a cause of cancer death in American women. In 2015, female breast cancer will account for 99% of the projected 235,000 new cases; the median age at diagnosis will be 61 years; and approximately 40,000 deaths will occur as a result of the disease. Even though the disease occurs more frequently in white women than any other ethnic group, the mortality rate is highest among African Americans. The etiology of breast cancer remains largely unknown though a number of factors have been associated with risk of developing the disease. Evidence also strongly suggests that breast cancer biology involves very complex interactions between sex hormones, genetic factors, environment, and lifestyle. The intrinsic and extrinsic components associated with the disease are discussed further.

Intrinsic Components

Aside from gender, the variable most strongly associated with breast cancer is age as disease risk and incidence increase with age. One of the most frequently quoted breast cancer statistic is the probability that one in eight will develop the disease. However, a more instructive way of explaining the age-related factor is shown in Table 89–1. Although the probability of developing breast cancer increases with age, more than half the risk occurs after 60 years of age.

Both personal and family history can influence the risk of developing breast cancer. For example, a woman who has a history of breast cancer has a fivefold increase in risk of developing contralateral breast cancer. Prior histories of cancers involving the uterus and ovary also appear to be associated with an increased risk of developing breast cancer. Breast tissue with atypical changes appears to be a premalignant lesion. Even though family history is often linked to disease risk, the percentage of familial breast cancer, in reality, is quite low (ie, ~10%). Nonetheless, clarification of several key elements related to family history includes findings that:

- A first-degree relative (ie, mother or sister) with breast cancer is associated with a 3-fold increase in risk.
- A first-degree relative diagnosed with breast cancer younger than 45 years is associated with a more than threefold increase in risk.
Experimental and epidemiologic evidence suggest an association between breast cancer and a diet high in calories, fat, and cooked meats. Obesity in postmenopausal women and distribution of body fat around the abdominal region also appear to increase the risk of breast cancer. This risk factor may be related, in part, to peripheral conversion of androgens to estrogens in adipose tissue. More dramatic evidence of the negative impact of obesity was presented at the 2014 meeting of American Society of Clinical Oncology (ASCO). In a large-scale analysis investigators reported that among premenopausal women with early-stage, ER positive breast cancer, obesity raised the risk of dying by 34% compared with the other breast cancer patients. Evidence also indicates a modest ingestion-dependent relationship between alcohol and breast cancer. While exercise may have a modest protective effect against breast cancer, neither cigarette smoking nor breast augmentation appears to modify disease risk.

• Multiple first-degree relatives with breast cancer have not been consistently shown to be associated with risk greater than one first-degree relative.
• A second-degree relative with breast cancer is associated with 1.5-fold increase in risk.
• Family members on the paternal side contribute to risk similar to the maternal side.

A number of endocrine factors have been linked to an increased risk for breast cancer. Many of the risks relate to the total duration of estrogen exposure. Hence, early menarche (before age 12 years) and late menstruation (after age 55 years) are associated with an increased risk of the disease. Support for this association is the finding that bilateral oophorectomy before age 35 years decreases the relative risk of developing breast cancer. Nulliparity and late age at first birth (30 years or older) have been reported to double the lifetime risk of developing breast cancer.

Long-term use of hormone replacement therapy and concurrent use of progestins appear to contribute to breast cancer risk. Use of postmenopausal estrogen replacement therapy in women with a history of breast cancer is generally contraindicated. However, most experts believe that the safety and benefits of low-dose oral contraceptives currently outweigh the potential risks and that changes in the prescribing practice for the use of oral contraceptives are not warranted. Moreover, oral contraceptives are known to reduce the risk of ovarian cancer by about 40% and the risk of endometrial cancer by about 60%.

In the early 1990s, the BRCA1 gene (locus 17q21) was found to be mutated in a large percentage of hereditary breast and ovarian cancer patients. A second breast cancer gene, called BRCA2, has been mapped to chromosome 13. Since BRCA1 and BRCA2 are tumor suppressor genes, mutations or functional aberrations result in loss of key inhibitory activities of both proteins.

Compelling evidence of their critical importance is the observation that women who carry germine mutations of BRCA1 are at high risk for breast and ovarian cancers (85% and 60% over their lifetimes, respectively). Carriers of the BRCA2 mutation have similar risks for breast cancer but much lower risks for ovarian cancer. Jewish people of Eastern European descent (Ashkenazi Jews) have an unusually high (2.5%) carrier rate of germine mutations in BRCA1 and BRCA2 compared with the rest of the US population. Women with strong family histories of breast cancer are candidates for BRCA1 and BRCA2 mutation analysis. If performed, genetic testing should be done under the guidance of a professional genetic counselor.

Prevention of Breast Cancer

Even though breast cancer is not the most lethal malignancy, disease-related morbidity and mortality is still significant. Current efforts at breast cancer prevention are directed toward the identification and removal of risk factors. Unfortunately, a number of risk factors such as age, family or personal history of the disease or other gynecologic malignancies cannot be modified.

The idea that prevention can be achieved pharmacologically is based on clinical trials of tamoxifen, an antiestrogen used as adjuvant therapy for certain women with early breast cancer. These trials demonstrated a reduction of contralateral breast cancer events as well as a survival advantage in this subset of patients who received the drug for 2 to 5 years following mastectomy.

Several clinical trials conducted with this antiestrogen provided proof of principle that breast cancer risk reduction could be achieved through chemoprevention. A meta-analysis of these trials indicated a consistent (and significant) benefit in reducing the risk of developing estrogen receptor (ER) positive breast cancers in premenopausal and postmenopausal women.

Results of these trials also confirmed the carcinogenic and thrombogenic effects of tamoxifen. Unfortunately, the increased
incidence of endometrial cancers and thrombotic events had a negative impact on both patient acceptance and physician willingness to prescribe tamoxifen in this setting. However, studies with another antiestrogen known as raloxifene demonstrated that this agent not only reduced spinal fractures in postmenopausal women, but also decreased the incidence of breast cancer without adversely affecting the endometrium. The latter finding led to a head-to-head clinical study of tamoxifen and raloxifene (STAR), which involved postmenopausal women considered to be at increased risk for developing breast cancer. Although the reduction in the incidence of breast cancer was similar, raloxifene had a superior safety profile with regards to cancer and thromboembolic events. Thus, raloxifene is considered the chemopreventive agent of choice for high-risk postmenopausal women. Because premenopausal women were not included in the STAR trial, tamoxifen is the only agent approved for reducing the risk of breast cancer in young women.

Despite these important findings, the role of tamoxifen in BRCA mutation carriers is still not clear. Surgical prophylaxis for these individuals includes bilateral mastectomy or oophorectomy at completion of childbearing. Importantly, the risk of developing breast and ovarian cancer following prophylactic surgery is significantly, but not absolutely, reduced. For those foregoing elective surgical options semiannual mammograms are recommended.

The impressive data of the aromatase inhibitors (AIs) in the adjuvant setting provided the impetus for studying their potential as breast cancer chemopreventive agents. The steroidal AI, exemestane, has been reported to be more effective than placebo in reducing the risk of breast cancer in high risk postmenopausal women. Although exemestane has not been compared directly with either tamoxifen or raloxifene, the superior results of AIs compared to tamoxifen in the adjuvant setting suggest that the AIs could outperform the antiestrogens in reducing breast cancer risk with lower endometrial and thrombotic events.

**PATHOPHYSIOLOGY**

Histologic evaluation of breast lesions serves to establish a pathologic diagnosis and confirm the presence or absence of other factors believed to influence prognosis. These **prognostic factors** are discussed later.

**Invasive Breast Cancer**

Breast cancer typically arises in the ducts or lobules of the mammary gland. When tumor cells infiltrate surrounding breast tissue, a diagnosis of invasive breast cancer is made. Even though the vast majority of tumors are adenocarcinomas, this does not imply that breast cancer is one disease. **Substantial progress has been made to further refine the way four intrinsic subtypes of breast cancer are classified. When defined by clinical and pathological features, the classification system also provides a guide to treatment (Table 89–2).**

**Noninvasive Carcinoma**

The annual breast cancer incidence does not include thousands of cases of carcinomas in situ (ie, noninfiltrating tumors confined to the ducts and lobules). Ductal carcinoma in situ (DCIS) accounts for approximately 85% of all in situ breast cancers;
Patient Encounter, Part 2

The repeat mammogram shows a calcified area approximately 2.1 cm in diameter suspicious for cancer. A core biopsy of the lesion is performed and pathology confirms a diagnosis of infiltrating intraductal carcinoma. Tumor samples indicated the absence of ER and PR, but overexpressed HER2 (3+ by IHC). The axillary nodes were negative by clinical examination. Staging workup indicated no evidence of distant disease. Surgical options were discussed with the patient. She desired BCS with sentinel node biopsy. Pathologic examination of the sentinel node was positive for tumor.

**Explain why the breast cancer is considered early-stage disease.**

**Classify the intrinsic subtype of this breast cancer.**

**Describe the treatment goal and management strategy for this patient’s breast cancer.**

**Appraise the patient’s overall prognosis.**

while lobular carcinoma in situ (LCIS) may not be a true cancer, but rather a high-risk premalignant lesion. The overwhelming majority of cases can be cured by surgery alone. Although there is no proven role for the application of cytotoxic chemotherapy, patients with hormone receptor-positive tumors may benefit from the addition of tamoxifen.8

### CLINICAL PRESENTATION AND DIAGNOSIS

#### Early Detection

The rationale for early detection of breast cancer is based on the clear relationship between early stage disease at diagnosis and greater probability of long-term survival. Thus, patients with tumors less than 2 cm and negative lymph nodes have a higher likelihood of being cured. KEY CONCEPT Screening guidelines for early detection of breast cancer have been put forward by the American Cancer Society, the United States Preventive Services Task Force (USPSTF), and the NCI (Table 89–3). All include recommendations for women at average risk, with some general statements regarding screening for high-risk women as well. Nearly 80% of all breast cancers occur in women 50 years of age or older, and regular use of screening mammography can reduce mortality from breast cancer by 20% to 40% in this age group. Controversy regarding the use of screening mammography is largely confined to women younger than 50 years. After many years of debate, three organizations recommended mammograms in this age group of women every 1 to 2 years except for the USPSTF, which modified its recommendation in 2009.9

#### Diagnosis

- Unless following up on abnormalities found during screening, the initial workup for women presenting with signs or symptoms (see Clinical Presentation and Diagnosis) suggestive of breast cancer should include a careful history, physical examination of the breast, three-dimensional mammography, and possibly other imaging techniques such as magnetic resonance imaging. Most (80%–85%) breast cancers are visualized on a mammogram as a

mass, a cluster of calcifications, or a combination of both. A breast biopsy is indicated for a mammographic abnormality that suggests malignancy or for a palpable mass on physical examination.

### Clinical Staging

Stage is determined by primary tumor size (T), axillary lymph node involvement (N), and presence or absence of distant metastases (M). See Table 88–2 for an example of TNM staging. Aside from carcinoma in situ (stage 0) multiple combinations of T and N are possible within a given stage. Simplistically, stage I disease is represented by tumors less than 2 cm in diameter and usually no lymph node involvement. **Stage I and II disease is referred to as early breast cancer, which carries a relatively good prognosis and correlates with the highest probability of cure (Table 89–4).** Stage III, or locally advanced breast cancer, has poorer disease features, including larger tumor size, positive node involvement, and tumor invasion of the chest wall. Stage IV disease is characterized by the presence of metastases (M) to organs or tissue distant from the primary tumor and is often referred to as advanced or metastatic breast cancer.

### Prognostic Factors

Prognostic factors are biological or clinical indicators associated with survival independent of therapy. Poor prognostic factors for breast cancer include:

- Age younger than 35 years
- Large tumor size
- High nuclear grade (correlates with tumor growth)
- Lymph node involvement
- Triple-negative disease (i.e., absence of ER, PR, and HER2 receptors)
- Overexpression of HER2 alone

### EARLY BREAST CANCER

#### TREATMENT

**Desired Outcome**

**KEY CONCEPT** Most patients presenting with invasive breast cancer today have small tumors with negative lymph nodes (stage I), or a stage II cancer. The goal of therapy for early breast cancer is cure. While surgery alone may be able to cure approximately one-third to one-half of all patients with early stage breast cancer, certain tumor features warrant addition of systemic therapy.

**Local-Regional Therapy**

Surgical procedures have changed drastically over the past 50 years. **KEY CONCEPT** Less aggressive surgical options for early invasive breast cancer include total mastectomy and breast conserving surgery (BCS) such as lumpectomy. The reason for favoring the latter is based on findings that BCS achieves similar survival outcomes as more extensive surgical procedures and is cosmetically superior. Additionally, breast conservation aids in preserving the emotional and psychological well-being of the patient. Only two contraindications to BSC considered absolute (or nearly absolute) include persistence of tumor on surgical margins and inability to perform postsurgery radiation, if indicated. **KEY CONCEPT** Equally important is the issue related to complete axillary lymph node dissection (CALND). Because of the morbidity associated with the procedure, clinical trials were conducted to determine when biopsy of the sentinel lymph nodes was sufficient. Results of these studies indicated that CALND can be avoided in patients with microscopic disease in the sentinel nodes as well as in patients undergoing BCS with postsurgery radiation to the breast.

Except for the elderly and patients with substantial comorbid medical conditions, radiation therapy is an integral adjunct to BCS. However, radiation therapy should also be considered in certain postmastectomy situations, especially in patients with more than three positive nodes or patients with positive sentinel nodes without CALND. What used to entail 4 to 6 weeks of external-beam radiation, newer clinical evidence supports the efficacy of a shorter 3-week course of whole breast irradiation. Complications associated with radiation therapy are usually minor and include erythema of the breast tissue and shrinkage of total breast mass beyond that predicted on the basis of surgical resection alone.

### Systemic Adjuvant Therapy

Breast cancer cells can spread by contiguity, lymphatic channels, and blood to distant sites. Tumor cells often metastasize early in cancer growth. Because these deposits cannot be detected with current diagnostic techniques, they are referred to as micrometastases. Systemic adjuvant therapy is treatment that follows definitive local therapy when there is no evidence of disease beyond the axillary nodes but a high likelihood of disease recurrence. Hence, administration of systemic therapy (at a time when the tumor burden is low) should theoretically increase the likelihood of cure and minimize the emergence of drug-resistant tumor cell clones. **KEY CONCEPT** Most published results confirm that chemotherapy (in selected patients), hormonal therapy (in patients with hormone receptor–positive disease), anti-HER2...
therapy (in tumors with amplification or overexpression of HER2) or appropriate combinations of these therapies improved disease-free survival (DFS) and/or overall survival (OS) in patients with early-stage breast cancer (see Table 89–2).

Among the most influential groups that provide treatment recommendations is the St. Gallen International Expert Consensus panel. Convened every 2 years to review new evidence related to therapies for early breast cancer, the most recent conference was held in 2013.16 In the 2 years since their previous meeting, additional evidence has emerged to support the various types of systemic therapies (see Table 89–2).

**Adjuvant Chemotherapy**

Cytotoxic drugs that have been used most frequently as adjuvant therapy of breast cancer include cyclophosphamide, anthracyclines, taxanes, methotrexate, and fluorouracil. The most common chemotherapy regimens used in the adjuvant setting are listed in Table 89–5. Dose-limiting and other significant toxicities have been previously described in Chapter 88 and are discussed in Table 89–6.

Chemotherapy is usually initiated within 3 weeks of the surgical procedure. Traditionally, treatment consisted of four to six cycles; and completed in less than 6 months. Dose reduction for standard chemotherapy regimens should be avoided in the absence of severe acute toxicity because of the negative impact on DFS and OS.18 Even though most patients are able to maintain a reasonable level of functional, emotional, and social well-being during treatment, there are some compelling data indicating that some toxicities can have chronic debilitating effects on quality of life.19 Various forms of supportive therapy including antiemetics and hematopoietic growth factors for patients receiving systemic adjuvant chemotherapy are discussed in Chapter 99.

As mentioned previously, the usefulness of the intrinsic subtype classification also extends to treatment strategies (see Table 89–2). Since the magnitude of the 10-year survival benefit with cytotoxic agents appears to be only 5% and 10% for patients with negative and positive nodes, respectively, there has been intensive research to identify patients with low-risk disease that could avoid treatment with chemotherapy. One validated multigene assay known as Oncotype DX is used to identify patients with luminal A disease, regardless of nodal involvement, who can be treated with endocrine therapy alone.20

(Continued)
Adjuvant Anti-HER2 Therapy

HER-2 amplification or overexpression is found in approximately 15% to 20% of all breast cancers. Because of its aggressive features, trastuzumab (plus chemotherapy) is usually indicated in this subset of patients, especially for tumors greater than or equal to 0.5 cm in size. Most experts also agree that HER2-positive tumors appear to derive greater benefit from anthracycline or taxane-based chemotherapy regimens. When used with these agents, trastuzumab is given either following completion of the anthracycline or concurrently with the taxane. Current evidence indicates that the duration of trastuzumab therapy is 12 months.21

► Adjuvant Anti-HER2 Therapy

HER-2 amplification or overexpression is found in approximately 15% to 20% of all breast cancers. Because of its aggressive features, trastuzumab (plus chemotherapy) is usually indicated in this subset of patients, especially for tumors greater than or equal to 0.5 cm in size. Most experts also agree that HER2-positive tumors appear to derive greater benefit from anthracycline or taxane-based chemotherapy regimens.20 When used with these agents, trastuzumab is given either following completion of the anthracycline or concurrently with the taxane. Current evidence indicates that the duration of trastuzumab therapy is 12 months.21

► Adjuvant Endocrine Therapy

Hormone receptors are used clinically as indicators of prognosis, predictors of response to endocrine therapies, and more recently, discriminators of luminal breast cancer subtypes. Estrogen and progesterone receptors (PR) are cytoplasmic proteins that bind to nuclear DNA and function as transcription factors. Approximately 50% to 70% of patients with primary and metastatic breast cancer have hormone receptor-positive tumors. However, receptor-positivity refers to tumors expressing both ER and PR, as well as either ER or PR alone. Furthermore,

“ER positive” tumors traditionally refer to ERα only. Although it is beyond the scope of this discussion, it is noteworthy to mention the existence, and accumulating data regarding the roles of ERβ and the ERα/ERβ heterodimer in breast cancer. Tumors with high expression of both ER and PR (ie, luminal A subtype) are associated with favorable prognoses, superior responses to endocrine therapy, and longer disease-free intervals following initial treatment. Hormone receptor–positive tumors are more common in postmenopausal patients. Many experts also believe that the premenopausal breast cancer is biologically more aggressive than breast cancers diagnosed after menopause.

**KEY CONCEPT**

**Hormonal therapies that have been studied in the treatment of early breast cancer include selective estrogen receptor modulators (SERMs, tamoxifen), ovarian suppression (surgical and pharmacologic), and the aromatase inhibitors (AIs).**

Tamoxifen, has been used in the adjuvant setting for nearly four decades. Analysis of long-term data indicates the drug’s antagonist (anti-estrogen) effect was associated with a significant reduction in disease recurrence and mortality. This observation, coupled with evidence of the drug’s beneficial agonist activity on the lipid profile and bone density supported tamoxifen’s role as standard endocrine therapy. However, the agonist properties are also associated with detrimental effects on endometrial tissue and blood coagulation.

In premenopausal women, tamoxifen alone is considered the adjuvant hormonal therapy of choice. Some disagreement exists among experts regarding the utility of combining ovarian function suppression with tamoxifen in women younger than 40 years. Tamoxifen is initiated shortly after surgery or as soon as pathology results are known. However, when chemotherapy is also indicated, tamoxifen is given after all cytotoxic agents have been completed. The rationale for sequential therapy is supported by some data which show a small negative effect on disease-free survival (DFS) when tamoxifen and chemotherapy are given concurrently.

Treatment with adjuvant tamoxifen (20 mg/day) has historically been for 5 years. However, results of a recent clinical trial indicate a survival benefit associated with extending therapy to a total of 10 years. While these data are noteworthy, it should also be noted that the additional 5 years of treatment may not apply to all women. Other issues that make the longer duration of therapy less appealing relate to drug-related toxicities and medication compliance.

Other new evidence of note relates to women who were premenopausal when starting, and postmenopausal at completion, of tamoxifen therapy. In this subset of women, continuation of endocrine therapy with an aromatase inhibitor was associated with a significant improvement in breast cancer-related events, including new primaries in the contralateral breast, disease recurrence, and disease-free survival. So compelling were the results, the clinical trial had to be stopped after a median follow-up of only 2.4 years.

**Patient Encounter, Part 4**

Four months after beginning treatment for the lung metastasis, repeat imaging indicates a complete response (ie, no radiographic evidence of disease) to therapy. However, the patient now states that she has been having more frequent headaches and some problems with balance. An MRI of the head shows several small ring-enhancing lesions in the cerebellum. Biopsy of one of the lesions indicates brain metastasis.

**Explain your choice of therapy in this patient with brain-only metastasis.**
**Patient Encounter, Part 5**

Routine mammography in your patient, a 62-year-old grandmother indicates an area on the right breast that appears to be consistent with atypical changes but not highly suspicious for cancer. However, because of her family history (sister with breast cancer), a fine-needle aspirate of the breast tissue was obtained for histologic examination. Molecular markers show great promise as an adjunct to a tissue diagnosis of cancer. On the other hand, we must ensure that these tests are accurate indicators of malignant disease. Pathology used a new molecular test with modest sensitivity (ie, 80%) but very high specificity (ie, 99%) on the tissue sample to further analyze the radiographic abnormality. Although the test was negative, the tissue findings were consistent with atypical hyperplasia.

**Summarize what would be appropriate to tell this 62-year-old woman regarding the needle aspirate findings.**

**Formulate a follow-up plan for this patient.**

Finally, the issue regarding the role of pharmacogenomics in tailoring tamoxifen therapy is both persuasive and controversial.\textsuperscript{26,27} As such, routine screening for germline variants of CYP2D6 has not been endorsed. Nonetheless, drugs that do inhibit the enzyme should be avoided if possible.

In postmenopausal women, the use of adjuvant AIs has been studied in three different ways: (a) direct comparison with tamoxifen, (b) after 5 years of tamoxifen therapy, and (c) sequentially after 2 to 3 years of tamoxifen.\textsuperscript{28} Based on the positive results of several studies, expert panels strongly recommend AIs for postmenopausal women with hormone-dependent breast cancer.\textsuperscript{29} Although 5 years of adjuvant AI therapy is considered standard, there is also strong support for continuing hormonal therapy (beyond 5 years) if tamoxifen was used initially, especially in patients with high-risk features such as node-positive disease. Further support of extended endocrine therapy that includes an AI has been noted previously.\textsuperscript{26} While these recommendations can be applied to most postmenopausal patients, tamoxifen can still be used first line or as an alternative in those who do not tolerate AI therapy.

AI therapy is associated with several adverse effects, including hypercholesterolemia, atherosclerotic cardiovascular disease, and skeletal-related events. The three available AIs are anastrozole, letrozole, and exemestane (Table 89–7).

**LOCALLY ADVANCED BREAST CANCER (STAGE III)**

**TREATMENT**

**Desired Outcome**

Locally advanced breast cancer is defined by tumors greater than or equal to 5 cm and a high likelihood of nodal involvement in the absence of demonstrable distant metastasis. A wide variety of clinical scenarios can be seen within this group of patients, including tumors that have been neglected for a period of time and inflammatory breast cancer, which is a unique clinical entity. Inflammatory breast cancer has, at times, been misdiagnosed as cellulitis.

- Treatment of stage III breast cancer consists of all modalities used in the management of early breast cancer. The goal of therapy is to achieve optimal systemic control of the disease. However, despite treatment, systemic relapse and death are common even when local-regional control is accomplished. One major difference related to the systemic therapies is the use of chemotherapy plus ant-HER2 therapy (if indicated) or hormonal therapy before surgery. This approach, referred to as neoadjuvant therapy, can render initially inoperable tumors resectable, even with the possibility of BCS. It is also conceivable that earlier administration of systemic therapy could have therapeutic benefits beyond surgical

Pharmacologic Therapy
For patients with inoperable breast cancer, including inflammatory breast cancer, one of the treatment objectives is to obtain tumor resectability. The guidelines for selection and duration of systemic neoadjuvant chemotherapy are similar to the adjuvant setting. Available data support the use of anthracycline-containing regimens, incorporation of the taxanes, and approaches to improve dose-density or dose-intensity. Neoadjuvant endocrine therapy may be an option for patients who have unresectable, strongly hormone receptor–positive tumors, low risk factors, or are unable to receive chemotherapy because of comorbid medical conditions. When endocrine therapy is used, treatment is continued to maximal response. Even though not an approved indication, several clinical studies have demonstrated the efficacy of neoadjuvant trastuzumab in combination with chemotherapy in patients with HER2-overexpressing tumors. Interestingly, pertuzumab is the only HER2-targeted agent approved in the neoadjuvant setting when used in combination with trastuzumab and docetaxel. Regardless of therapeutic approach, about two-thirds of the tumors can be downstaged.

In terms of local therapy, the extent of surgery will be determined by tumor response to neoadjuvant therapy, patient wishes, and cosmetic results likely to be achieved. To minimize local recurrence, adjuvant radiation therapy should be administered to all patients with locally advanced breast cancer who undergo mastectomy or BCS. Inoperable tumors that are unresponsive to systemic chemotherapy may require radiation for local management; however, these tumors may be ineligible for subsequent surgical resection. This situation is associated with a very poor prognosis though not commonly seen.

Patient Encounter, Part 6
The patient missed her next two mammograms and returned to the clinic 30 months later than originally scheduled. Imaging studies performed at this time showed definite changes and an irregular lesion measuring 1.6 × 1.9 cm at its greatest diameters. Core biopsy of the mass lesion was interpreted by pathology as malignant adenocarcinoma of the breast. Further testing indicated an ER-positive/PR-negative, HER2-negative, well-differentiated tumor. Staging indicated several “hot spots” in the femur and pelvis consistent with metastatic disease. There is no tumor involvement of visceral organs, lungs, or brain.

Outline the most appropriate way to manage this patient’s breast cancer. Appraise the patient’s overall prognosis.

Pharmacologic Systemic Therapy

Endocrine Therapy
The operative mode of all endocrine therapies is estrogen deprivation. The pharmacologic goals of treatment include decreasing the levels of circulating estrogen and/or preventing the effects of estrogen on tumor tissue through hormone receptor blockade or downregulating receptor expression. Achievement of these goals is independent of menopausal status. Many available endocrine therapies can accomplish these goals. Combined endocrine therapies have also been studied in an attempt to improve patient outcomes with negative results. As such, patients usually receive sequential endocrine therapies before chemotherapy is considered.

Until the turn of the century, evidence did not support the superiority of one type of endocrine therapy with regards to
response or survival. Because of the similarity in efficacy, selection of endocrine therapy was based primarily on their toxicity profile (see Table 89–7), which favored tamoxifen. The only exception to this choice of therapy occurred in patients who received adjuvant tamoxifen and subsequently developed metastatic disease within 1 year of drug cessation.

Over the past 15 years, accumulating evidence related to the AIs has changed the way postmenopausal women with hormone-dependent metastatic breast cancers are treated. After menopause, estrogens continue to be produced by extragonadal conversion of androstenedione and testosterone to estrone and estradiol. This biosynthetic process, which is dependent on aromatase, occurs in peripheral tissue, including muscle, adipose, and even the breast itself. Therefore, AIs effectively reduce the level of circulating estrogens, as well as estrogens in the target gland. Their toxicity profile has been described in Chapter 88 and Table 89–7. Anastrozole and letrozole are nonsteroidal compounds that competitively inhibit aromatase. Exemestane is a steroidal compound that binds irreversibly (by forming a covalent bond) to aromatase. However, this biochemical distinction does not translate into clinical superiority with exemestane.

The AIs are used as first-line therapy for ER-positive advanced breast cancer in postmenopausal women.40 Large trials have compared these agents with tamoxifen and have found similar response rates and a longer median time to progression for patients receiving the selective AIs. A consistent observation in these trials was a lower incidence of thromboembolic events, endometrial cancer, and vaginal bleeding in patients treated with an AI. Collectively, these findings led to the recommendation that AI therapy be used as first-line therapy for advanced breast cancer in postmenopausal women. Of note also, several small studies indicate that regardless of which subclass of AI is used initially, approximately 50% of the patients will have further antitumor benefit after switching to the other subclass suggesting that cross-resistance is incomplete. Therefore, postmenopausal patients may receive two AIs as first- and second-line therapies.

The AIs are only used in postmenopausal women. Even though ovarian estrogen production relies on the same enzymatic pathway discussed earlier, premenopausal or perimenopausal women with functioning ovaries are not appropriate candidates for these therapies. The reason is physiologic as evidence indicates that negative endocrine feedback will overcome aromatase inhibition. Early clinical data also suggested that the strategy of combining an AI with ovarian suppression (ie, oophorectomy or LHRH agonists) may be a therapeutic option in premenopausal women. Currently, this option is considered inappropriate unless a strict contraindication to tamoxifen exists.

The use of AIs in men with advanced breast cancer should be avoided. Available data suggest the use of these agents in men increases circulating levels of testosterone, which may negate the therapeutic effects of the drug.

Antiestrogens bind to ERs, preventing receptor-mediated gene transcription, and therefore are used to block the effect of estrogen on the end target. This class of agents is subdivided into two pharmacologic categories, SERMs and SERDs (selective estrogen-receptor downregulators). SERMs like tamoxifen have tissue-specific estrogenic and antiestrogenic activities. The effort to minimize or eliminate the adverse estrogenic effects led to the development of SERDs, which are pure estrogen receptor antagonists. The distinguishing feature of SERDs is their ability to degrade the ligand–ER complex.

Tamoxifen can be used in both premenopausal and postmenopausal women with ER positive, metastatic breast cancer. Toxicities associated with tamoxifen have been previously described. The only additional acute adverse effect, which occurs in about 5% of the patients with bone metastasis is tumor flare or hypercalcemia following initiation of tamoxifen. Generally, this acute reaction is not an indication to discontinue treatment. Conversely, this finding appears to correlate with subsequent response to endocrine therapy.

Fulvestrant is the only SERD approved for clinical use in the United States. The drug is approved as second-line therapy of postmenopausal patients with hormone-dependent advanced breast cancer. Clinical studies conducted in postmenopausal patients with disease progressing on tamoxifen compared fulvestrant against anastrozole. Results of these trials indicated similar efficacy and acceptable tolerability. The side effect observed with fulvestrant only was dermal reactions at the injection site. Even though fulvestrant is a good option for patients who are unable to take an oral medication, some patients may be averse to the drug because it must be given intramuscularly. There is no biological reason why fulvestrant should not produce similar outcomes in premenopausal women; however, safety or efficacy data are lacking.

Estrogen production in premenopausal women can be effectively achieved by surgery, pharmacologic agents, or radiation. Results of two randomized clinical trials evaluating the overall response rate between oophorectomy and tamoxifen were not significantly different. Interestingly, secondary response rates to oophorectomy after tamoxifen treatment were somewhat higher than response rates to tamoxifen after oophorectomy (33% versus 11%). Interpretation of these findings suggests that tamoxifen does not completely antagonize available estrogen, particularly in premenopausal women. Ovarian ablation (surgically or chemically) is still commonly performed in parts of the United States and is considered by some to be the endocrine therapy of choice in premenopausal women with advanced disease. The mortality rate with surgical oophorectomy is less than 3% in appropriately selected patients.

Castration can also be achieved pharmacologically with LHRH agonists. An initial surge in luteinizing hormone (LH) and estrogen production during the first few weeks of treatment can cause a tumor flare reaction similar to tamoxifen. With continued therapy, this strategy induces remission in about one-third of unselected patients. LHRH agonists purportedly downregulates LHRH receptors in the pituitary resulting in decreased LH release and castrate levels of estrogens. Of the three agents available in the United States (ie, leuprolide, goserelin, and triptorelin), only goserelin is approved for the treatment of metastatic breast cancer.

In randomized trials, progestins such as megestrol acetate and medroxyprogesterone acetate have been shown to induce inferior response rates when compared with tamoxifen. Megestrol acetate is used more frequently in the United States. Despite their efficacy, these agents are generally used after patients have received an AI and/or tamoxifen. The most common side effects are listed in Table 89–7. One side effect, weight gain, occurs in 20% to 50% of patients. Patients experiencing weight gain may have fluid retention, but fluid retention is not responsible for all of the weight gain. In cachectic cancer patients, the weight gain may be desirable, but this is not uniformly true of all patients with metastatic breast cancer.

High-dose estrogens and androgens are rarely used because they are more toxic than other hormonal agents and in some cases less effective. About one-third of patients placed on high-dose estrogens will discontinue the use of these agents because
side effects, the most important of which are thromboembolic events, vomiting, and fluid retention.

**Cytotoxic Chemotherapy**

Except for brain and spine (with impending cord compression), chemotherapy is given as initial treatment of metastasis in patients with hormone receptor–negative tumors. The median time to an objective response is 2 to 3 months, but this period depends largely on the site of measurable disease. For example, time to response is 3 to 6 weeks for disease localized primarily to skin and lymph nodes; 6 to 9 weeks lung lesions; 15 weeks for liver metastasis; and 18 weeks for bone involvement. Once chemotherapy has been initiated, it is usually continued until maximal response, disease progression, or intolerable toxicity.

Unlike endocrine therapy, no clinical characteristic or established test has been shown to predict benefit from chemotherapy. However, a number of factors are associated with likelihood of tumor response, including good performance status, limited number (one or two) of disease sites, treatment naive status, and previous response to chemotherapy with a long disease-free interval. Tumors that progress while being treated may respond to different agents. Importantly, tumors that do not respond to endocrine therapy are as likely to respond to chemotherapy as tumors treated with cytotoxic agents first. If not used initially, chemotherapy is eventually required in most patients with advanced breast cancer.

Although many chemotherapeutic agents have demonstrated activity in the treatment of breast cancer, the most frequently used agents include all of the agents used in the adjuvant setting plus nab-paclitaxel, capecitabine, gemcitabine, ixabepilone, and vinorelbine. **Key Concept** The most active classes of chemotherapy in metastatic breast cancer are the anthracyclines and the taxanes with response rates as high as 50% to 60% in patients who have not received prior chemotherapy for metastatic disease. A brief discussion of some chemotherapy-related issues specific to breast cancer extends upon what is described in Chapter 88.

**Taxanes**

In the metastatic setting the most effective weekly dose of paclitaxel appears to be 80 mg/m²/week with no breaks in therapy. With this approach, the toxicity profile of paclitaxel changes with less myelosuppression and delayed onset of peripheral neuropathy but slightly more fluid retention and skin and nail changes.

A dose-response relationship has been demonstrated with docetaxel. However, at 100 mg/m² every 21 days, the positive impact was limited to ORR. Therefore, asymptomatic patients who may not require a rapid clinical response, dosages in the range of 60 mg/m² to 75 mg/m² are appropriate. While less

**Antimetabolites**

Capecitabine has activity against tumors progressing on anthracycline- and taxane-containing regimens. Moreover, the drug exhibits somewhat selective activity against cancer cells. This belief is supported by the presence of higher tumor cell levels of thymidine phosphorylase, the enzyme which catalyzes the final step in the conversion of capecitabine to 5-FU. In previously treated patients, capecitabine produced response rates of about 25%, which was impressive compared with other tested chemotherapy agents.

Gemcitabine is another agent that is used frequently in patients with advanced breast cancer. This nucleotide analogue has a unique mechanism of action and a favorable toxicity profile. As a single agent, response rates of nearly 40% have been achieved in the first-line setting. However, ORRs up to 90% have been obtained when gemcitabine was combined with doxorubicin or epirubicin and paclitaxel as first-line treatment. Response rates to gemcitabine monotherapy in the second- and third-line settings are approximately 18% to 26%. When combined with one other agent such as a taxane, vinorelbine, cisplatin, or an anthracycline, results of clinical studies consistently demonstrated higher efficacy than either single agent. In patients who have been exposed to an anthracycline and a taxane, gemcitabine appears to provide similar benefit to capecitabine.

**Epothilone**

In vitro studies show that the antimicrotubule activity of ixabepilone is similar to the taxanes. The results of a phase 3 clinical trial demonstrated that the combination of ixabepilone plus capecitabine significantly improved PFS by 38% while the ORR was more than twice as high with the combination compared with capecitabine alone (35% vs 14%, respectively). Even in patients with disease intrinsically resistant to previous taxane therapy, response rates were twice as high with the combination. The findings from this study support preclinical data that the antitumor activity between ixabepilone and capecitabine are at least additive and, possibly, synergistic. However, the improved outcomes must be balanced against a much higher incidence of adverse effects involving the bone marrow and peripheral nervous system. Five infection-related deaths occurred with combination therapy. In addition, two-thirds of the patients developed variable grades of sensory neuropathy; 21% of the all patients discontinued treatment because of this adverse effect. Ixabepilone is approved for use in combination with capecitabine for patients with advanced breast cancer resistant to or progressing on previous anthracycline and taxane therapy or for patients with hormone receptor–negative tumors.
in whom anthracyclines are contraindicated. The use of single-agent ixabepilone is approved for use in patients with disease resistant to capecitabine.

**Vinca alkaloid**

Although not approved for breast cancer, activity has been observed with vinorelbine therapy in patients with advanced disease. However, some of the more intriguing data are associated with the combination of vinorelbine and trastuzumab. In a small cohort of patients with HER2-positive, metastatic breast cancer, an ORR of 68% was achieved; 38% of patients were progression-free after 1 year. Importantly, none of the antimicrotubule agents appears to be cross-resistant with the anthracyclines.

**General Comments**

Combination chemotherapy regimens are usually associated with higher response rates than are single-agent therapies, but the higher response rates do not necessarily translate into significant differences in OS. The use of sequential single-agent therapy versus combination chemotherapy regimens has been debated widely for metastatic breast cancer. In fact, current consensus regarding first-line chemotherapy is the use of single agents or combination chemotherapy.\(^\text{21}\) In the palliative metastatic setting, the least toxic approach is preferred when efficacy is considered equal. In clinical practice, patients who require a rapid response to chemotherapy (eg, those with symptomatic bulky metastases) often receive combination therapy despite the added toxicity. This decision is complex and should be made on an individual patient basis.

Because many patients receive adjuvant chemotherapy, regimens chosen for first-line use in the metastatic setting often are different from those used in the adjuvant setting with the following caveat. If the patient’s cancer recurs more than 1 year after the end of adjuvant chemotherapy, the same agents may have activity in the metastatic disease setting.

▶ **Targeted Biologic Therapy**

All breast cancers are tested for HER2 by immunohistochemistry (IHC) and/or fluorescence in situ hybridization (FISH). Notably, an IHC score of 2+ (on a 0–3+ scale) for HER2 is associated with little to no benefit with trastuzumab therapy. Moreover, the 2+ IHC score is often negative by the more sensitive and specific FISH technique. As such, targeted anti-HER2 therapies are only indicated for breast cancers that overexpress the receptor.\(^\text{31}\) Because cardiac toxicity is associated with the antibody, trastuzumab is given after all cycles of the anthracyclines have been completed. A non–anthracycline-containing regimen with excellent activity is the combination of docetaxel and carboplatin with concurrent trastuzumab.\(^\text{34}\) Other chemotherapy agents that are being evaluated in combination with trastuzumab include vinorelbine, gemcitabine, capcitabine, and the platinum agents (eg, cisplatin and carboplatin).

Trastuzumab is reasonably well tolerated. The most common adverse effects are first dose infusion-related chills which occur in about 40% of patients. To alleviate the symptoms, acetaminophen and diphenhydramine may be given and/or the infusion rate may be reduced. Rare severe adverse effects including hypersensitivity and/or pulmonary reactions have also been reported. It is important to educate patients regarding the pulmonary reactions because they may occur up to 24 hours after the infusion and can be fatal if not treated promptly. Trastuzumab may increase the incidence of infection, diarrhea, and/or other adverse events when given with chemotherapy. When trastuzumab is given with an anthracycline, the rates of heart failure are unacceptably high; even as a single agent, cardiac events have approached 5%. Fortunately, this toxicity is usually reversible though patients may require pharmacologic management. Some patients have even continued therapy with trastuzumab after their left ventricular ejection fraction has returned to normal. Close monitoring for clinical signs and symptoms of heart failure is important in order to intervene with appropriate cardiac treatments.

Lapatinib is a dual inhibitor of HER2 and the epidermal growth factor receptor (EGFR, HER1). In contrast to the extracellular recognition site of trastuzumab, the specific targets of lapatinib are the receptors’ intracellular kinase domain. A pivotal phase 3 clinical trial was conducted to assess the efficacy and safety of lapatinib plus capecitabine versus capecitabine alone in patients with disease progressing on trastuzumab. The trial was terminated early when a preplanned interim analysis indicated a significant reduction in risk of disease progression that favored the combination arm. Of note, the incidence of brain metastasis was significantly lower in the lapatinib-treated group.\(^\text{35}\)

The side-effect profile of lapatinib is described in Chapter 88. A few side effects such as diarrhea, dyspepsia, and rash occurred more frequently when lapatinib was combined with capecitabine. Importantly, the lapatinib doublet was not associated with cardiac events resulting in subject withdrawal.

In May 2014, the American Society of Clinical Oncology (ASCO) issued two clinical practice guidelines related to lapatinib for the treatment of advanced, HER2-positive breast cancer. First, depending on hormone receptor status, third-line therapy may include hormonal therapy or chemotherapy with trastuzumab and in some cases with lapatinib or the combination of trastuzumab and lapatinib; and second, in patients with brain metastases systemic therapies with lapatinib and capecitabine is one option that can be considered for patients with a poor prognosis for survival.

A new HER2-targeted agent called pertuzumab received FDA approval in June 2012. Although both pertuzumab and trastuzumab are monoclonal antibodies that inhibit HER2-mediated signaling, a number of differences exist. First, each agent recognizes different extracellular epitopes, a finding that could have important therapeutic ramifications. Second, the unique binding site of pertuzumab induces structural changes that hinder receptor dimerization. Theoretically, by inhibiting HER2 signaling initiated by ligand-activated HER1 or HER3, pertuzumab could provide even greater inhibition of HER2 than trastuzumab. However, this does not appear to be case. In fact, compared to trastuzumab, pertuzumab has exhibited less activity. Based on results of a phase 3 clinical trial, pertuzumab is indicated for use as first-line therapy (in combination with trastuzumab and docetaxel) for HER2-positive metastatic breast cancer.\(^\text{36}\)

The most frequently reported adverse observed in clinical trials involving pertuzumab was diarrhea; cardiac toxicity was similar to, but does not appear to be increased when used concurrently with trastuzumab.

One of the most significant limitations of cytotoxic chemotherapy is the lack of tumor specificity. Coupling target selectivity with the observation that trastuzumab’s modest antitumor
effect was substantially improved by the addition of chemotherapy led to the idea that antibodies could be used to deliver chemotherapy rather specifically to tumor cells. However, the efficacy of antibody-chemotherapy (drug) conjugates (ADCs) has historically been limited by variable expression of the target antigen, defective tumor cell uptake mechanisms, and unreliable linkers used in the conjugation process.

A novel therapeutic compound known as trastuzumab-DM1 (T-DM1, trastuzumab emtansine) has been developed that appears to have resolved all of the above issues. Because HER2 is overexpressed in approximately 20% of breast cancers, trastuzumab was identified as a reasonable vehicle for drug delivery. In order to improve the therapeutic index of the attached chemotherapeutic agent, a maytansine derivative was synthesized. The resulting maytansinoid, emtansine, was configured to have an easily cleavable linker to trastuzumab. The resulting ADC has the potential not only of retaining the antitumor properties of the individual agents but also maintaining a tolerable side-effect profile.

The most significant results were reported in a phase 3 clinical trial which compared T-DM1 against the combination of lapatinib plus capecitabine as second-line therapy for patients with HER2-positive breast cancer progressing on trastuzumab and a taxane. Primary end points were PFS, OS, and tolerability. Compared to the capecitabine/lapatinib arm, T-DM1 significantly reduced the risk of disease progression or death by 35%. Median OS at the second interim analysis crossed the prespecified efficacy stopping boundary. The most common grade more than or equal to 3 toxicity observed in patients receiving T-DM1 arm was thrombocytopenia. Platelet nadirs occurred 7 days after drug administration and recovered within a week. Other frequently occurring side effects included liver function test abnormalities, hypokalemia, fatigue, nausea, and headache. However, none of these adverse events were greater than grade 2. Cardiac toxicity requiring treatment discontinuation was not observed. The results of this study led to FDA approval in February 2013.

Two noteworthy phase 3 clinical trials involving this novel ADC are in progress. The first compares T-DM1 with or without pertuzumab against trastuzumab plus a taxane as first-line treatment of HER2-positive, progressive or recurrent locally advanced or metastatic breast cancer; the second, T-DM1 versus trastuzumab as adjuvant therapy for patients with HER2 positive primary breast cancer who have residual tumor present pathologically in the breast or axillary lymph nodes following preoperative therapy.

Bisphosphonates

For women whose breast cancer has metastasized to bone, bisphosphonates are recommended, in addition to chemotherapy or endocrine therapy, to reduce bone pain and fractures. Pamidronate (90 mg) and zoledronate (4 mg) can be given IV once each month. These bisphosphonates are given in combination with calcium and vitamin D.

Local-Regional Control

Radiation Therapy

Radiation is an important modality in the treatment of symptomatic metastatic disease. The most common indication for treatment with radiation therapy is painful bone metastases or other localized sites of disease refractory to systemic therapy. Approximately 90% of patients who are treated for painful bone metastases experience significant pain relief with radiation therapy. Additionally, radiation is an important modality in the palliative treatment of metastatic brain lesions and spinal cord lesions, which respond poorly to systemic therapy, as well as eye or orbit lesions and other sites where significant accumulation of tumor cells occurs. Open or painful skin wounds and/or lymph node metastases confined to the chest wall area may also be treated with radiation therapy for palliation.
OUTCOME EVALUATION

Early breast cancer is resected completely with curative intent and adjuvant chemotherapy and/or hormonal therapy with trastuzumab in selected patients are initiated to prevent recurrence. During adjuvant chemotherapy, laboratory values to monitor chemotherapy toxicity are obtained before each cycle of treatment. After completion of adjuvant therapy, patients are monitored every 3 months for the first few years after diagnosis, with intervals between examinations extended as time from diagnosis lengthens. Evaluation includes:

- Physical examination to detect breast cancer recurrence
- Annual mammography
- Symptom-directed workup

Patients with locally advanced breast cancer are often treated with neoadjuvant therapy to make the tumor surgically resectable. However, many believe that neoadjuvant therapy may have benefits that extend beyond downstaging. During neoadjuvant chemotherapy, laboratory values to monitor chemotherapy toxicity are obtained before each cycle and weekly thereafter while on treatment; physical and ultrasound examinations to determine the size of the tumor are performed following a complete course of neoadjuvant therapy. Generally, no further chemotherapy is given after surgery. After complete surgical resection, monitoring proceeds as described for early breast cancer.

Metastatic breast cancer is not curable, and therapy is intended to palliate symptoms and prolong survival. In most cases, hormonal therapy is the mainstay for tumors that are ER positive. While on therapy, patients are monitored monthly for signs of disease progression or metastasis to common sites, such as the bones, brain, or liver. Evaluations include:

- Pain
- Mental status or other neurologic findings
- Laboratory tests
- Liver function tests
- Complete blood count
- Calcium, electrolytes

Lung Cancer
Val Adams and Justin Balko

LEARNING OBJECTIVES
Upon completion of the chapter, the reader will be able to:
1. Identify major risk factors for the development of lung cancer.
2. Explain the pathologic progression of lung cancer and its relationship with signs and symptoms of the disease.
3. Make appropriate recommendations for screening or preventive measures in high-risk patients.
4. Understand staging of lung cancer patients and how it influences treatment decisions.
5. List the rationale, advantages, disadvantages, and place in therapy for adjuvant and neoadjuvant chemotherapy.
6. Identify the chemotherapeutic or molecularly targeted regimens of choice for limited and extensive small cell lung carcinoma, as well as local, locally advanced, and advanced non–small cell lung carcinoma.
7. Monitor patients for treatment-associated toxicity and recommend appropriate management.

INTRODUCTION
Lung cancer has a major health impact both in the United States and worldwide. Before 1930, lung cancer was a relatively rare disease, but a sharp incline in industrialization and smoking in the early 1900s has bred an epidemic. Lung cancer has a high mortality rate, and although treatment can cure some patients, most therapies only prolong survival for months. Recent advances in lung cancer research provide good reason for optimism but antismoking campaigns still appear to offer the best opportunity to reduce lung cancer incidence and mortality.

EPIDEMIOLOGY AND ETIOLOGY
Incidence and Mortality
Cancers of the lung and bronchus rank first in cancer-related mortality, comprising more than 28% of cancer-related deaths. In 2015, more than 1,500 new cases of lung cancer are expected. A close correlation exists between incidence and mortality of lung cancer, reflecting the reality that approximately 70% of lung cancer patients ultimately die of the disease.

Clinical Risk Factors

Other Air-Related Risks
In addition to direct inhalation of cigarette smoke, other environmental factors have been identified as risks for the development of primary lung tumors. Environmental tobacco smoke (ETS) presents a significant occupational hazard for nonsmokers working in environments that have a high smoking population, such as bars or restaurants. Each year approximately 3000 cases of lung cancer in nonsmokers are caused by ETS. In response, the majority of states have enacted clean indoor air acts. Other
environmental factors linked to lung cancer include radon, arsenic, nickel, and chloromethyl ethers. Those who live in an urban environment are also at an increased risk for lung cancer owing to exposure to high concentrations of combustion fumes. Asbestos exposure increases the risk of developing a distinct but rare type of lung cancer called mesothelioma.

**Nutrition**

Diet and nutrition are suspected to play a role in cancer susceptibility, and many studies have sought to define specific foods or nutrients that influence cancer risk. Because not all heavy smokers develop lung cancer, nutritional factors may explain part of this variation. Epidemiologic studies focusing on diet and nutrition in lung cancer have shown reduced rates of lung cancer in smoking individuals who report higher fruit and vegetable consumption. However, studies attempting to identify specific chemical components of fruits and vegetables that are responsible for this effect have not been successful.

Recommendations to patients who are at risk owing to smoking or other factors or those who are simply interested in reducing their risk of cancer should include an increase in dietary intake of fruits and vegetables.

**Hereditary or Genetic Risk Factors**

Although smoking is a key risk factor for lung cancer, the majority of people who smoke never develop lung cancer. Genetic risk factors may predispose certain smokers to lung cancer. After adjustments for age, smoke exposure, occupation, and gender, relatives of a lung cancer patient have approximately a twofold risk of developing lung cancer. The degree of inherited risk inversely correlates with the age of the relative at the time of diagnosis. First-degree relatives of a lung cancer patient diagnosed between the ages of 40 and 59 years have a sixfold relative risk for lung cancer. Familial lung cancer that develops at an early age in nonsmokers fits a Mendelian codominant inheritance model. However, a lung cancer gene has not been identified.

**Chemoprevention**

Chemoprevention refers to the use of prophylactic medications to prevent the development of cancer. Many studies have been conducted testing potential chemopreventatives, including nonsteroidal anti-inflammatory drugs, retinoids, inhaled glucocorticoids, vitamin E, selenium, and green tea extracts, but none have been successful. A large randomized trial testing the effects of selenium, previously considered a promising chemopreventative agent for lung cancer, was stopped early due to lack of any observable effect at its first interim analysis.

Interestingly, data from a placebo-controlled double blind study demonstrated that selective cyclooxygenase-2 (COX-2) inhibition with celecoxib reduces the proliferation of bronchial epithelial cells, lowers inflammatory markers, and may resolve benign or premalignant lung nodules in former smokers. Existing data suggest that bronchial epithelial cell proliferation may be a surrogate endpoint for chemopreventative lung cancer trials. However, at this time, routine use of celecoxib as a chemopreventative agent is not warranted.

**Screening and Early Detection**

Overall 5-year survival in lung cancer is only 15%, but those who are diagnosed at a localized stage exhibit a 5-year survival rate of 50%. Currently, more than three quarters of newly diagnosed lung cancers present with locally advanced or metastatic disease, and therefore, very few patients are able to undergo surgical resection. In an attempt to identify tumors when they are localized and have higher cure rates, many studies have evaluated different screening modalities, which have led to screening recommendations.

The landmark trial, the National Lung Screening Trial (NLST) randomized more than 53,000 patients at high risk for lung cancer to three annual low-dose spiral computed tomography (CT) scans or chest x-ray. Chest x-ray has been shown in large trials to be equivalent to no screening and can be considered a placebo control for mortality. In the CT arm 6.9% of patients were diagnosed with lung cancer and 63% were diagnosed with stage Ia or Ib disease with over 90% having surgery with curative intent. Screening by CT reduced lung cancer mortality by 20% and was subsequently approved and recommended for high-risk patients. High-risk patients are defined by the following criteria:

1. Age greater than or equal to 55 years
2. Smoking within the last 15 years
3. A 20 pack-year history plus an additional risk factor or greater than a 30 pack-year history

The challenge with utilizing low-dose CT scans in screening is the high sensitivity, which translates into frequent detection of nonmalignant lesions. In the NLST, the CT screening arm had positive findings in 24.2% of patients with 96.4% of the lesions being benign (false positives). Due to this high false positive rate, screening should be perceived as a two-step process in order to prevent excessive patient workup and anxiety. The plan for a patient (biopsy, PET scan evaluation, or repeat CT scan at 3, 6, or 12 months) with a positive finding on spiral CT is determined by an algorithm that evaluates the number, size, and characteristics of lesions.

The United States Preventative Services Task Force guidelines provide lung cancer screening a grade B recommendation, which means the magnitude of benefit is moderate. The proposed action for grade B recommendations is to offer or provide this service for qualifying patients.

**PATHOPHYSIOLOGY**

Most lung cancers arise from the epithelium of the airways and are classified as carcinomas. There are four major and several rare histologic types of lung cancer. They appear to form through different mutagenic pathways; however, they all appear to transition through a premalignant state. The presence of a transitional state from normal tissue to cancerous tissue is important because the premalignant cells contain damage that is generally thought to be reversible. Researchers are currently trying to develop methods to identify people with premalignant lesions as well as drugs that can reverse the damage.

Continued damage to premalignant cells can lead to cancer. The first appearance of cancer cells that have not yet become invasive is referred to as carcinoma in situ. Patients are rarely diagnosed with this early stage of cancer owing to a lack of symptoms and relatively rapid progression from this state to larger invasive tumors. As the tumor grows, cells may become dislodged from the tumor bulk and enter the hematologic or lymphatic circulatory systems, where they can travel to either local or distant parts of the body. Hematologic spread usually results in metastatic sites in the bones, liver, and central nervous system (CNS). Lymphatic spread is more orderly in nature, with the hilar and mediastinal lymph nodes in the pleural cavity commonly being involved. Once the tumor has spread to multiple
locations, curative treatment is rare because surgical excision and radiotherapy cannot remove all or nearly all of the cancer cells.

**Histologic Classification**

Histologic classification of lung cancer involves determining the cellular origin of the tumor. Knowing the histology of the tumor influences treatment decisions as well as prognosis.

There are four major histologic types of lung cancer that are divided into three classes based on response to treatment and prognosis: small cell lung cancer (SCLC), squamous cell non–small cell lung cancer (NSCLC) and non–squamous NSCLC. The four major types of lung cancer are outlined by class in Table 90–1. However, it is important to note that certain other rare malignancies can be seen and many lung cancers may consist of multiple histologic subtypes. Furthermore, a recent phenomenon has been observed where pharmacologic treatments may selectively kill different components of the tumor, resulting in a conversion of the remaining tumor to a different subtype (ie, NSCLC becomes SCLC after treatment). Therefore, repeat biopsies of lung tumors before each line of treatment may become a standard of care, although it is not routinely performed at this time.

**Clinical Staging**

Once the diagnosis of lung cancer is confirmed through visualization and biopsy, the extent of disease must be determined. NSCLC (squamous and non–squamous subsets) are staged using the American Joint Committee on Cancer (AJCC) tumor, node, and metastasis (TNM) staging system. SCLC is typically staged using the Veterans Administration Lung Cancer Study Group method. Clinical staging serves two primary purposes: predicting prognosis and guiding therapy.

> **Non–Small Cell Lung Cancer**

Clinical staging of NSCLC with the TNM system evaluates the size of the tumor (T), extent of nodal involvement (N), and presence of metastatic sites (M). The combination of these three evaluations determines the stage. Clinical stages and associated survival rates are outlined in Table 90–2. Local disease includes tumors that are confined to a single hemithorax and those cancers which have spread to the ipsilateral hilar lymph nodes. Once malignancy invades the mediastinal lymph nodes or contralateral hilar nodes, the disease becomes locally advanced. When signs of cancer are detected outside the pleural cavity, it is classified as advanced disease. Local disease is associated with the highest cure and survival rates, whereas those with advanced disease have a 5-year survival rate of less than 5%.

Mutation (genetic) testing plays a key role in the treatment plan for NSCLC. Tumors bearing mutations or rearrangements of the EGFR or ALK genes have specific treatment options that offer improved response rates over traditional therapies. In non–squamous NSCLC histology, mutational testing should always be performed to further guide therapy.

> **Small Cell Lung Cancer**

The most common system for staging SCLC was developed originally by the Veterans Administration Lung Cancer Study Group. This system categorizes SCLC into two classifications, limited and extensive disease:• Limited disease: evidence of the tumor is confined to a single hemithorax and can be encompassed by a single radiation port• Extensive disease: any progression beyond limited disease

### Patient Encounter, Part 1

A 61-year-old woman presents at your clinic complaining of new-onset cough. She has had several upper respiratory infections in the last 2 months, with occasional hemoptysis. She smoked about a pack of cigarettes per day beginning in her early 30s, but quit about 10 years later, and has not smoked since. She lives downtown in the city and has worked at her own restaurant/bar since she bought the establishment 10 years ago.

**What risk factors for lung cancer are present?**

**Calculate this patient’s pack-year history.**
Clinical Presentation and Diagnosis

**Pulmonary Symptoms**
Symptoms related to the direct effects of the primary tumor often appear first and are the most common. These include the following:

- Cough
- Chest pain
- Shortness of breath

**Extrapulmonary Symptoms**
Once the tumor invades tissues outside the pleural cavity, it can produce a wide array of symptoms, including:

- General bone pain
- Adrenal insufficiency
- Confusion
- Personality changes
- Enlarged lymph nodes
- Weight loss
- Seizures
- Nausea and vomiting
- Focal neurologic symptoms
- Horner syndrome
- Fatigue
- Headache
- Pancoast syndrome
- Subcutaneous skin nodules

**Paraneoplastic Syndromes**
Symptoms that are not a result of the direct effects of the tumor are termed paraneoplastic syndromes. They may be caused by substances secreted by the tumor or in response to the tumor and often occur in tissues far from the site of malignancy. Paraneoplastic syndromes are numerous and affect a wide variety of systems, including the endocrine, neurologic, skeletal, renal, metabolic, vascular, and hematologic systems.

**Diagnosis**
Diagnosis requires visualization of one or more lesions as well as biopsy of the lesion to confirm malignancy. Both visualization and sampling can be performed by invasive or noninvasive methods. These methods are summarized in Table 90–3.

### Table 90–3
**Diagnostic Tools**

<table>
<thead>
<tr>
<th>Technique</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Visualization</strong></td>
<td></td>
</tr>
<tr>
<td>Chest x-ray</td>
<td>The least expensive visualization method in the diagnosis of lung cancer. Readily accessible and does not require systemic administration of contrast dye. However, it often detects lesions that are not cancerous and is not capable of assessing lymph node status.</td>
</tr>
<tr>
<td>CT</td>
<td>More accurate when providing information on size, location, and invasion than chest radiography. It is recommended as part of the standard workup in most cases.</td>
</tr>
<tr>
<td>PET scanning</td>
<td>Uses a substance called 5-FDG to produce a functional image of the lungs. Cells that are actively growing and dividing use greater amounts of glucose and therefore take up more 5-FDG. Focal regions of fluorescence can be visualized in cancerous lesions. PET scanning combined with a CT scan is more accurate than CT scan alone; however, the exact role of PET scanning in staging and monitoring is unclear. The apparent benefit and common role in staging is to evaluate mediastinal disease when it can influence the tumor resectability.</td>
</tr>
<tr>
<td><strong>Tumor sampling</strong></td>
<td></td>
</tr>
<tr>
<td>Fine-needle aspiration</td>
<td>A method of aspirating cells from the tumor via insertion of a small-bore needle into the lesion and aspirating. Commonly used to evaluate lymph nodes or other poorly accessible sites, it has the advantage of being faster and less invasive than other biopsy methods; however, it does not preserve the architecture of the tumor and may return cells that are undergoing cell death, which negates histologic analysis.</td>
</tr>
<tr>
<td>Bronchoscopy</td>
<td>A fiberoptic camera is inserted through the airways to examine the site of the suspected lesion. Once the lesion is visualized, a tool attached to the camera allows for a tissue biopsy. Newer technologies incorporate fluorescence to differentiate malignant tissue from premalignant lesions.</td>
</tr>
<tr>
<td>Core needle biopsy</td>
<td>A method of obtaining tissue and preserving the tumor architecture. A large-bore needle is inserted into a lesion, where it cuts a core of tissue out that then can be evaluated.</td>
</tr>
<tr>
<td>Thoracentesis</td>
<td>Involves removal of fluid in the pleural cavity via a needle. The fluid then is assayed for presence of cancerous cells. This procedure has low sensitivity and depends on the presence of a pleural effusion.</td>
</tr>
<tr>
<td>Sputum cytology</td>
<td>Detects cancerous cells that become dislodged from the airways into the sputum. Sputum cytology is useful because it is not invasive, but it has much lower sensitivity for detecting cancer.</td>
</tr>

CLINICAL PRESENTATION AND DIAGNOSIS
**KEY CONCEPT**
Signs and symptoms of lung cancer can be classified into three subdivisions: pulmonary, extrapulmonary, and paraneoplastic syndromes. Distinguishing among these classes of symptoms is important because it can aid in determining the severity of the disease, guide treatment options, and affect prognosis.

TREATMENT
**Desired Outcome and General Approach to Patient**
The treatment of lung cancer depends on tumor histology, genetic alterations; stage of disease; and patient characteristics such as age, gender, history, and performance status (PS). All these aspects must be assessed before appropriate treatment can
be recommended. In the development of a patient care plan, keep in mind the ultimate goals of therapy. Treatment modality based on histology and stage is outlined in Figure 90–1. In general patients with early stage disease, a definitive cure is the primary goal of treatment, although this end point is not always met. Additional goals of treating lung cancer patients include prolongation of survival and improvement of quality of life through alleviation of symptoms. The goals of treatment must be considered when selecting a therapeutic plan. Some treatments may prolong survival by a few months but at the expense of

significant decreases in patient quality of life. Treatment decisions must include both the health care team and an informed and well-counseled patient.

**Performance Status**

The performance status (PS) of an individual patient predicts response and likelihood of toxicity to chemotherapy as well as overall survival. The PS evaluation system used most frequently was developed by the Eastern Cooperative Oncology Group (ECOG) (see Chapter 88). **Key Concept** Categorizing patients by their ECOG PS allows for an objective measure of capability to tolerate systemic therapies that may severely compromise the patient’s health. Patients with a good PS (0–1) are more likely to tolerate intense therapy. PS 2 may receive chemotherapy, and PS 3 to 4 may receive supportive therapy or treatment with targeted therapies if they have targetable activating mutations. Patients with localized disease may be treated more aggressively in this scenario because the intent of treatment is curative.

**Treatment Modality**

**Surgery (NSCLC)**

**Key Concept** Of all treatment modalities, surgical resection of the affected lobe or lung leads to the greatest improvement in survival for patients with early stage and locally advanced NSCLC tumors (clinical stage IA, IB, or IIA). In patients with advanced disease NSCLC, surgery is not curative and as a general approach does not prolong survival. However, surgery for advanced disease is an important palliative treatment that can improve quality of life in some patients. In this respect, surgery is limited to local sites where the tumor is causing significant morbidity (eg, spinal cord compression).

**Surgery (SCLC)**

Patients with SCLC are rarely treated with surgery because the results of a randomized trial published in 1969 showed that surgery did not result in any 5- or 10-year survivors, but radiation produced a 4% survival rate at 5 and 10 years. With improved imaging and surgical techniques as well as the use of effective adjuvant therapy, some clinicians believe that surgery does have a role in early stage SCLC. However, this has yet to be proven in a clinical trial.

**Radiotherapy (NSCLC)**

Patients with localized NSCLC are best treated with surgery; however, many of these patients are inoperable because of comorbidities (eg, lung disease from smoking). In these situations, radiation therapy can be used with curative intent in place of surgery, and the success rate is approximately 50% that of surgery. Patients with locally advanced (stage IIIIB, nonsurgically resectable) disease have prolonged survival with combined chemotherapy and radiotherapy. Patients with late stage NSCLC can receive radiation therapy to palliate symptomatic metastases. Although radiation is less invasive than surgery, it can have marked toxicity on normal tissue, and patients may experience esophagitis, pneumonitis, cardiac abnormalities, myelopathies, and skin irritation. These adverse events can be decreased by using stereotactic radiation and/or hyperfractionated administration. Postoperative radiotherapy (PORT) is thought to eliminate remnants of the resected tumor that might be deposited in nearby tissue, but is only recommended for patients with positive margins after surgical resection, when a local recurrence is of concern.

**Radiotherapy (SCLC)**

Radiotherapy (concurrent with chemotherapy) is the treatment of choice for limited-stage SCLC. Limited- and extensive-stage SCLC patients who respond to therapy should also receive prophylactic cranial irradiation (PCI), which treats micrometastatic disease in the CNS. This improves cure rates for limited-stage disease and prolongs survival for extensive stage disease.

**Pharmacologic Therapy**

Traditional chemotherapy has been the mainstay for most lung cancer patients and will be administered to the large majority of patients, despite recent advances with targeted therapy for patients with EGFR and ALK mutations. Cisplatin and carboplatin are arguably the most effective traditional chemotherapy agents regardless of histology. **Key Concept** Doublet chemotherapy regimens offer superior response rates compared with single-agent chemotherapy regimens and should be used when the patient can tolerate the increased toxicity. The effective chemotherapy agents that are added to the platinum include etoposide, paclitaxel, docetaxel, gemcitabine, vinorelbine, and pemetrexed (see Table 90–4 for regimen details).

Monoclonal antibodies targeting vascular endothelial growth factor (VEGF) signaling (bevacizumab and ramucirumab), and epidermal growth factor receptor (EGFR; cetuximab and necitumumab) have been combined with traditional chemotherapy to improve outcomes. Tyrosine kinase inhibitors (TKI) targeting EGFR such as afatinib and erlotinib can be appropriate as monotherapy (usually in those patients with an EGFR-activating mutation in exons 19 or 21). Similarly, tyrosine kinase inhibitors targeting an anaplastic leukemia kinase (ALK) gene rearrangement (gene fusions and translocations) can be treated with crizotinib or ceritinib as monotherapy. Selecting the best regimen for a specific patient is aided by patient characteristics (PS, comorbid conditions, etc), extent of tumor spread, histology, and genetics as discussed in more detail below. Preventing and managing therapy induced toxicity (see Chapter 88) is crucial to optimizing patient outcomes (eg, curing, prolonging life, or palliating symptoms). Furthermore, decisions to start chemotherapy must include the full consent and understanding of risks by the patient. Counseling on the therapeutic regimen and risk of toxicity is imperative before dosing. Lung cancer regimens and their associated toxicities are shown in Table 90–4. Refer to Chapter 88 for dosing recommendations in renal and hepatic failure.

**Treatment of Small Cell Lung Cancer**

SCLC typically presents as extensive disease (approximately 60%–70% of new cases) and progresses very quickly. SCLCs are very responsive to chemotherapy and radiation but have a short duration of response. Radiotherapy became the standard in 1969, when a randomized trial showed that it offered the potential for...

AUC, area under the curve; CAV, cyclophosphamide–doxorubicin–vincristine; EC, etoposide–carboplatin; EP, etoposide–cisplatin; IC, irinotecan–cisplatin; IM, intramuscular; IV, intravenous.

See Chapter 88 for dose reductions for hepatic and renal dysfunction.

The regimen of choice for limited-disease SCLC is etoposide–cisplatin (EP). In patients who are able to tolerate combined modality therapy, concomitant chemoradiotherapy offers the greatest survival benefit. Carboplatin may be substituted for cisplatin in patients who cannot tolerate cisplatin toxicity. Cisplatin is preferred over carboplatin because of a small study that randomized patients to cisplatin or carboplatin plus etoposide. There was a numerically higher complete response rate with cisplatin, which is believed to be requisite for cure. Consequently, the guidelines recommend that the EP regimen be used with concurrent radiotherapy.13

Because patients with SCLC commonly have a recurrence in the CNS, trials have been performed to evaluate the benefit of PCI. A pivotal study showed that PCI reduces the incidence of brain metastasis and increases the 3-year survival rate from 15% to 21%.14 Patients with limited stage SCLC who achieve a complete response with treatment should be offered PCI.

The first step in treatment of NSCLC involves confirmation of the clinical stage and determination of likelihood of resection of the tumor. When the histology results are not of squamous cell histology (adenocarcinoma and large cell), tissue should be sent for genetic analysis of EGFR mutations and ALK rearrangement. Treatment options depend on the stage of disease (ie, eligibility for resection), PS, histology, and genetic findings.

Concurrent radiotherapy is not used routinely in extensive disease; however, PCI provides significant benefit in patients responding to chemotherapy. A pivotal study demonstrated that median survival from the time of randomization increased from 5.4 to 6.7 months and 1-year survival rates increased from 13.3% to 27.1% with PCI. An additional benefit was a lower rate of brain metastases (14.6% vs 40.4%).16

The treatment of recurrent SCLC depends on the time to recurrence. If the time to recurrence is less than 6 months, second-line therapy should be considered if the patient has an acceptable PS (see Patient Care Process). The most widely accepted second-line therapies in SCLC are topotecan alone or CAV (cyclophosphamide, doxorubicin [Adriamycin], and vincristine). Relapses occurring more than 6 months after treatment warrant a repeat of the initial regimen. Patients with a poor PS (3–4) are typically managed with best supportive care, including palliative care therapies.

The treatment of non–small cell lung cancer.
Non–squamous cell histology—send for genetic analysis to identify EGFR+ or ALK+ tumors for Squamous histology (25% of lung cancers) consider sending for genetic analysis if never smoker or mixed histology. Consider additional therapy for responding patients or best supportive care.  

**EGFR+** (15% of adenocarcinomas) 

- Erlotinib or Afatinib 
  - Treat to progression 

**ALK+** (3%–7% of non–small cell lung cancers) 

- Crizotinib 
  - Treat to progression 

**EGFR and ALK WT or unknown** 

- Platinum Doublet with or without bevacizumab 
  - Treat for 4–8 cycles 

- Maintenance therapy with pemetrexed or erlotinib 
  - Treat to progression 

- Second-line therapy with nivolumab or pembrolizumab or gemcitabine or pemetrexed or docetaxel 
  - Treat to progression 

- Afatinib 
  - Treat to progression 

- Ceritinib 
  - Treat to progression 

*Pemetrexed and bevacizumab are not indicated for squamous histology* 

*Pembrolizumab is only indicated for patients with tumors expressing PD-L1*

From adjuvant (postsurgical) chemotherapy leading to a survival advantage of 4% to 15%. Consequently, adjuvant therapy has become the standard of care in resectable NSCLC and should be offered to patients after resection, particularly those with stage II or III disease.

Although the regimen of choice is unclear, studies evaluating pemetrexed in squamous cell histology demonstrate that it has minimal to no activity in this subtype. Thus, regimens containing pemetrexed should be avoided in patients with squamous cell histology. Based on prospective randomized trials, cisplatin–vinorelbine appears to be the regimen with the most evidence regardless of histology and genetics.

**Locally Advanced Disease (Stages IIB and IIIA)**

Patients with locally advanced disease should also be considered for surgery, which would be followed with adjuvant treatment as outlined in local disease. However, neoadjuvant (aka. induction) chemotherapy could also be considered before surgery. The rationale behind neoadjuvant therapy is to decrease the size of the tumor so that it can be extracted more easily with clean margins, as well as to eliminate distant micrometastases before invasive local treatment. Meta-analysis of neoadjuvant trials suggests that neoadjuvant chemotherapy in all early stages improves 5-year survival by 5%. However, the methods used in many of these studies did not give adjuvant chemotherapy, which could also improve survival by about the same degree.

One concern of giving neoadjuvant therapy is that the toxicity of induction regimens may delay surgery, and if the tumor does not respond to the treatment, there is a risk of disease progression. Nonetheless, current data suggest that more than 90% of patients who are treated with neoadjuvant therapy maintain their scheduled surgery. The utilization of neoadjuvant chemotherapy is inconsistent, but is most common in patients with locally advanced tumors (stage III). Neoadjuvant chemotherapy regimens are platinum-based doublets that do not include a targeted therapy (see Table 90–4). None of the large studies prospectively controlled/individualized therapy choices based on histology or genetics, which could improve results. Three cycles of carboplatin and paclitaxel administered on a 3-week schedule is a common and supported approach. The benefit of combining neoadjuvant therapy and surgery with additional adjuvant therapy is being investigated but is of unknown value at this time. Relatively small studies have evaluated using three treatment modalities (chemotherapy, radiation, and surgery) to two treatment modalities (chemotherapy and radiation). Improvements have been shown for progression-free survival, but not overall survival. Consequently, the value of trimodal therapy is unknown and does not have a clear role.
Advanced disease is treated with systemic therapy if the patient has an acceptable ECOG PS score (0–1). Historically, patients with NSCLC received the same treatment and had a similar prognosis regardless of tumor characteristics. With that approach platinum-containing doublets given for four to eight cycles produced the highest overall response rates (25%–35%) and survival times (30%–40% 1-year survival) in well-performing patients with advanced disease. A number of different platinum doublet treatment regimens have been used in this setting. In some patients with stage IIIB disease, cisplatin and etoposide may be given concurrently with radiotherapy. However, treating unresectable stage III patients with a platinum-containing doublet regimen and omitting the radiation is common. NSCLC chemotherapy doublets that are considered generally equivalent include:

- Paclitaxel–cisplatin
- Paclitaxel–carboplatin
- Cisplatin–docetaxel
- Carboplatin–docetaxel
- Cisplatin–vinorelbine
- Gemcitabine–paclitaxel
- Gemcitabine–docetaxel
- Cisplatin–pemetrexed
- Carboplatin–nab-paclitaxel

A large randomized trial comparing the first four regimens reported similar response rates and survival with all treatments, although there were less life-threatening toxicity and treatment-related deaths associated with paclitaxel–carboplatin. Consequently, some argued that paclitaxel–carboplatin was the treatment of choice.

Individualized treatment is now the standard approach. Beyond patient characteristics, tumor histology and genetic analysis (in non–squamous cell histology) for activating EGFR mutations and ALK rearrangements guide treatment selection (see Figure 90–2).

**Drug Considerations for Squamous Cell NSCLC**

There are specific drug considerations that must be made with squamous histology. In squamous NSCLC, pemetrexed is associated with decreased efficacy. This is true for combination studies as well as monotherapy studies and the inactivity with this histology is reflected in current treatment guidelines. Furthermore, bevacizumab is associated with an increased risk of fatal hemorrhage in squamous NSCLC. In the randomized phase II study that included 13 patients with squamous cell histology, four had a life-threatening bleed, which led to the exclusion of this population in the phase III trial. Tumor EGFR activating mutations and ALK rearrangements can identify patient most likely to respond to TKI-targeted therapy. Since the incidence of these mutations in squamous cell histology is so low, current guidelines do not recommend testing squamous cell tumors for these mutations. Although these guiding factors are well established, the best combination is still unclear. Based on subset analysis of randomized controlled trials, it appears that gemcitabine and albumin-bound nanoparticle paclitaxel (nab-paclitaxel) have greater activity in squamous histology. The recent randomized trial comparing carboplatin with nab-paclitaxel versus carboplatin with traditional paclitaxel did not find a difference in overall survival (including the squamous histology subset); however, the response rate in patients with squamous cell histology was 41% with nab-paclitaxel and 24% with traditional paclitaxel.

Based on this subset analysis, patients who have a symptomatic tumor might preferentially be treated with carboplatin and nab-paclitaxel. Alternatively, cisplatin and gemcitabine appear to be an acceptable option in squamous NSCLC, although no randomized clinical trials have proven an overall survival advantage in this histology, meaning that any platinum doublet is acceptable for advanced squamous cell lung cancer.

Squamous cell NSCLC frequently overexpresses the EGFR protein. Thus, there has been interest in adding an EGFR-targeted monoclonal antibody with chemotherapy for advanced squamous cell NSCLC. The anti-EGFR monoclonal antibody cetuximab has been shown to improve survival when combined with cisplatin and vinorelbine. The FLEX trial demonstrated a 1.2-month survival advantage of cetuximab when added to cisplatin and vinorelbine in recurrent or metastatic NSCLC (stages IIIB–IV all histologies). However, despite the small survival advantage shown, cetuximab was not approved by the FDA for this indication.

**Drug Considerations for non–squamous cell NSCLC**

Treatment options for non–squamous histology are broader than squamous histology and targeted therapies are making a significant impact, particularly for patients with a genetic alteration that can be targeted with drug therapy.

Approximately 10% to 15% of NSCLC patients have tumors with mutations in exon 19 and/or 21 in the EGFR gene. These mutations define a population likely to respond to treatment with EGFR TKIs (erlotinib or afatinib). In this population, first-line therapy progression-free survival is approximately 4 to 6 months longer with EGFR TKIs than platinum-doublet chemotherapy. Since afatinib and erlotinib have not been compared in a randomized trial, it is not possible to determine which one is better. However, there is evidence that afatinib works in EGFR-mutant tumors in patients who fail erlotinib or have an exon 20 T790M mutant (which predicts resistance to erlotinib). Based on these data, patients who are started on erlotinib, respond, and then progress can be treated with afatinib although going straight to chemotherapy may still be considered the standard. Since there are no data showing that patients who recur after afatinib will respond to erlotinib, patients failing afatinib first line should then go on to treatment with chemotherapy like genetic wild-type adenocarcinoma patients (see Figure 90–2).

Crizotinib is a new targeted therapy that was designed for a subset of patients with an ALK rearrangement (ALK+ ~ 5% of patients). It received accelerated approval based on a single-arm trial in the salvage setting that resulted in a 55% survival rate at 2 years. Despite the lack of data in the first-line setting, the NCCN guidelines recommend that patients with a known ALK rearrangement can be treated with crizotinib in the first-line setting. Response rates are approximately 60% with a progression free survival of 8 to 10 months, and most patients have a recurrence within 12 months. Ceritinib was recently approved for patients who fail crizotinib. In this setting about half of patients respond and the duration of response is approximately 7 months. Although neither have been tested in a randomized trial as first-line therapy or against each other, based on the data and guidelines; ALK+ patients should receive first-line crizotinib, then ceritinib, and then start treatment with chemotherapy like genetic wild-type adenocarcinoma patients (see Figure 90–2).
In summary, targeted therapy as monotherapy or in combination with chemotherapy has become a mainstay in first-line treatment of advanced NSCLC. Targeted agents utilized in NSCLC are presented in Table 90–5.

### Special Populations

Patients who cannot tolerate platinum can be treated with gemcitabine–paclitaxel or gemcitabine–docetaxel. Randomized trials have produced response durations and survival times similar to the platinum-containing doublet regimens. However, these regimens are only recommended for patients who are unlikely to tolerate the toxicity of platinum regimens owing to comorbidities or other factors.26

Poorly performing patients, defined as those with a PS of 2, is a subject of debate. Although patients with a PS of 2 typically have inferior survival rates and higher toxicity to platinum chemotherapy than higher performing patients, low-toxicity single-agent regimens may offer a survival advantage in this subset. Use of these regimens also presents a method of providing symptomatic care for advanced stage patients. Agents such as pemetrexed, gemcitabine, and docetaxel may be used in this scenario. In patients with a PS of 3 or 4, chemotherapy typically results in high rates of toxicity and fails to convey a survival benefit. Consequently, treatment should be aimed at relief of symptoms instead of a definitive cure. Because targeted agents typically have lower rates of severe toxicity, they also have been used in appropriate subsets of patients with a poor PS (ECOG PS of 2 or 3). Unfortunately, we do not have adequate clinical trial data regarding the efficacy and toxicity of targeted agents in these patients. In summary, debilitated patients should not be treated with combination chemotherapy with or without targeted agents because of historically high rates of toxicity without benefit. Single-agent therapy with less toxicity can be used to help palliate symptoms.

### Duration of Therapy

Because advanced stage NSCLC is not curable, an argument can be made that the goal is to extend the number of quality days, rather than just overall survival. With this goal in mind and an assumption that quality of life is lower during chemotherapy treatment, it is important to consider the duration of therapy. Over the last decade, treatment has moved toward fewer chemotherapy cycles. Typical therapy regimens have decreased from planning eight cycles to six cycles, to four cycles, which was the standard until several years ago. It was at this time that positive data were reported from two studies using pemetrexed, erlotinib, and bevacizumab as maintenance therapy. Both key studies included patients who had a response or stable disease who were then randomized to placebo or treatment.27 The pemetrexed study reported a 3-month survival advantage with maintenance therapy. A subgroup analysis of this study demonstrated that patients with squamous histology did not benefit from therapy leaving an overall survival benefit of 5 months for the non–squamous cell group. Similarly, the erlotinib maintenance study reported a 1-month overall survival advantage, which does not appear as robust; however, the subset analysis showed benefit was much more likely in nonsmokers and those with adenocarcinoma histology and particularly in patients who had an activating mutation (exon 19 or 21). Similar to the pemetrexed study, patients whose tumor was of squamous cell histology did not appear to benefit from maintenance. In summary, the duration of therapy depends highly on histology; patients with squamous cell histology will likely be treated for four cycles, but patients with nonsquamous cell histology will be treated until progression.27

### Recurrent and Progressive Disease

- Although patients frequently experience a response to initial therapy, disease recurs in most cases. If the recurrence is...
Patient Encounter, Part 4

The patient undergoes surgery for her disease, which is successful, with negative margins. After 1 year, however, the patient returns for routine follow-up and is found to have recurrent disease, with metastases present in both the brain and in the liver. Molecular diagnostics reveals an ALK rearrangement (ALK-EML4 translocation/fusion).

What is the patient’s new clinical stage?

Discuss the significance of the genetic alteration identified in the tumor.

Based on the information provided, develop a care plan for this patient. Include (a) treatment goals, (b) monitoring parameters for anticipated toxicities, and (c) a follow-up plan to determine response to treatment and surveillance.

localized, surgery options may be assessed. If the patient’s PS remains acceptable (0–1), second-line systemic chemotherapy has been shown to improve survival. Although platinum doublets may be used at this point in care, a single-agent therapy with docetaxel, pemetrexed, erlotinib, or crizotinib is recommended, depending on the tumor genotype.25,28 A recent phase III trial tested the addition of ramucirumab (a VEGFR2-targeted monoclonal antibody) to docetaxel as second-line therapy regardless of histology. The results show that ramucirumab increases overall survival and progression-free survival by approximately 1.5 months.29 Currently ramucirumab is not approved for lung cancer, but is approved for gastric cancer and might be used off label with docetaxel.

Recurrences in poorly performing patients (3–4) usually are not treated with chemotherapy and are instead treated with supportive care. Additional recurrences (eg, third-line therapy) may be treated with single-agent therapy not previously used or best supportive care.

Progression on targeted TKIs such as erlotinib or crizotinib in appropriately (genetically) selected patients after an initial response occurs frequently. This phenomenon is a sign of acquired resistance of the tumor to the molecular effects of the agent. Order of therapy for TKIs is discussed previously in “Drug considerations for non–squamous cell NSCLC.” An overwhelming amount of clinical and preclinical data suggests that patients with molecularly targetable tumors should never lose the opportunity to be treated with TKIs, and perhaps the best opportunity of maintaining quality of life and survival is to enroll in clinical trials testing these second-generation agents. Furthermore, it is important to note that patients who initially benefit from erlotinib and acquire resistance to therapy may benefit from retreatment with erlotinib after other lines of therapy.

OUTCOME EVALUATION

Evaluating outcomes is a goal-oriented process and should begin from that perspective. Patients with localized disease are treated with localized therapy with or without systemic therapy with curative intent as the goal. Monitoring for toxicity and recurrence on a regular basis is essential.

Following surgery or pharmacologic treatment, the patient should be monitored regularly to detect recurrence or progression of disease. Methods include a physical examination and chest x-ray every 3 to 4 months for 2 years. If no disease is detected during this time, follow-up frequency can be prolonged to every 6 months for 3 years and then annually. Low-dose spiral CT scanning is also recommended annually.

Smoking cessation counseling with or without pharmacologic treatment should be a priority. Although studies have shown that patients who continue to smoke through treatment in NSCLC do not perform more poorly compared with those that quit before treatment, those who respond to treatment and continue to smoke probably have an increased risk of developing secondary malignancies.30 In contrast to NSCLC, some data suggest that SCLC patients with limited stage disease have poorer outcomes if they continue to smoke during treatment.31

For those with advanced disease, the goal of treatment is to prolong the duration of life, particularly the number of quality...
days. Ultimately, most lung cancer patients succumb to their disease. Palliative care involves management of symptoms and improvement of quality of life when curative treatment options are no longer available. Often, problematic metastases can be removed by surgery (depending on location) or can be treated with radiotherapy to reduce tumor size. In selecting options at this point in treatment, it is important to keep the goals of therapy (ie, maximizing the duration and quality of life) in mind. Low-toxicity single-agent chemotherapy, targeted therapy, and best supportive care (including fatigue and pain management) are commonly the mainstays of palliative care.

**Abbreviations Introduced in This Chapter**

- 5-FDG: 5-Fluorodeoxyglucose
- ALK: Anaplastic lymphoma kinase
- CAV: Cyclophosphamide, doxorubicin [Adriamycin], vincristine
- CT: Computed tomography
- ECOG: Eastern Cooperative Oncology Group
- EGF: Epidermal growth factor
- EGFR: Epidermal growth factor receptor
- EML4: Echinoderm microtubule-associated protein-like 4
- EP: Etoposide, cisplatin
- ETS: Environmental tobacco smoke
- NSCLC: Non–small cell lung cancer
- PCI: Prophylactic cranial irradiation
- PET: Positron-emission tomography
- PS: Performance status
- SCLC: Small cell lung cancer
- TNM: Tumor, node, and metastasis staging
- VEGF: Vascular endothelial-derived growth factor
- VEGFR: Vascular endothelial-derived growth factor receptor

**REFERENCES**

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Identify the risk factors for colorectal cancer.
2. Recognize the signs and symptoms of colorectal cancer.
3. Describe the treatment options for colorectal cancer based on patient-specific factors, such as stage of disease, age of patient, genetic mutations, and previous treatment received.
4. Outline the pharmacologic principles for agents used to treat colorectal cancer.
5. Develop a monitoring plan to assess the efficacy and toxicity of agents used in colorectal cancer.
6. Educate patients about the adverse effects of chemotherapy that require specific patient counseling.
7. Outline preventive and screening strategies for individuals at average and high risk for colorectal cancer.

INTRODUCTION

Colorectal cancer is one of the four most common cancers diagnosed in the United States and includes cancers of the colon and rectum. In 2015, an estimated 139,970 new cases of colon cancer with an estimated 50,710 deaths, making colorectal cancer the second leading cause of cancer-related deaths in the United States. The prognosis is primarily determined by the stage of disease with the majority of patients with early stage (I or II) disease cured. Treatment options for colorectal cancer include surgery, radiation, chemotherapy, and targeted molecular therapies.

EPIDEMIOLOGY AND ETIOLOGY

Colorectal cancer occurs more frequently in industrialized regions such as North America and Europe, while the lowest rates are seen in less-developed areas, suggesting that environmental and dietary factors influence the development of colorectal cancer. In addition to environmental factors, colorectal cancers develop more frequently in certain families, and genetic predisposition to this cancer is well known.

The incidence of colorectal cancer in men is approximately 1.5 times greater than observed in women. Overall, colon and rectal cancers make up approximately 12% of all cancer diagnoses in men and women in the United States. The median age at diagnosis is 68 years with very few cases occurring in individuals younger than 45 years of age. Age appears to be the biggest risk factor for the development of colorectal cancer with 70% of cases diagnosed in adults older than 65 years of age.

Although still the second leading cause of cancer death, mortality rates for colorectal cancer have declined over the past 30 years as a result of better, and increasingly used screening modalities, and more effective treatments.

RISK FACTORS

In addition to age, dietary or environmental factors, inflammatory bowel disease, and genetic susceptibility increase the risk of colorectal cancer. Table 91–1 lists well-known risk factors for developing colorectal cancer.

Diets high in fat and low in fiber are associated with increased colorectal cancer risk. While data is not entirely consistent, long-term consumption of red and processed meats is associated with an increased risk of colorectal cancer. A large pooled analysis of 13 prospective cohort studies found dietary fiber intake to be inversely associated with the risk of colorectal cancer; however, upon multivariate analysis for other dietary risk factors, the benefit was no longer observed. This analysis does not consider for the known benefits of a fiber-rich diet for noncancerous conditions such as diabetes and coronary artery disease.

Foods that are high in fiber include vegetables, fruit, grains, and cereals. The protective effects of fiber may be a result of reduced absorption of carcinogens in the bowel, reduced bowel transit time, or a reduction in dietary fat intake associated with high-fiber diets.

Physical inactivity and elevated body mass index (BMI) are associated with up to a twofold increase in the risk of colorectal cancer. Decreased bowel transit time and exercise-induced alterations in body glucose, insulin levels, and other hormones may reduce tumor cell growth. Type 2 diabetes mellitus, independent of body mass size and physical activity level, is also associated with an increased risk of colorectal cancer in women and supports a role for hyperinsulinemia as a possible link between obesity, sedentary lifestyle, diabetes mellitus, and colorectal cancer. Additional lifestyle choices that increase the risk of colorectal cancer include alcohol consumption and smoking that may increase the risk of colorectal cancer by generating carcinogens or their direct toxic effects on bowel tissue.
Inflammatory bowel diseases, such as chronic ulcerative colitis, particularly when it involves the entire large intestine, and to lesser extent Crohn disease, confer increased risk for colorectal cancer. Overall, individuals with inflammatory bowel disease account for about 1% to 2% of all new cases of colorectal cancer each year.

Finally, as many as 10% of cases are thought to be hereditary. The two most common forms of hereditary colorectal cancer are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). FAP is a rare autosomal dominant trait that is caused by mutations of the adenomatous polyposis coli (APC) gene and accounts for 1% of all colorectal cancers. The disease is manifested by hundreds to thousands of polyps arising during adolescence. The risk of developing colorectal cancer for individuals with untreated FAP is virtually 100%, and patients require early screening for the disease and likely prophylactic total colectomy. HNPCC, also an autosomal dominant syndrome, accounts for up to 5% of colorectal cancer cases. In contrast to FAP, juvenile polyps occur rarely, and the average age of colorectal cancer in these patients is closer to that of average risk patients, with most patients diagnosed in their 40s. Testing for HNPCC mutations is available but reserved for individuals who meet strict diagnostic criteria.

Up to 25% of patients who develop colorectal cancer have a family history of colorectal cancer unrelated to a mutation described earlier. First-degree relatives of patients diagnosed with colorectal cancer have an increased risk of the disease that is at least two to four times that of persons in the general population without a family history.

**Summary of Risk Factors**

In summary, the true association between most dietary factors and the risk of colorectal cancer is unclear. The protective effects of fiber and a diet low in fat are not completely known at this time. Physical inactivity, alcohol use, and smoking appear to increase the risk of colorectal cancer. Clinical risk factors and genetic mutations are well-known risks for colorectal cancer.

**Screening**

Effective colorectal cancer screening programs incorporate annual fecal occult blood testing in combination with digital examination of the entire colon starting at age 50 years for average-risk individuals and should be recommended by all health care providers. Appropriate screening of patients at normal and high risk for colorectal cancer leads to the detection of smaller, localized lesions and higher cure rates.

Screening techniques include fecal occult blood tests (FOBTs) and imaging of the colon. The use of FOBTs annually in combination with digital rectal examinations has led to diagnosis of early stages of disease and may reduce colorectal cancer mortality by up to one-third. However, FOBT using a single stool sample collected during a digital rectal examination is not a recommended option for screening because this method has a decreased sensitivity for detecting advanced disease. Recommendations for adequate FOBT require the patient to collect two stool samples from three consecutive specimens using at-home testing procedures. Two main methods are available to detect occult blood in the feces: guaiac dye and immunochemical methods. The Hemoccult II is the most commonly used FOBT in the United States and is a guaiac-based test. Proper counseling by health care providers is required to receive accurate test results. Consumption of red meat, blood sausages, peroxidase-containing vegetables, iron products, or NSAIDS may result in false-positive results. Vitamin C and dehydrated samples may lead to false-negative results. These products should be avoided for 3 days prior to testing. Fecal immunochemical tests (FITs) (InSure and others), which use antibodies to detect hemoglobin, are also available for use. Though more expensive, an advantage of FITs is that they do not react with dietary factors or medications. Both FOBTs can be recommended in screening protocols for patients.

In addition, imaging of the colon with a sigmoidoscopy, colonoscopy, or double-contrast barium enema is required every 5 to 10 years in most individuals. Colonoscopy is the preferred procedure as it allows for greater visualization of the entire colon and simultaneous removal of lesions found during screening. A sigmoidoscopy only examines the lower half of the colon, and a double-contrast barium enema requires a supplemental colonoscopy to remove any lesions found during the screening process. Several revisions to the colorectal cancer screening guidelines have been made in an attempt to increase the compliance to screening guidelines. These include the use of computed tomographic colonography (CTC) and stool DNA testing as acceptable screening methods. CTC, also known as “virtual colonoscopy,” uses integrated two- and three-dimensional images...
COLORECTAL CANCER PREVENTION

There are currently no pharmacologic agents approved for colorectal cancer prevention. Strategies under investigation to prevent colorectal cancer include pharmacologic and surgical interventions and involve either preventing the initial development of colorectal cancer (primary prevention) or preventing cancer in patients who demonstrate early signs of colorectal cancer (secondary prevention).

The most widely studied agents for the chemoprevention of colorectal cancer are agents that inhibit COX-2 (aspirin, NSAIDs, and selective COX-2 inhibitors) and calcium supplementation. Individual studies have demonstrated that regular (at least two doses per week) nonsteroidal anti-inflammatory drug (NSAID) and aspirin use is associated with a 20% to 40% reduction in risk of colorectal cancer in individuals at average risk. However, a meta-analysis of over 40 trials suggests the benefit of these agents may be limited to individuals at high risk for developing colorectal cancer. Chronic use of aspirin and other NSAIDs are associated with significant potential adverse effects, including gastrointestinal (GI) and cardiovascular toxicities. These risks limit health care professionals from routine recommendations for use in patients of average risk for colorectal cancer.

CHRONIC USE OF ASPIRIN AND OTHER NSAIDS ARE ASSOCIATED WITH SIGNIFICANT POTENTIAL ADVERSE EFFECTS, INCLUDING GASTROINTESTINAL (GI) AND CARDIOVASCULAR TOXICITIES. THESE RISKS LIMIT HEALTH CARE PROFESSIONALS FROM ROUTINE RECOMMENDATIONS FOR USE IN PATIENTS OF AVERAGE RISK FOR COLORECTAL CANCER.

The risk of colorectal cancer appears to be inversely related to calcium and folate intake. Calcium supplementation appears to be associated with a moderate reduction in risk of recurrent colorectal adenomas with prospective studies demonstrating a nonstatistical decrease in adenoma recurrence, its role as a chemoprevention agent in the average-risk patient remains under investigation.

Additional agents, including selenium and folic acid, show promise as chemopreventive agents in colorectal cancer and preliminary, and confirmatory studies evaluating their effectiveness have been completed or are ongoing. Exogenous hormone use, particularly postmenopausal hormone replacement therapy, is associated with a significant reduction in colorectal cancer risk in most studies with the greatest benefit in women who are on current hormone replacement therapy. Unfortunately, the known risks of hormone replacement therapy outweigh this benefit, and routine use of hormone replacement therapy to prevent colorectal cancer is not recommended.

Surgical resection remains an option to prevent colorectal cancer in individuals at extremely high risk for its development such as patients diagnosed with FAP. Individuals with FAP who are found to have polyps on screening examinations require total abdominal colectomy. In addition, removal of noncancerous polyps detected during screening colonoscopy is considered the standard of care to prevent the progression of premalignant polyps to cancer.

PATHOPHYSIOLOGY

Anatomy and Bowel Function

The large intestine consists of the cecum; ascending, transverse, descending, and sigmoid colon; and rectum (Figure 91–1).

Four major tissue layers, from the lumen outward, form the large intestine: the mucosa, submucosa, muscularis externa, and serosa. Complete replacement of surface epithelial cells occurs every 7 to 10 days with the total number of epithelial cells remaining constant in normal colonic tissue. As patients age, abnormal cells accumulate on the surface epithelium and...
protrude into the stream of fecal matter; their contact with fecal mutagens can lead to further cell mutations and eventual adenoma formation.6

**Colorectal Tumorigenesis**

The development of a colorectal neoplasm is a multistep process of several genetic and phenotypic alterations of normal bowel epithelium leading to unregulated cell growth, proliferation, and tumor development. A genetic model has been proposed for colorectal tumorigenesis that describes a process of transformation from adenoma to carcinoma. This model of tumor development reflects an accumulation of mutations within colonic epithelium that gives a selective growth advantage to the cancer cells.6 Genetic changes include activating mutations of oncogenes, mutations of tumor suppressor genes, and defects in DNA mismatch repair genes.

Additional genes and protein receptors are believed important in colorectal tumorigenesis. COX-2, which is induced in colorectal cancer cells, influences apoptosis and other cellular functions in colon cells, and overexpression of the EGFR, a transmembrane glycoprotein involved in signaling pathways that affect cell growth, differentiation, proliferation, and angiogenesis, occurs in the majority of colon cancers.14 These mechanisms are potentially important because of the availability of pharmacologic agents targeted to inhibit these processes.

More than 90% of colorectal cancers that develop are adenocarcinomas and are assigned a grade of I to III based on how similar they are compared with normal colorectal cells. Grade I tumors most closely resemble normal cellular structure, but grade III tumors have frequently lost the characteristics of mature normal cells. Grade III tumors are associated with a worse prognosis than grade I tumors.15

**CLINICAL PRESENTATION AND DIAGNOSIS**

- The signs and symptoms associated with colorectal cancer can be extremely varied, subtle, and nonspecific. Most patients are asymptomatic but may develop changes in bowel or eating habits, fatigue, abdominal pain, and blood in the stool.

**TREATMENT**

**Desired Outcomes**

Patients are staged with the tumor, node, metastasis (TNM) classification system (TNM) (See Chapter 88) to determine treatment options and assess prognosis. Figure 91–2 depicts how the three categories are used in combination to determine the stage of disease. **Key Concept** The stage of colorectal cancer upon diagnosis is the most important prognostic factor for survival and disease recurrence. Stages I, II, and III disease are considered potentially curable and are aggressively treated in an attempt to cure these patients. Patients who develop stage IV disease are treated to reduce symptoms, avoid disease-related complications, and prolong survival.

**General Approach to Treatment**

The treatment approaches for colorectal cancer reflect two primary treatment goals: curative therapy for localized disease (stages I–III) and palliative therapy for metastatic cancer (stage IV). Surgical resection of the primary tumor is the most important part of therapy for patients in whom cure is possible.16 Depending on the stage of disease and whether the tumor originated in the colon or rectum, further adjuvant chemotherapy or chemotheraphy plus radiation may be needed after surgery to cure these patients. In the metastatic setting, pharmacologic intervention is the main treatment option.

Pharmacogenetic and pharmacogonomic testing has become an integral component to designing the optimal pharmacologic intervention for patients with colorectal cancer. The choice of treatment agents is largely dictated by individualized patient and tumor-specific factors. For example, data have demonstrated specific tumor characteristics that may assist clinicians in predicting who will respond to EGFR inhibitors. Early immunohistochemical staining for EGFR status is not useful in predicting response because both EGFR-positive and EGFR-negative patients respond at the same rate. However, RAS gene mutation status has demonstrated predictive value. Patients should be tested for both KRAS and NRAS, patients with mutated RAS are unlikely to benefit from cetuximab or panitumumab therapy.15 In particular, testing for RAS mutational status is now part of the disease workup to define patients who may derive benefit from cetuximab or panitumumab. Characteristics of the tumor are also vital in making treatment decisions for patients with stages II and III disease. The degree of microsatellite instability (MSI) within a tumor tells clinicians information about both prognosis and treatment options. More detail on specific pharmacogenetic and pharmacogenomic information is provided the pertinent pharmacologic therapy sections.

**Nonpharmacologic Therapy**

- **Operable Disease (Stages I–III)**

**Surgery** Individuals with stages I to III colorectal cancer should undergo a complete surgical resection of the tumor mass with removal of regional lymph nodes as a curative approach for their disease.16 Surgery for rectal cancer depends on the region of tumor involvement with attempts to retain rectal
function as a goal of the surgical procedure. Overall, surgery for colorectal cancer is associated with low morbidity and mortality rates. Common complications include infection, anastomotic leakage, obstruction, adhesion formation, and malabsorption syndromes.

**Radiation Therapy** There is currently no role for adjuvant radiation in colon cancer. However, patients who receive surgery for rectal cancer receive radiation therapy to reduce local tumor recurrence. Adjuvant radiation plus chemotherapy is considered standard treatment for patients with stage II or III rectal cancer after the surgical procedure is complete. Preoperative radiation may be used to reduce the initial size of rectal cancers to make the surgical procedure easier.

► **Metastatic Disease (Stage IV)**

**Surgery** Unlike stages I to III disease, the benefit of surgical resection in most patients with metastatic disease is limited to symptomatic improvement. Select patients who have from one to three small nodules isolated to the liver, lungs, or abdomen may have a prolongation of survival, although cure is rare. Five-year survival for patients who undergo surgical resection of metastases isolated to the liver is approximately double that of patients who are not surgical candidates with approximately 33% of patients alive at 5 years. Alternatives to surgery include destroying the tumor through freezing and thawing (cryoablation), heat (radiofrequency), or alcohol injection, although these appear to be less successful than surgical resection. Because the majority of these patients will relapse, many practitioners offer adjuvant chemotherapy to select patients following potentially curative resection, but further studies are needed to determine an optimal treatment regimen.

**Radiation** Symptom reduction is the primary goal of radiation for patients with advanced or metastatic colorectal cancer.

**Pharmacologic Therapy**

Table 91–3 lists common chemotherapy regimens used in colorectal cancer and the abbreviations used in the literature to describe them.

---

**Patient Encounter, Part 2**

**PMH:** Hypertension since age 40 years; obesity; the patient is 55% over her ideal body weight

**FH:** Father died at age 60 years after a stroke. Mother died at age 75 years with breast cancer; older sister with breast cancer; maternal aunt died at age 47 years from rectal cancer

**SH:** Works in a department store. Married with three grown children

**Meds:** Atenolol 50 mg daily; glyburide 10 mg daily; gabapentin 300 mg three times a day; aspirin 81 mg daily

**ROS:** (+) Abdominal cramping, loss of appetite, diarrhea, and fatigue

**PE:**

**VS:** 154/88 mm Hg, P 80, RR 17, T 37.1°C (98.8°F), Ht 168 cm (66 in), Wt 89 kg (196 lb)

**Abd:** Distended and tender to touch, (+) bowel sounds

**Labs:** Positive hemoglobin 11.8 g/dL (118 g/L or 7.32 mmol/L) decreased from 13.4 g/dL (134 g/L or 8.32 mmol/L) last year

**Imaging and Diagnostic Studies**

- Colonoscopy revealed multiple polyps in her transverse colon
- Biopsy revealed four polyps positive for adenocarcinoma of the colon
- Staging CT scan negative for disease outside of her colon
- Three lymph nodes positive for disease

Because the patient has stage III colon cancer, how does this affect the goal of your treatment plan compared with stage IV disease?

What nonpharmacologic and pharmacologic options are available to this patient?
Operable Disease (Stages I–III)

Adjuvant chemotherapy is administered after tumor resection to decrease relapse rates and improve survival in patients with colon cancer by eliminating micrometastatic disease that is undetected on imaging studies. Patients diagnosed with stage I colon or rectal cancer are usually cured by surgical resection, and adjuvant chemotherapy is not indicated in these patients. The role of adjuvant chemotherapy for stage II colon cancer is controversial but may benefit certain high-risk groups. Adjuvant chemotherapy is standard therapy for patients with stage III colon cancer. Table 91–4 lists adjuvant treatment regimens based on stage and performance status (PS). Adjuvant chemotherapy for patients with stage II disease has not been shown to be superior to surgery alone with the possible exception of high-risk patients, including those with inadequate nodes sampled for staging, bowel perforation upon diagnosis, T4 lesions, and those with unfavorable histology. The risks and benefits of adjuvant chemotherapy should be discussed with medically fit patients who have stage II disease with high-risk features. However, the American Society of Clinical Oncology does not recommend the routine use of adjuvant chemotherapy in the general patient population unless part of a clinical trial.

There is currently insufficient data to recommend the use of tumor gene profiling to determine need for adjuvant therapy in stage II disease, but it is an area of active research. An additional consideration for deciding on adjuvant therapy is the status of MSI within the tumor. MSI results from defective DNA mismatch repair (dMMR) genes leading to damaged DNA. Patients with tumors that display high levels of MSI may have better prognosis than patients with microsatellite-stable

5-FU, 5-fluorouracil.

*aIndividualized assessment of patient risk is necessary to determine if treatment is required. Clinical trials or observation may be an appropriate option.

bT3 lesions may be considered high risk by some clinicians.
(MSS) tumors. Despite being associated with a better prognosis, tumors that display high levels of MSI do not respond as well to certain chemotherapy, including 5-fluorouracil (5-FU). It is recommended that stage II patients should be tested for the status of MSI if 5-FU is being considered for therapy, and an alternative therapy should be considered if high levels of MSI are displayed. In general, patients with stage II colon cancer should be enrolled into clinical trials to assess the impact of new agents and prognostic models.

Adjuvant chemotherapy is standard therapy for patients with stage III colon cancer. The presence of lymph node involvement in the resected specimen places patients with stage III colon cancer at high risk for relapse; the risk of death within 5 years of surgical resection alone is as high as 70%. In this population of patients, adjuvant chemotherapy significantly decreases the risk of cancer recurrence and death and is considered the standard of care.

**KEY CONCEPT**

5-FU, leucovorin, and oxaliplatin (FOLFOX)-based chemotherapy is the standard regimen used in adjuvant colon cancer. It is usually given for 6 months. Refer to Tables 91–3 and 91–4 for recommended treatment regimens and schedules. 5-FU alone results in a small improvement in survival that can vary based on the method of 5-FU administration and the status of MSI.

The combination of 5-FU plus leucovorin has undergone extensive study in the adjuvant setting with decreased rates of recurrence and improved survival seen in patients receiving 5-FU plus leucovorin compared with surgery alone. Though various schedules of 5-FU and leucovorin can be administered, continuous infusions may be less toxic and have improved response rates (although no survival advantage) compared with bolus regimens. Capecitabine is an oral prodrug of 5-FU that is also effective in the adjuvant setting and is being used as a replacement in certain regimens for 5-FU. Data suggest that capecitabine is at least equivalent to bolus 5-FU and leucovorin in efficacy and is better tolerated by patients in the adjuvant setting. An increase in hand-foot syndrome and decreased mucositis and neutropenia are seen with capecitabine compared with bolus 5-FU.

More often, 5-FU or capecitabine is administered as part of a combination regimen with oxaliplatin and leucovorin (FOLFOX or CapeOx). FOLFOX is considered standard of care for patients with stage III disease unless their PS is so poor that clinicians do not believe the patients could tolerate intensive combination therapy. Every effort should be made to minimize adverse treatment effects and use this regimen in patients with stage III colon cancer because this is the only regimen demonstrated to improve overall survival in these patients. Several variations on the original FOLFOX regimen have been studied with mFOLFOX6 being the most routinely used in clinical practice (Refer to Table 91–4). CapeOx resulted in improved DFS compared with bolus 5-FU–leucovorin, but no overall survival benefit in stage III patients and is considered an acceptable adjuvant regimen in this patient population.

Targeted therapies, including cetuximab and bevacizumab, have been evaluated for their role in their adjuvant treatment of colon cancer. At this time, no targeted agents are approved for use as adjuvant therapy in stage II or III colorectal cancer patients. Additionally, irinotecan should not be used in the adjuvant setting because its addition to 5-FU–based regimens has increased toxicity without therapeutic benefit.

### Metastatic Disease (Stage IV)

Traditional chemotherapy and targeted biological therapies are the mainstay of treatment for metastatic colon or rectal cancer and have improved the median survival time of these patients to more than 2 years. Most often, a combination of chemotherapy agents with biological therapies is administered to these patients. Currently, metastatic colorectal cancer is incurable, and treatment goals are to reduce patients’ symptoms, improve quality of life, and extend survival. Combination chemotherapy regimens have been demonstrated to result in prolongation of survival with tolerable adverse effects. Similar to the adjuvant setting, 5-FU plus leucovorin continues to be in most first-line chemotherapy regimens used for metastatic colorectal cancer. A variety of continuous intravenous (IV) infusion 5-FU and bolus regimens can be used; however, compared with IV bolus 5-FU, response rates with continuous infusion 5-FU are approximately doubled. In a large meta-analysis of patients with advanced colorectal cancer, continuous infusions of 5-FU had a significantly higher tumor response rate, a small increase in survival, and lower incidence of myelosuppression, diarrhea, and mucositis when compared with bolus regimens.

Additional agents including irinotecan and oxaliplatin have been added to the 5-FU and leucovorin regimen with superior response and survival rates compared to the two drugs used alone. A large European study compared a combined bolus and infusional 5-FU regimen plus irinotecan (FOLFIRI) with the FOLFOX regimen (using a slightly different schedule) with crossover to the opposite arm upon relapse. No difference in patient survival was seen with either regimen, and toxicity was as expected. Neuropathy and neutropenia were more common with FOLFOX, while diarrhea, nausea, vomiting, dehydration, and febrile neutropenia were more common with FOLFIRI. Based on improved survival data with the FOLFOX and FOLFIRI regimens, irinotecan-based regimens should only be administered outlined as described in Table 91–3.

Capecitabine also has activity in the metastatic setting. When combined with oxaliplatin in regimens known as CapeOx or XELOX, capecitabine appears to be as safe as 5-FU–based regimens. Additionally, progression-free survival (PFS) with capecitabine and oxaliplatin is similar to that of FOLFOX and is considered noninferior to the FOLFOX regimen as first-line therapy in advanced disease. This noninferiority with capecitabine may be specific to its use with oxaliplatin because capecitabine in combination with irinotecan (CAPIRI) demonstrated decreased PFS compared with FOLFIRI and the routine substitution of 5-FU with capecitabine in irinotecan-based regimens is not recommended.

5-FU plus leucovorin, or capecitabine alone, is appropriate first-line treatment options for individuals for whom three-drug combination regimens are believed to toxic. The site(s) of tumor involvement, history of prior chemotherapy, and patient-specific factors help define the appropriate management strategy.

**KEY CONCEPT**

The most important factor in patient survival is not the initial regimen but whether or not patients receive all three active chemotherapy drugs (5-FU, irinotecan, and oxaliplatin) at some point in their treatment course. Some clinicians choose to use all three agents in combination in the first-line setting in a regimen termed FOLFOXIRI, although only in patients who are able to tolerate intensive therapy.

Targeted or biologic agents have been approved for use in metastatic colorectal cancer. Bevacizumab in combination with 5-FU–based chemotherapy (either FOLFOX or FOLFIRI) is approved by the FDA for initial treatment of patients with metastatic colorectal cancer. Results from randomized trials show increased benefit compared with chemotherapy alone. The efficacy of bevacizumab in this patient population shows
the relevance of angiogenesis as an important target for the treatment of metastatic colorectal cancer. The addition of bevacizumab to first-line oxaliplatin-based chemotherapy has also been demonstrated to improve PFS but did not positively impact response rates or overall survival. Similar results were demonstrated with bevacizumab in combination with capcitabine and oxaliplatin. Based on these results, bevacizumab is recommended as part of 5-FU–based chemotherapy regimens used for the first-line treatment of metastatic colorectal cancer unless contraindicated. Bevacizumab is contraindicated in patients with GI perforation or fistulas involving a major organ, recent (within 28 days) major surgeries or open wounds, wound dehiscence requiring medical intervention, hypertensive crisis or uncontrolled severe hypertension, hypertensive encephalopathy—serious bleeding, a severe arterial thromboembolic event, moderate or severe proteinuria (urine protein excretion 2 g/24 hours or more), nephrotic syndrome, and reversible posterior leukoencephalopathy syndrome.

The EGFR inhibitors, cetuximab and panitumumab, demonstrate improved PFS as first-line therapy in the metastatic setting when individually combined with either the FOLFOX or FOLFIRI regimens in KRAS wild-type individuals. Before using these agents, testing for KRAS mutation status should occur. Extensive literature exists demonstrating poor response rates of EGFR inhibitors in patients whose tumors have a mutation in codon 12 or codon 13 of the KRAS gene. Consequently, cetuximab or panitumumab may be used in the first-line setting in combination with traditional chemotherapy agents in KRAS WT patients only.

Attempts to combine the vascular endothelial growth factor (VEGF) inhibitor bevacizumab with cetuximab and panitumumab as part of traditional chemotherapy regimens have resulted in inferior outcomes to regimens with bevacizumab alone. Based on these results, the use of bevacizumab with either EGFR inhibitor is not recommended.

In summary, most practitioners select first-line treatment for metastatic colorectal cancer from among these treatments: oxaliplatin plus 5-FU plus leucovorin (FOLFOX); irinotecan plus 5-FU plus leucovorin (FOLFIRI); capcitabine plus oxaliplatin (CapeOx or XELOX); oxaliplatin plus irinotecan plus 5-FU plus leucovorin (FOLFIRI); bevacizumab plus 5-FU or capcitabine-based chemotherapy (FOLFOX or FOLFIRI or CapeOx or FOLFOXIRI); or cetuximab or panitumumab plus 5-FU–based chemotherapy (FOLFOX or FOLFIRI) in KRAS WT patients.

**Second-Line Therapy**

Treatment of relapsed or refractory metastatic disease uses agents not given in the first-line setting. Patients who receive all effective chemotherapy options have improved outcomes compared with those who do not. Because most patients will have received a combination of 5-FU or capcitabine with either irinotecan or oxaliplatin, second-line therapy with the alternate regimen should be considered. For example, a patient who received FOLFOX plus bevacizumab as first-line therapy for metastatic disease should be offered FOLFIRI as part of their second-line regimen. EGFR inhibitors are an additional option for use in the second-line setting in patients with WT KRAS only. Patients who did not have an EGFR inhibitor in their first-line regimens are candidates for single-agent cetuximab or panitumumab or either agent in combination with 5-FU and irinotecan (FOLFIRI + EGFR inhibitor). Additionally cetuximab plus irinotecan can be used without the inclusion of 5-FU. The use of EGFR inhibitors may be beneficial as monotherapy, but response rates and PFS appear to be increased in combination with irinotecan-based chemotherapy. The results appear to be best when irinotecan is continued because of synergy demonstrated between the two classes of agents.

If targeted agents such as bevacizumab were not part of the initial regimen, addition to the second-line regimen should be strongly considered. The addition of bevacizumab to FOLFOX has been shown to increase overall survival. Bevacizumab as monotherapy was shown to be inferior to FOLFOX4 in efficacy and should not be considered as a treatment option in the second-line setting. In patients receiving bevacizumab as part of first-line therapy, continuation of bevacizumab with second-line therapy is associated with increased survival. Based on these findings, continuation of bevacizumab in combination with traditional second-line chemotherapy regimens (5-FU-irinotecan or 5-FU-oxaliplatin based) can be considered in patients treated with a first-line bevacizumab containing regimen. A second agent targeting VEGF, ziv-aflibercept, in combination with FOLFIRI can also be considered for use in the second-line setting in patients who have progressed following an oxaliplatin-based first-line regimen. A modest increase in overall and PFS was found in patients receiving FOLFIRI plus ziv-aflibercept compared to FOLFIRI alone. Adverse events and warnings for use with ziv-aflibercept are similar to those with bevacizumab and described in the section of specific agents. Table 91–5 lists treatment options for first- and second-line treatment of metastatic colorectal cancer. Patients with good PS are treated more aggressively than those with poor PS because of their ability to better tolerate chemotherapy.

**Salvage Therapy**

Third-line options for patients with metastatic colorectal cancer are limited. Panitumumab is approved for patients who have progressed after 5-FU, oxaliplatin, and irinotecan. Compared with best supportive care, it improves time to disease progression. Based on improvement in PFS compared to best supportive care, the multiple tyrosine kinase inhibitor, regorafenib, was approved as a single agent for metastatic colorectal cancer in the third- or fourth-line setting. Patients who fail standard treatment for metastatic colorectal cancer should be encouraged to participate in a clinical trial evaluating new treatment approaches for this incurable disease.

**SPECIFIC AGENTS USED IN COLORECTAL CANCER**

Table 91–6 lists all FDA-approved drugs used in colorectal cancer along with their mechanisms of action, common toxicities, and recommended dose adjustments for hepatic and renal dysfunction as well pharmacogenetic considerations.

### 5-Fluorouracil

5-Fluorouracil (5-FU) acts as a “false” pyrimidine inhibiting the formation of the DNA base thymidine as described in Chapter 88. 5-FU is commonly used in the adjuvant and metastatic treatment of colon and rectal cancers with common regimens listed in Table 91–3. Clinical studies comparing efficacy of bolus and continuous infusion schedules generally favor continuous infusion of 5-FU. This is consistent with evidence that suggests that the duration of infusion may be an important determinant of the biologic activity of 5-FU, particularly because of its short plasma half-life, S-phase specificity, and relatively slow growth of colon tumors.

Clinically significant differences in toxicity also differ based on the dose, route, and schedule of 5-FU administration. Leukopenia and mucositis are the primary dose-limiting toxicities of bolus 5-FU, whereas palmar-plantar erythrodysesthesia (“hand–foot syndrome”) and diarrhea occur most frequently with continuous infusions of 5-FU. Health care practitioners can offer valuable patient advice to decrease the impact of these adverse effects. Patients can be informed to suck on ice chips before and for up to 30 minutes after 5-FU boluses to decrease the incidence of mucositis. Hand–foot syndrome, characterized by painful swelling and redness of the soles of the feet and palms of the hand, can be minimized with loose-fitting clothing and keeping skin moist. Additional toxicities include moderate nausea and vomiting, skin discoloration, nail changes, photosensitivity, and neurologic toxicity.

An additional determinant of 5-FU toxicity, regardless of the method of administration, is related to its catabolism and pharmacogenomic factors. Dihydropyrimidine dehydrogenase (DPD) is the main enzyme responsible for the catabolism of 5-FU to inactive metabolites. A number of polymorphisms in DPD have been identified in which patients have a complete or near-complete deficiency of this enzyme. This results in unusually severe toxicity, including death, after the administration of 5-FU. Approximately 3% of patients have a complete lack of DPD activity with other patients demonstrating a partial deficiency in enzyme activity. Although patients may be tested for level of DPD activity, it is not routinely done but may be considered in patients who develop severe toxicity after 5-FU administration. The response to 5-FU is also influenced by the status of MSI within the tumor. Tumors with high levels of MSI are generally more resistant to 5-FU despite being associated with better prognosis.

Leucovorin is commonly given with 5-FU. Leucovorin acts to increase the affinity of 5-FU to thymidine synthase, thus increasing the pharmacologic activity of 5-FU. Leucovorin is most effective when administered before 5-FU and can be given by IV bolus or as a continuous infusion. Health care practitioners can also expect an increase in 5-FU toxicities (leukopenia, mucositis, and diarrhea) when leucovorin is given in combination with 5-FU.

### Capecitabine

Capecitabine (Xeloda) is an oral prodrug of 5-FU that is designed to be selectively activated by tumor cells. Capecitabine undergoes a three-step conversion to 5-FU, the last step being phosphorylation by thymidine phosphorylase (TP). TP levels are reported to be higher in tumor cells than normal tissues; therefore, the systemic exposure of active drug is minimized, and tumor concentrations of the active drugs are optimized. After the drug is converted to 5-FU, it has the same mechanism of action. The current FDA-approved indication for capecitabine is for use in metastatic and adjuvant colorectal cancer when monotherapy is desired, although it is actively being investigated as a replacement for 5-FU in most combinations of colon and rectal cancer regimens. Capecitabine has been demonstrated to be at least equivalent to bolus IV 5-FU in the metastatic and adjuvant setting with improved patient tolerability. Hand–foot syndrome and diarrhea are common with capecitabine because its toxicities (and pharmacologic activity) appear to mimic those of continuous infusions of 5-FU. Both irinotecan and oxaliplatin have been combined with capecitabine. Capecitabine in combination with oxaliplatin appears to be as safe and effective as IV-based 5-FU in the treatment of patients with colorectal cancer. Combinations with irinotecan have had mixed results and are not routinely recommended.

The dose of capecitabine ranges from 1000 to 1250 mg/m² twice a day when used by itself; lower doses are often used when it is given in combination with irinotecan or oxaliplatin or in patients with renal insufficiency. The dose should be taken on a full stomach with breakfast and dinner. Capecitabine administered with warfarin can result in significant increases in patients’ international normalized ratio (INR) and requires close monitoring.

</table>

5-FU, 5-fluorouracil; CrCl, creatinine clearance; EGF, epidermal growth factor; EGFR, epidermal growth factor receptor; RPLS, Reversible posterior leukoencephalopathy syndrome; TGF, transforming growth factor; VEGF, vascular endothelial growth factor; WT, wild type.
The convenience of oral administration, potentially requiring fewer clinic visits, and an improvement in toxicity make capecitabine a useful alternative to IV 5-FU both by itself and incorporated into other regimens used in colorectal cancer.

**Irinotecan**

Irinotecan (Camptosar) is a topoisomerase-I inhibitor that forms a complex with the covalently bound DNA topoisomerase I enzyme and interferes with the DNA breakage–resealing process. Binding permits uncoiling of the double-stranded DNA, but it prevents subsequent resealing of the DNA, resulting in double-stranded DNA breaks. Irinotecan is a prodrug that is converted by carboxylesterases to its active form, SN-38. Irinotecan is indicated for the first-line treatment of metastatic colorectal cancer in combination with 5-FU and leucovorin or as a single agent in patients who fail first-line therapies. Irinotecan is not recommended as part of the adjuvant treatment of colorectal cancer at this time.

The major toxicity of irinotecan is diarrhea, which can occur both early and late in therapy. The early diarrhea is a cholinergic reaction that occurs in the first 24 hours (often during the infusion) in up to 10% of patients and responds to atropine 0.25 to 1 mg IV. The late diarrhea seen in a larger percent of patients occurs 7 to 14 days after the irinotecan infusion. Health care practitioners should have to be diligent in counseling patients on this adverse reaction and counseling them on the proper use of anti-diarrheals. At the first change in bowel habits, an intensive loperamide regimen should be started by patients (4 mg initially followed by 2 mg every 2 hours until diarrhea free for 12 hours). If diarrhea does not stop or if it worsens, patients should be instructed to call their health care provider immediately. Late-onset diarrhea may require hospitalization or discontinuation of therapy, and fatalities have been reported. Additional toxicities with irinotecan include leukopenia (including neutropenic fever) and moderate nausea and vomiting. Toxicities of irinotecan appear to be greater when the drug is given weekly compared with other administration schedules.

Similar to 5-FU, a pharmacogenomic abnormality is associated with irinotecan toxicity. UDP-glucuronosyltransferase (UGT1A1) is an enzyme that is responsible for the glucuronidation of SN-38 to inactive metabolites, and reduced or deficient levels of this enzyme correlate with irinotecan-induced diarrhea and neutropenia. The FDA approved a blood test that detects variations in this gene. This test may assist health care providers in predicting which patients may develop severe toxicities from “normal” doses of irinotecan and can be ordered before patients receive irinotecan. The package insert recommends dose reductions of one level in patients who are UGT1A1 homozygous variants. Irinotecan is administered as an IV bolus over 60 to 90 minutes in a variety of dosing schedules.

**Oxaliplatin**

Oxaliplatin (Eluxatin) is similar to other platinum analogues (cisplatin) in that it binds to the N-7 position of guanine that results in cross-linking of DNA and double-stranded DNA breaks. Oxaliplatin differs from cisplatin in that the DNA damage induced by oxaliplatin may not be as easily recognized by DNA repair genes often seen in colorectal cancer. Oxaliplatin, in combination with 5-FU-based regimens, is indicated for the first- and second-line treatment of metastatic colorectal cancer as well as the adjuvant treatment of colorectal cancer.

The dose-limiting toxicity of oxaliplatin is acute and chronic neuropathy. Acute neuropathies occur within 1 to 2 days of dosing, resolve within 2 weeks, and usually occur peripherally. These acute neuropathies occur in almost all patients to some degree and are exacerbated by exposure to cold temperature or cold objects. Health care providers should instruct patients to avoid cold drinks, avoid use of ice, and cover skin before exposure to cold or cold objects. In addition, gabapentin, and calcium and magnesium infusions have been used to both prevent and treat oxaliplatin-induced neuropathies, although use of these agents is not widely accepted. Persistent neuropathies generally occur after eight cycles of oxaliplatin and are characterized by defects that can interfere with daily activities (eg, walking, buttoning, swallowing, and walking). Patients may receive predefined breaks from oxaliplatin to decrease the onset of these toxicities with reintiation of therapy. This strategy varies among protocols but involves administering a certain number of predefined oxaliplatin cycles and then stopping. Maintenance therapy with another agent is usually administered and then the oxaliplatin-based regimen is restarted based on the protocol. These neuropathies occur in up to half of patients receiving oxaliplatin but usually resolve with dosage reductions or after oxaliplatin is stopped. A recent phase III trial in the adjuvant setting demonstrated a decrease in greater than grade 2 chronic sensory neuropathies in patients receiving IV calcium and magnesium infusions before and after oxaliplatin infusion. Oxaliplatin has minimal renal, myelosuppressive effects, and nausea and vomiting when compared with other platinum drugs. Oxaliplatin is given IV in a variety of dosing schedules with a typical dose of 85 mg/m² IV every 2 weeks.

**Bevacizumab**

Bevacizumab (Avastin) is a recombinant, humanized monoclonal antibody that inhibits VEGF. VEGF is a proangiogenic growth factor found in many cancers, including colorectal, and is thought to promote blood vessel formation and metastasis of the tumor by binding to VEGF receptors on tumors. Bevacizumab inhibits circulating VEGF, preventing it from binding to receptors and decreasing the formation of new blood vessels. Additionally, bevacizumab may allow for increased concentrations of traditional chemotherapy such as irinotecan to reach the tumor to exert its pharmacologic effect. Bevacizumab is not effective alone and must be used in combination with other agents effective in colorectal cancer. It is indicated for first-line and second-line treatment of patients with metastatic colorectal cancer in combination with IV 5-FU–based regimens. Bevacizumab is also approved for use in combination with 5-FU–irinotecan or 5-FU-oxaliplatin-based chemotherapy for treatment of patients with metastatic colorectal cancer whose disease has progressed on a first-line bevacizumab-containing regimen.

Adverse effects associated with bevacizumab include hypertension, which is common but easily managed with oral anti-hypertensive agents. Thrombotic events (including myocardial infarctions, pulmonary embolisms, and deep vein thrombosis) occur more frequently in the elderly patients with cardiovascular risk factors and need to be monitored routinely. Because bevacizumab interferes with normal wound healing, it should not be given shortly before or after surgical procedures. Initiation within 28 days of surgery is not recommended to allow for proper wound healing and decrease the risk of bleeding. The amount of time needed after bevacizumab discontinuation to perform elective surgical procedures is less clear, but health care providers should take into consideration bevacizumab’s half-life of approximately 20 days when making clinical decisions. Patients should have their urine checked for protein
before each dose of bevacizumab to check for potential kidney damage. Patients who have developed 2+ protein on the urinalysis require additional testing before receiving therapy. These patients will have their 24-hour urine collected and assessed for protein. Therapy is interrupted if urine protein excretion exceeds 2 g/24 hours or more and resumed when urine protein excretion decreases to less than 2 g/24 hours.

Finally, there is a risk of GI perforation that is rare but potentially fatal. Patients complaining of abdominal pain associated with vomiting or constipation should be counseled to call their physician immediately. Bevacizumab is commonly given at a dose of 5 mg/kg IV every 14 days until disease progression. Once disease progresses and salvage chemotherapy is initiated, the benefit of continuing bevacizumab is unclear.

Ziv-aflibercept

Ziv-aflibercept (Zaltrap) is a soluble recombinant fusion protein developed by fusing sections of the VEGFR-1 and VEGFR-2 immunoglobulin domains to the Fc portion of human IgG1 antibody. This results in trapping the VEGF-A, VEGF-B, and PIGF ligands before they get to the native transmembrane receptors, and therefore, inhibiting the angiogenic process.6 It is FDA approved for the treatment of metastatic colorectal cancer in combination with FOLFIRI after progression on an oxaliplatin-based regimen. The dose is 4 mg/kg as an IV infusion over 1 hour every 2 weeks in combination with FOLFIRI.

Toxicities include severe and potentially fatal hemorrhage, GI perforation, and compromised wound healing for which the FDA has given ziv-aflibercept a black-box warning. Other adverse effects common to VEGF inhibition (thromboembolic events, hypertension, proteinuria) are seen. As a result ziv-aflibercept shares similar monitoring parameters and warnings to those mentioned in the bevacizumab section. Finally additional warnings for neutropenia, diarrhea and dehydration, and reversible posterior leukoencephalopathy syndrome (RPLS) require monitoring patients for signs and symptoms of these toxicities.

Regorafenib

Regorafenib (Stivarga) is an oral medication that inhibits multiple protein kinases. Its main mechanism of action in colorectal cancer appears to be related to inhibition of vascular endothelial receptors involved in angiogenesis. The importance of additional protein kinase inhibited by regorafenib is unknown in colorectal cancer. Regorafenib is FDA approved as a single agent for metastatic colorectal cancer in the third- or fourth-line setting.66 The dose of regorafenib is 160 mg orally, once daily for the first 21 days of each 28-day cycle and it must be taken with a low-fat breakfast to improve absorption.

Adverse effects for regorafenib include those typical for VEGF inhibition (hemorrhage, hypertension, wound healing complications, GI perforation) mentioned with bevacizumab and ziv-aflibercept. Regorafenib has a black-box warning for hepatotoxicity that requires baseline liver function tests (ALT, AST, and bilirubin), then every 2 weeks during the first 2 months of therapy, and then monthly. In patients with elevated liver function tests holding doses, dose reductions, or permanent discontinuation of regorafenib may be necessary. Also, asthenia, fatigue, decreased appetite, hand-foot syndrome, diarrhea, mucositis, weight loss, infection, and dysphonia occurred in over 30% of patients. Refer to chapter 99 on supportive care for management. Finally, regorafenib is a substrate of CYP3A4 and patients should be screened for potential drug interactions.

Cetuximab and Panitumumab

Cetuximab (Erbitux) and panitumumab (Vectibix) are monoclonal antibodies directed against the EGFR. Cetuximab is a chimeric antibody, whereas panitumumab is a fully human monoclonal antibody. EGFR is overexpressed in colorectal cancers and leads to an increase in tumor proliferation and growth.67 Cetuximab received FDA approval for use in EGFR-expressing metastatic colorectal cancer in irinotecan-relapsed or irinotecan-refractory patients. Cetuximab should be administered in combination with irinotecan but can be used as a single agent in patients who cannot tolerate irinotecan-based chemotherapy. Panitumumab is approved as monotherapy agent and as first-line therapy in combination with FOLFOX in metastatic colorectal cancer.

Both agents are well tolerated with infusion-related reactions being the dose-limiting toxicity of cetuximab and rash most commonly seen with panitumumab. Patients receiving cetuximab require premedication with acetaminophen and diphenhydramine and may require modifications to their administration schedule or permanent discontinuation if they develop severe allergic toxicity. A skin rash and diarrhea are also commonly seen with both agents, and health care practitioners should provide counseling to patients about these adverse effects. Treatment options include common medications used to treat acne (doxycycline), topical and systemic steroids, and general skin care. Patients may be offered these agents prophylactically, upon initiation of therapy, to decrease the potential impact the rash has on their quality of life. Development of rash may be a surrogate marker of response, and clinicians should attempt to minimize the complications of the rash before discontinuing therapy.15 Other toxicities common to both agents include low magnesium, calcium, and potassium levels that require checking levels and replacement therapy as clinically indicated. A rare adverse effect (less than 1%), interstitial lung disease is seen with all agents that inhibit EGFR, and patients should be instructed to report any new-onset shortness of breath. Cetuximab has an initial loading dose of 400 mg/m² IV infusion. Weekly doses of 250 mg/m² are then administered starting the following week. Panitumumab is given 6 mg/kg every 2 weeks.

RECTAL CANCER

Although often treated similarly to colon cancer, there are some important differences in the treatment of rectal cancer, especially in the adjuvant setting. Rectal cancer involves tumors found in the distal 15 cm of the large bowel and, as such, is very distinct from colon cancer in that it has a propensity for both local and distant recurrence. The higher incidence of local failure and poorer overall prognosis associated with rectal cancer are attributable to limitations in surgical techniques.

Patient Encounter, Part 4

Despite completing six cycles of adjuvant chemotherapy, the patient’s disease progresses, and a CT scan reveals metastases to her bone and liver. The tumor is sent for pharmacogenomic profiling and is found to be positive for the wild-type KRAS gene (no mutation detected).

What pharmacologic treatment options are available for the treatment of her metastatic disease?
Therefore, multimodality therapies with a combination of chemotherapy, radiation, and surgery are at the forefront in the treatment of rectal cancer with the main goal of survival and quality of life by preserving the function of the anal sphincter. In addition, because treatment with surgery, radiation, or systemic chemotherapy at the time of the recurrence is often suboptimal, adjuvant therapy after tumor resection is an important aspect of treatment of the primary tumor. Similar to adjuvant therapy for colon cancer, 5-FU provides the basis for chemotherapy regimens for rectal cancer.

**Key Concept**  Adjuvant therapy consisting of 5-FU-based chemotherapy in combination with radiation therapy should be offered to patients with stage II or III cancer of the rectum. Radiation therapy decreases the rate of local recurrences, but 5-FU decreases the risk of distant tumor recurrence as well as acting as a radiosensitizer. Toxicities from combined modality therapy include severe hematologic toxicity, enteritis, and diarrhea. Additional trials have sought to determine optimal combinations of concurrent radiation and 5-FU. Similar to tumors in the colon, continuous infusions of 5-FU appear to be superior to bolus doses. However, leucovorin does not appear to improve efficacy of adjuvant treatment for rectal cancer. Use of oral alternatives to 5-FU that are also known to enhance radiation effects, such as capecitabine, are under investigation with preliminary data suggesting the combination of capecitabine and radiation is likely to be safe and effective. In addition, based on the efficacy in colon cancer, FOLFOX regimens have moved into clinical trials in the adjuvant setting.

Another unique aspect of rectal cancer is the use of neoadjuvant therapy. Preoperative radiation (with or without chemotherapy) is given to downstage the tumor before surgical resection to improve sphincter preservation.

**Key Concept**  Metastatic rectal cancer is treated with similar regimens as outlined in the colon cancer section are used for palliation of symptoms.

### OUTCOME EVALUATION

The goals of monitoring are to evaluate whether the patient is receiving any benefit from the management of the disease, detect recurrence, and minimize the adverse effects of treatment. During treatment for active disease, patients should undergo monitoring for measurable tumor response, progression, or new metastases; these tests may include chest CT scans or x-rays, abdominal or pelvic CT scans or x-rays, depending on the site of disease being evaluated for response; and carcinoembryonic antigen (CEA) measurements every 3 months if the CEA level is or was previously elevated. A PET scan can be considered to identify localized sites of metastatic disease when a rising CEA level suggests metastatic disease but results of CT scans and other imaging studies are negative. Symptoms of recurrence such as pain, changes in bowel habits, rectal bleeding, pelvic masses, anorexia, and weight loss develop in fewer than 50% of patients. Patients who undergo curative surgical resection, with or without adjuvant therapy, require close follow-up because early detection and treatment of recurrence could still result in patient cures. In addition, early treatment for asymptomatic metastatic colorectal cancer appears superior to delayed therapy. Colorectal cancer surveillance guidelines published by the American Society of Clinical Oncology recommend against routinely monitoring liver function tests, complete blood count (CBC), FOBT, CT scans, annual chest x-rays, or pelvic imaging in asymptomatic patients.

In addition, a CBC should be obtained before each course of chemotherapy administration to ensure that hematologic values are adequate. In particular, white blood cell counts and absolute neutrophil counts can be decreased in patients receiving chemotherapy such as irinotecan and 5-FU. Baseline liver function tests and an assessment of renal function should be evaluated.

### Patient Care Process

#### Patient Assessment:
- Based on a review of symptoms and presenting signs and symptoms, determine what signs and symptoms the patient is experiencing are related to their colon cancer diagnosis.
- Review the medication history (including prescription and OTC medications) to identify agents that may worsen the patient’s symptoms of colon cancer. Identify agents that effect bowel function (resulting in diarrhea or constipation) or agents such as NSAIDs that may cause GI bleeding.
- Review all laboratory and imaging studies, focus on the CBC, serum creatinine, and hepatic function.
- Determine performance status of the patient (see Chapter 88).

#### Therapy Evaluation:
- Determine if the patient requires chemotherapy to treat the colon cancer. If you determine they need therapy, evaluate treatment options for the patient.
- Review the chemotherapy order and assess efficacy, dosages, drug-interactions, and possible adverse effects from the regimen (see Tables 91–3 and 91–5).

#### Care Plan Development:
- Discuss lifestyle modifications that may assist in symptom and disease management.
- Calculate the body surface area (BSA) and determine if doses are optimal and correct for this patient. Evaluate laboratory values to assist in this process.
- Review supportive care options to decrease the impact of adverse effects for this patient (see Chapters 88 and 99).
- Counsel patient on potential adverse effects of the regimen.

#### Follow-up Evaluation:
- Follow up when the patient is scheduled for their next round of chemotherapy. Assess the patient for adverse effects of the regimen or other supportive care measures that may need to be added (eg, pain management).
- Review medication history, physical examination, laboratory results, and other imaging and diagnostic tests to evaluate if the patient should continue on their current chemotherapy regimen.
before and periodically during therapy. Other selected laboratory tests include checking for the presence of protein in the urine in patients receiving bevacizumab and monitoring of magnesium, calcium, and potassium in patients receiving cetuximab or panitumumab.

Patients should be evaluated during every treatment visit for the presence of anticipated side effects from their treatment, and health care practitioners should anticipate these adverse reactions and aggressively treat and prevent them from occurring. These generally include loose stools or diarrhea from irinotecan, 5-FU, and capecitabine; hand–foot syndrome from 5-FU and capecitabine; nausea or vomiting from irinotecan, 5-FU, and oxaliplatin; mouth sores from 5-FU; neuropathies from oxaliplatin; bleeding and hypertension from bevacizumab; and skin rash associated with cetuximab and panitumumab.

**SUMMARY**

Recent advances in the treatment of cancer of the colon and rectum now offer the potential to improve patient survival, but for many patients, improved DFS and PFS represent equally important therapeutic outcomes. In the absence of the ability of a specific treatment to demonstrate improved survival, important outcome measures should include the effects of the treatment on patient symptoms, daily activities, PS, and other quality-of-life indicators. Individualized patient care to balance the risks associated with treatment and benefits of a specific treatment regimen is necessary to optimize patient outcomes.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the risk factors associated with the development of prostate cancer.
2. Discuss the benefits and risks associated with screening for prostate cancer.
3. Determine the prognostic- and patient-specific data needed to determine appropriate treatment options.
4. Recommend an initial treatment for prostate cancer on the basis of stage, Gleason score, prostate-specific antigen, patient age, and symptoms.
5. State adverse effects associated with androgen deprivation therapy.
6. List adverse effects associated with treatment options for castrate-resistant prostate cancer.
7. Determine an appropriate treatment for a patient with metastatic castrate-resistant prostate cancer.

INTRODUCTION

Prostate cancer is the most commonly diagnosed cancer in US men and the second leading cause of cancer-related death in men.1 The disease course varies from a slow growing, asymptomatic tumor that may not require treatment to a rapidly progressing, aggressive tumor resulting in distant metastasis, morbidity, and mortality.

EPIDEMIOLOGY AND ETIOLOGY

Prostate cancer is the most frequently diagnosed cancer among US men and represents the second leading cause of cancer-related deaths in all men.1 In the United States alone, it was predicted that more than 280,000 new cases of prostatic cancer will be diagnosed and more than 27,000 men would die from this disease in 2015.1 Although prostate cancer incidence increased during the late 1980s and early 1990s, owing to widespread prostate-specific antigen (PSA) screening, deaths from prostate cancer have been declining since 1995.2 In the United States, 1 in 6 men will be diagnosed with prostate cancer, with 1 in 35 eventually succumbing to the disease.

The widely accepted risk factors for prostate cancer are age, race, and family history of prostate cancer (Table 92–1). Age is the greatest predictor of risk, the disease is rare under the age of 40, but the incidence sharply increases with each subsequent decade of life.2 In an evaluation of autopsies from men in Michigan dying of unrelated causes, prostate cancer was identified in 2%, 29%, 32%, 55%, and 64% of men in their third, fourth, fifth, sixth, and eighth decades of life, respectively.3 Men of older age have had a greater lifetime exposure to testosterone, a known growth signal for the prostate.

Race

The incidence of clinical prostate cancer varies across geographic regions. Scandinavian countries and the United States report the highest incidence of prostate cancer, but the disease is less common in Japan and other Asian countries.2 African American men have the highest rate of prostate cancer in the world, and prostate cancer mortality in African Americans is approximately twice that seen in the white population. Hormonal, dietary, and genetic differences, as well as differences in access to health care, may contribute to the variability in incidence and mortality in these populations.2 Testosterone, commonly implicated in the pathogenesis of prostate cancer, is 15% higher in African American men compared with white men. Activity of 5-α-reductase, the enzyme that converts testosterone to its more active form, dihydrotestosterone (DHT), in the prostate is decreased in Japanese men compared with African Americans and whites.2,3 In addition, genetic variations in the androgen receptor exist. Activation of the androgen receptor is inversely correlated with trinucleotide (CAG) repeat length. Shorter CAG repeat sequences have been found in African Americans. The combination of increased testosterone and increased androgen receptor activation may account for the increased risk of prostate cancer in African American men.2

Family History

Men with a brother or father with prostate cancer have twice the risk for prostate cancer compared to the rest of the population.2 Genome-wide scans have identified potential prostate cancer susceptibility candidate genes, and there appears to be a familial clustering of a prostate cancer syndrome. Common exposure
to environmental and other risk factors may also contribute to increased risk among patients with first-degree relatives with prostate cancer. Male carriers of germline mutations of *BRCA1* and *BRCA2* are known to have an increased risk for developing prostate cancer, although sequencing of these genes is not commonly performed. However, as evidence has accumulated that several additional germline DNA sequence variants may be associated with prostate cancer, the possibility that genetic testing might be used to aid in prostate cancer screening, detection, diagnosis, or risk stratification has emerged. In one analysis, five such sequence variants, three single nucleotide polymorphisms (SNPs) at 8q24 and one each at 17q12 and 17q24.3, were found to have a marked association with prostate cancer, especially for men with a family history of the disease, showing a 9.46-fold increased risk (with 95% confidence interval of 3.62–24.72) for a prostate cancer diagnosis.

### Diet

A number of epidemiologic studies support an association between high fat intake and risk of prostate cancer. Dietary factors that are potentially protective for prostate cancer include retinol, carotenoids, lycopene, calcium, and vitamin D consumption. Tomatoes, pink grapefruit, and watermelon are rich in lycopenes, antioxidants that help prevent damage to DNA. Studies suggest that lycopenes may help lower prostate cancer risk, but prospective clinical trials are needed. A large trial of selenium and vitamin E supplementation to prevent prostate cancer failed to show any benefit.

### Other Factors

Benign prostatic hyperplasia (BPH) is a common problem among elderly men, affecting more than 40% of men older than the age of 70 years. BPH results in the urinary symptoms of hesitancy and frequency. Because prostate cancer affects a similar age group and often has similar presenting symptoms, the presence of BPH often complicates the diagnosis of prostate cancer, although it does not appear to increase the risk of prostate cancer.

Smoking has been associated with an increased risk of aggressive prostate cancer and smokers with prostate cancer have an increased mortality resulting from the disease compared with nonsmokers with prostate cancer.

### PATHOPHYSIOLOGY

The prostate gland is a solid, round, walnut-shaped organ positioned between the neck of the bladder and the urogenital diaphragm (Figure 92–1). Adenocarcinoma, the major pathologic cell type, accounts for more than 95% of prostate cancer cases. Much rarer tumor types include small cell neuroendocrine cancers, sarcomas, and transitional cell carcinomas. Prostate cancer can be graded systematically according to the histologic appearance of the malignant cell and then grouped into categories of well, moderately, or poorly differentiated grades. Prostate cancer is graded using the Gleason scale, in which tumors are divided into categories 1–5 (well to poorly differentiated). Two different specimens are examined, and the score for

each specimen is added. Groupings for total Gleason score are 2 to 4 for well differentiated, 5 or 6 for moderately differentiated, and 7 to 10 for poorly differentiated tumors. Poorly differentiated tumors grow rapidly (poor prognosis), while well-differentiated tumors grow slowly (better prognosis).

Metastatic spread can occur by local extension, lymphatic drainage, or hematogenous dissemination. Lymph node metastases are more common in patients with large, undifferentiated tumors that invade the seminal vesicles. The pelvic and abdominal lymph node groups are the most common sites of lymph node involvement (see Figure 92–1). Skeletal metastases from hematogenous spread are the most common sites of distant metastases. Typically, the bone lesions are osteoblastic or a combination of osteoblastic and osteolytic. The most common site of bone involvement is the lumbar spine. Other sites of bone involvement include the proximal femurs, pelvis, thoracic spine, ribs, sternum, skull, and humerus. The lung, liver, brain, and adrenal glands are the most common sites of visceral involvement, although, these organs usually are not involved initially. About 25% to 35% of patients have evidence of lymphangitic or nodular pulmonary infiltrates at autopsy.

Normal growth and differentiation of the prostate depends on the presence of androgens, specifically DHT. The testes and the adrenal glands are the major sources of circulating androgens. Hormonal regulation of androgen synthesis is mediated through a series of biochemical interactions among the hypothalamus, pituitary, adrenal glands, and testes (Figure 92–2).

Testosterone, the major androgenic hormone, accounts for 95% of the androgen concentration. The primary source of testosterone is the testes; however, 3% to 5% of testosterone is derived from direct adrenal cortical secretion of testosterone or C19 steroids such as androstenedione. In the prostate 5a-reductase converts testosterone to a more active form, DHT.

In early stage prostate cancers, aberrant tumor cell proliferation is promoted by the presence of androgens, namely testosterone and dihydrotestosterone. Blockade and reduction in the level of circulating androgens induces tumor regression in most patients. Hormonal manipulations to reduce circulating androgens can occur through several mechanisms (Table 92–2). The tests, the organs primarily responsible for androgen production, can be removed surgically (orchiectomy). Hormonal pathways that modulate prostatic growth can be interrupted at several steps (see Figure 92–2). Interference with gonadotropin-releasing hormone (GnRH) or LH (by estrogens, GnRH agonists, direct GnRH antagonists, progesterones, and cyproterone acetate) can reduce testosterone secretion by the testes. Estrogen administration reduces androgens by directly inhibiting LH release, acting directly on the prostate cell, or decreasing free androgens by increasing steroid-binding globulin levels.

The physiologic response to GnRH depends on both the dose and the mode of administration. Intermittent pulsed GnRH administration, which mimics the endogenous release pattern, causes sustained release of both LH and FSH, but high dose or continuous administration of GnRH inhibits gonadotropin release via receptor downregulation. Structural modification of the naturally occurring GnRH and innovative delivery have produced a series of GnRH agonists that cause a similar down-regulation of pituitary receptors and a decrease in testosterone production.

Androgen synthesis can also be inhibited in the testes or adrenal gland. Aminoglutethimide inhibits the desmolase–enzyme complex in the adrenal gland, thereby preventing the conversion of cholesterol to pregnenolone. Pregnenolone is the precursor substrate for all adrenal-derived steroids, including androgens, glucocorticoids, and mineralocorticoids. Abiraterone is a specific and potent inhibitor of CYP17A1, decreasing the conversion of pregnenolone to dihydroepiandrosterone (DHEA), a

---

required precursor for testosterone. Ketoconazole, an imidazole antifungal agent, causes a dose-related reversible reduction in serum cortisol and testosterone concentration through a similar mechanism. Megestrol is a synthetic derivative of progesterone that exhibits a secondary mechanism of action by inhibiting the synthesis of androgens. This inhibition appears to occur at the adrenal level, but circulating levels of testosterone also are reduced, suggesting that inhibition at the testicular level also may occur.\(^5\)\(^11\)

Antiandrogens inhibit the formation of the DHT–receptor complex and thereby interfere with androgen-mediated action at the cellular level. Megestrol acetate, a progestational agent, also is available and has antiandrogen actions.\(^5\)\(^11\) Finally, the conversion of testosterone to DHT may be inhibited by 5-α-reductase inhibitors.

In advanced stages of the disease, prostate cancer cells may be able to survive and proliferate without the signals normally provided by circulating androgens.\(^9\)\(^11\) When this occurs, these tumors are referred to as castrate resistant and were formally known as hormone refractory or androgen independent. Because tumors remain amenable to secondary hormonal manipulations, and because the reintroduction of androgens can continue to promote tumor growth, the term castrate resistant more accurately reflects the clinical picture.

### PREVENTION AND EARLY DETECTION

#### Chemoprevention

Significant decreases in the risk of prostate cancer have been demonstrated by the 5-α-reductase inhibitors finasteride and dutasteride.\(^13\)\(^14\) Finasteride selectively inhibits the 5-α-reductase type-II isoenzyme, whereas dutasteride inhibits both type I and type II. Both finasteride and dutasteride lower the PSA by approximately 50%.\(^9\)\(^13\) This lowering may vary across individuals or within the same individual over time. Although no prospective studies have validated a specific threshold for PSA monitoring in patients receiving a 5-α-reductase inhibitor, common clinical practice is to lower the PSA threshold by one-half, for example, a PSA of 4 ng/mL (4 mcg/L) for a man on dutasteride would be considered the same as a PSA of 8 ng/mL (8 mcg/L) for a man not on dutasteride.

The Prostate Cancer Prevention Trial compared 5 mg/day of finasteride for 7 years with placebo for the prevention of prostate cancer in men 55 years of age or older with normal digital rectal examination findings and a PSA of 3.0 ng/mL (3.0 mcg/L) or less. When compared with placebo, the prevalence of prostate cancer was reduced for those on finasteride by 24.8%. However, in those who did develop prostate cancer, there was an increase in the number of high-grade (Gleason grade, 7–10) tumors detected at biopsy in the finasteride group. Overall, finasteride did reduce the frequency of prostate cancer; however, the prostate cancers that were diagnosed in the finasteride group were more aggressive. There were no differences in overall survival. Common adverse events included decreased libido, erectile dysfunction, and gynecomastia.\(^13\)

Dutasteride was evaluated in a different population of men.\(^19\) The study randomized men that were 50 to 75 years of age with PSA levels of 2.5 to 10 ng/mL (2.5–10 mcg/L) and a recent negative prostate biopsy result to dutasteride 0.5 mg/day or placebo. Treatment with dutasteride resulted in a significant reduction in the risk for prostate cancer (RR reduction of 22.8%) as well as a reduction in acute urinary retention. There were no significant differences in overall survival.\(^15\)

5-α-Reductase inhibitors decrease the period prevalence of for-cause prostate cancer by approximately 26% (RR, 0.74; 95% CI, 0.67–0.83). The absolute risk reduction is about 1.4%, although this may vary with the age of the treated population. On the basis of these outcomes, the ASCO and AUA guidelines recommend that asymptomatic men with a PSA less than or equal to 3 ng/mL (3 mcg/L) who are regularly screened with PSA may benefit from a discussion of both the benefits of 5-α-reductase inhibitors for 7 years for the prevention of prostate cancer and the potential risks (including adverse effects and the possibility of high-grade prostate cancer). Men who are taking 5-α-reductase inhibitors for benign conditions such as lower urinary tract symptoms may benefit from a similar discussion.\(^16\)

### Screening

Early detection of potentially curable prostate cancers is the goal of prostate cancer screening. For cancer screening to be beneficial, it must reliably detect cancer at an early stage, and identify those cancers that would benefit from an early intervention and decrease mortality. Whether prostate cancer screening fits these criteria has generated considerable controversy.\(^17\)\(^18\) Digital rectal examination (DRE) has been recommended since the early 1900s for the detection of prostate cancer. The primary advantage of DRE is its specificity, reported at greater than 85%, for prostate cancer. Other advantages of DRE include low cost, safety, and ease of performance. However, DRE is relatively insensitive and is subject to interobserver variability. DRE as a single-screening method has poor compliance and had little effect on preventing metastatic prostate cancer in one large case-control study.

**KEY CONCEPT** Prostate-specific antigen (PSA) is a useful marker for detecting prostate cancer at early stages, predicting outcome for localized disease, monitoring disease-free status, and monitoring response to treatment of advanced-stage disease. PSA is a member of the human kallikrein gene family of serine proteases. PSA is produced by columnar secretory cells in the prostate and plays a role in the liquefaction of seminal fluid. Periodic PSA monitoring is used widely for prostate cancer screening in the United States, with simplicity as its major advantage and low specificity as its primary limitation.\(^18\) Although PSA is often elevated in men with prostate cancer, the PSA may also be elevated in men who are smokers or with acute urinary retention, acute prostatitis, and prostatic ischemia or infarction, as well as BPH, a common condition in men at risk for prostate cancer. PSA elevations between 4.1 ng/mL (4.1 mcg/L) and 10 ng/mL (10 mcg/L) cannot distinguish between BPH and prostate cancer, limiting the utility of PSA alone for the early detection of prostate cancer. Additionally, not all men with clinically significant prostate cancer have a serum PSA outside the reference range.\(^17\)

---

**Patient Encounter 1: Prevention and Screening**

A 56-year-old man comes into the pharmacy for a refill of his finasteride, which he is taking for BPH. He wants to know what he can do to reduce his risk of prostate cancer.

This patient does not have a family history of prostate cancer. He has never been screened for prostate cancer.

**What do you recommend for prostate cancer screening?**

**What do you recommend for prostate cancer chemoprevention?**
The benefit of prostate cancer screening is controversial. PSA measurements can identify small, subclinical prostate cancers, in which no intervention may be required. Detecting prostate cancer in those not needing therapy subjects some patients to unnecessary workups and psychological stress related to a cancer diagnosis. Currently, the American College of Physicians recommends that rather than screening all men for prostate cancer as a matter of routine, physicians should describe the potential benefits and known risks of screening, diagnosis, and treatment; listen to the patient’s concerns; and then decide on an individual’s screening method. The US Preventative Task Force rates PSA screening for prostate cancer a grade D, intended to “discourage the use of the service.”

**CLINICAL PRESENTATION AND DIAGNOSIS (Table 92–3)**

**KEY CONCEPT** The prognosis for patients with prostate cancer depends on the histologic grade and stage of the prostate cancer. Details of staging is discussed in Chapter 88. One of the most important prognostic criteria appears to be the histologic grade, assessed by Gleason score. Poorly differentiated tumors are highly associated with both regional lymph node involvement and distant metastases. Once the tumor has spread into locoregional lymph nodes, there is a significantly increased risk of recurrence of disease after curative intent therapy.

**TREATMENT**

**Desired Outcome**

The desired outcome in early stage prostate cancer is to minimize morbidity and mortality from prostate cancer with consideration that some degree of morbidity may be caused by the toxicity of treatment. Early stage disease may be treated with surgery, radiation, or observation. Although surgery and radiation are curative, they are associated with significant morbidity and a low rate of mortality. Because the overall goal is to minimize morbidity and mortality associated with the disease, observation is appropriate in selected individuals with a low risk of rapid disease progression. Advanced prostate cancer (metastatic spread) is not curable, and treatment of advanced disease should focus on providing symptom relief and maintaining quality of life.

**General Approach to Treatment**

The initial treatment for prostate cancer depends on the disease stage, Gleason score, presence of symptoms, and life expectancy of the patient. For asymptomatic patients, determining risk for disease progression and recurrence are critical for determining treatment options. Asymptomatic patients with a low risk of recurrence, those with a T1 or T2a tumor, with a Gleason score of 2 through 6, and a PSA of less than 10 ng/mL (10 mcg/L) may be managed by active surveillance. However, radiation or radical prostatectomy may also be offered (Table 92–4). Because patients with asymptomatic, early stage disease generally have an excellent 10-year survival rate, immediate morbidities of prostatectomy or radiation must be balanced with the lower likelihood of dying from prostate cancer. In general, more aggressive treatments of early stage prostate cancer are reserved for younger men, although patient preference is a major consideration in all treatment decisions. In a patient with a life expectancy of less than 10 years, observation or radiation therapy alone may be preferred. In those with a life expectancy of equal to or greater than 10 years, radiation (external beam or brachytherapy), or radical prostatectomy with a pelvic lymph node dissection may be offered; however, observation can still be used.

Radical prostatectomy and radiation therapy generally are considered therapeutically equivalent for localized prostate cancer. Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence). Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence. Because radiation and prostatectomy have significant and immediate morbidity compared with observation alone, some patients may elect to postpone therapy.

PSA, prostate-specific antigen.

Individuals with T₃a disease or a Gleason score of 7 or a PSA ranging from 10 to 20 ng/mL (10 to 20 mcg/L) are considered at intermediate risk for prostate cancer recurrence. Individuals with less than a 10-year expected survival may be offered observation, radiation therapy, or radical prostatectomy with or without a pelvic lymph node dissection, and those with a greater than or equal to 10-year life expectancy may be offered either radical prostatectomy with or without a pelvic lymph node dissection or radiation therapy (see Table 92–4).

The patients at high risk of recurrence (stages T₃b, a Gleason score ranging from 8 to 10, or a PSA value greater than 20 ng/mL [20 mcg/L]) should be treated with androgen deprivation therapy for 2 to 3 years combined with radiation therapy (Table 92–5). Selected individuals with a low tumor volume may receive a radical prostatectomy with or without a pelvic lymph node dissection.

Patients with T₃a and T₄ disease have a very high risk of recurrence and are usually not candidates for radical prostatectomy because of extensive local spread of the disease.

aAndrogen ablation = serum testosterone levels less than 50 ng/dL (1.74 nmol/L).
bLuteinizing hormone–releasing hormone agonist (medical castrations or surgical are equivalent).

Patient Encounter 2: Initial Presentation and Treatment

A 58-year-old man presents to the clinic for follow-up of routine screening with DRE and PSA.

Physical examination is positive for a 1-cm nodule in the prostate, and his laboratory study results reveal the following: PSA, 22 ng/mL (22 mcg/L); PSA from 2 years ago was 2.4 ng/mL (2.4 mcg/L).

A prostate biopsy by TRUS reveals adenocarcinoma of the prostate with a Gleason score of 7. CT scanning and bone scan reveal disease that is metastatic to regional lymph nodes and the lumbar vertebrae.

Based on his metastatic disease, what are treatment options for this patient?
**Orchiectomy**

Bilateral orchiectomy, or removal of the testes, rapidly reduces circulating androgens to castrate levels (ie, serum testosterone levels less than 50 ng/dL [1.74 nmol/L]). However, many patients find this procedure psychologically unacceptable, and others are not surgical candidates. Orchiectomy may be preferred in the initial treatment of patients with impending spinal cord compression or ureteral obstruction.

**Radiation**

The two commonly used methods for radiation therapy are external-beam radiotherapy and brachytherapy. In external-beam radiotherapy, doses of 70 to 75 Gy are delivered in 35 to 41 fractions in patients with low-grade prostate cancer and 75 to 80 Gy for those with intermediate- or high-grade prostate cancer. Brachytherapy involves the permanent implantation of radioactive beads of 145 Gy 125-iodine or 124 Gy of 103-palladium and is generally reserved for individuals with low-risk cancers. Radiation therapy may be used to treat local or locally advanced prostate cancer with curative intent. In later stages of disease, short courses of external beam radiation therapy can be used to palliate symptoms.

**Radical Prostatectomy**

Radical prostatectomy is performed in patients who are surgical candidates with disease that requires definitive therapy based on risk factors and patient preference; additionally, the disease must be amenable to complete surgical resection. Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. Acute complications from radical prostatectomy and radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence). Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence. Because radiation and prostatectomy have significant and immediate mortality when compared with observation alone, many patients may elect to postpone therapy until symptoms develop.

**Pharmacologic Therapy**

**Gonadotropin-Releasing Hormone Agonists**

GnRH agonists are a reversible method of androgen deprivation and are as effective as orchiectomy in treating prostate cancer. Currently available GnRH agonists include leuprolide, leuprolide depot, leuprolide implant, triptorelin depot, triptorelin implant, and goserelin acetate implant. Leuprolide acetate is administered once daily, whereas leuprolide depot and goserelin acetate implant can be administered once monthly, once every 12 weeks, or once every 16 weeks (leuprolide depot). The leuprolide depot formulation contains leuprolide acetate in coated pellets. The dose is administered intramuscularly, and the coating dissolves at different rates to allow sustained leuprolide levels throughout the dosing interval. Goserelin acetate implant contains goserelin acetate dispersed in a plastic matrix of D,L-lactic and glycolic acid copolymer and is administered subcutaneously. Hydrolysis of the copolymer material provides continuous release of goserelin over the dosing period. Another formulation of leuprolide is a miniosmotic pump implanted intramuscularly that delivers 120 mcg of leuprolide daily for 12 months. After 12 months, the implant is removed, and a different implant can be placed. Triptorelin LA is administered as an intramuscular injection of 11.25 mg every 84 days. Triptorelin depot is administered once every 28 days as a 3.75-mg dose.

Several randomized trials have demonstrated that leuprolide, goserelin, and triptorelin are effective agents when used alone in patients with advanced prostate cancer. Response rates around 80% have been reported, with a lower incidence of adverse effects compared with estrogens. The choice between the three GnRH agonists is usually made on the basis of cost and patient and physician preference for a dosing schedule.

The most common adverse effects reported with GnRH agonist therapy include vasomotor symptoms such as hot flashes, erectile impotence, decreased libido, and injection site reactions. Long-term adverse effects include decreased bone mineral density and metabolic syndrome. Disease flare-up in the first weeks of therapy can be caused by an initial induction of LH and FSH by the GnRH agonist, leading to an initial phase of increased testosterone production. It manifests clinically as an exacerbation of disease-related symptoms, usually increased bone pain or urinary symptoms. This flare reaction usually resolves after 2 weeks and has a similar onset and duration pattern for the depot GnRH products. Initiating an antiandrogen before the administration of the GnRH agonist and continuing for 2 to 4 weeks is a frequently used strategy to minimize this initial tumor flare.

GnRH agonist monotherapy can be used as initial therapy of advanced prostate cancer, with response rates similar to orchiectomy. They are preferred to orchiectomy for the adjuvant treatment of locally advanced prostate cancer as they are reversible. There is a lower incidence of cardiovascular-related adverse effects associated with GnRH therapy than with estrogen administration. A short course of concomitant antiandrogen therapy may need to be considered before initiating the GnRH agonist. Caution should be exercised if initiating GnRH agonist monotherapy in patients with widely metastatic disease involving the spinal cord or having the potential for ureteral obstruction because irreversible complications may occur.

Another potentially serious complication of androgen deprivation therapy is a resultant decrease in bone-mineral density, leading to an increased risk for osteoporosis, osteopenia, and an increased risk for skeletal fractures. Most clinicians recommend that men starting long-term androgen deprivation therapy should have a baseline bone mineral density test and be initiated on a calcium and vitamin D supplement.

**Gonadotropin-Releasing Hormone Antagonists**

An alternative to GnRH agonists is the GnRH antagonist, degarelix. Degarelix reversibly binds to GnRH receptors in cells in the pituitary gland, reducing the production of testosterone to castrate levels. The major advantage of direct GnRH agonists is the speed at which they can achieve the drop in testosterone levels; castrate levels are achieved in 7 days or less with degarelix, compared with 28 days with leuprolide, eliminating the tumor flare seen and need for antiandrogens with GnRH agonists. Degarelix is equivalent to leuprolide in lowering testosterone levels for up to 1 year and is approved by the Food and Drug Administration for the treatment of advanced prostate cancer. Degarelix is available as 40-mg/mL and 20-mg/mL vials for subcutaneous injection, and the starting dose is 240 mg followed by 80 mg every 28 days. The starting dose should be split into two injections of 120 mg.

The most frequently reported adverse reactions are injection site reactions, including pain (28%), erythema (17%), swelling (6%), induration (4%), and nodule (3%). Most adverse effects were transient and mild to moderate, leading to discontinuation.
in fewer than 1% of study subjects. Other adverse effects included elevations in liver function tests, which occurred in approximately 10% of study subjects. Similar to other methods of androgen deprivation therapy, osteoporosis may develop, and calcium and vitamin D supplementation should be considered. Degarelix is not approved in combination with antiandrogens.

**Antiandrogens**

The first generation of nonsteroidal antiandrogens include flutamide, bicalutamide, and nilutamide (Table 92–6). Monotherapy with first-generation antiandrogens is less effective than GnRH agonist therapy. Therefore, for advanced prostate cancer, all currently available antiandrogens are indicated only in combination with androgen-deprivation therapy, flutamide and bicalutamide are indicated in combination with a GnRH agonist, and nilutamide is indicated in combination with orchiectomy. Enzalutamide is a second-generation antiandrogen that is indicated in metastatic castrate-resistant prostate cancer.

The most common antiandrogen-related adverse effects are listed in Table 92–6. Diarrhea is reported more frequently with flutamide than bicalutamide. Few clinical trials have made direct comparisons among the first-generation antiandrogens.

**Combined Androgen Blockade**

Although up to 80% of patients with advanced prostate cancer respond to initial hormonal manipulation, almost all patients progress within 2 to 4 years after initiating therapy. Multiple mechanisms have been proposed to explain this tumor resistance. The tumor could be heterogeneously composed of cells that are hormone dependent and hormone independent, or the tumor could be stimulated by extratesticular androgens that are converted intracellularly to DHT. The rationale for combination GnRH agonists and first-generation antiandrogens is to interfere with multiple hormonal pathways to more completely eliminate androgen action. In clinical trials, combination hormonal therapy, also referred to as combined androgen blockade (CAB), has been used. The combination of GnRH agonists or orchiectomy with antiandrogens is the most extensively studied CAB approach.

Many studies comparing CAB with conventional medical or surgical castration have been performed. CAB likely results in a small extension in overall survival compared to GnRH agonist alone or orchiectomy. However, adverse effects such as diarrhea, elevated liver function test results, and anemia are more common in those patients who receive CAB. Because the benefits of CAB are relatively small and the increased adverse effects are not insignificant, it is appropriate to use either GnRH agonist monotherapy or CAB as initial therapy for metastatic prostate cancer. CAB may be most beneficial for improving survival in patients with minimal disease and for preventing tumor flare. All other patients may be started on GnRH monotherapy, and an antiandrogen may be added after several months if androgen ablation is incomplete, or if disease progression occurs despite a castrate level of testosterone.

There is considerable debate concerning when to start hormonal-deprivation therapy in patients with advanced prostate cancer. The original recommendation to start therapy when symptoms appeared was based on trials in which no overall survival difference was demonstrated in patients who either started DES initially or crossed over to active treatment when symptoms appeared; the excess mortality rate was attributed to estrogen administration. Because GnRH agonists and antiandrogens have less cardiovascular toxicity, it is not clear whether delaying therapy is justified with these agents. Thus, early intervention before symptoms appear is appropriate.

**Secondary Therapies**

Secondary or salvage therapies for patients who progress after their initial therapy depend on what was used for initial management. For patients initially diagnosed with localized prostate cancer, radiotherapy may be used for local disease recurrence after radical prostatectomy. Alternatively, androgen deprivation therapy can be used in patients who progress after either radiation therapy or radical prostatectomy.

In patients treated initially with one hormonal modality, secondary hormonal manipulations may be attempted. This may include adding an antiandrogen for a patient who either incompletely suppresses testosterone secretion with a GnRH agonist or experiences disease progression while a castrate level of testosterone is maintained. In patients who have progression while receiving CAB, withdrawing antiandrogens, or using agents that inhibit androgen synthesis may be attempted.

For patients who initially received a GnRH agonist alone, castration testosterone levels should be documented. Patients with inadequate testosterone suppression more than 20 ng/dL (0.7 nmol/L) can be treated by adding an antiandrogen or performing an orchietomy. If castration testosterone levels have been achieved, the patient is considered to have castrate-resistant disease, and palliative salvage therapy can be used. Supportive care, enzalutamide, abiraterone, radium-223, chemotherapy, immunotherapy, and local radiotherapy can be used in patients who have failed androgen deprivation.

GI, gastrointestinal.
If the patient initially received CAB with a GnRH agonist with an antiandrogen, then anti androgen withdrawal is the first salvage manipulation. Objective and subjective responses have been reported following the discontinuation of flutamide, bicalutamide, or nilutamide in patients receiving these agents as part of CAB. Patient responses to androgen withdrawal manifest as significant PSA reductions and improved clinical symptoms. Androgen withdrawal responses lasting 3 to 14 months have been reported in up to 35% of patients, and predicting response seems to be most closely related to longer antiandrogen exposure times. Incomplete cross-resistance has been noted in some patients who received bicalutamide after they had progressed while receiving flutamide, suggesting that patients who fail one antiandrogen may still respond to another agent.22

**KEY CONCEPT** Once advanced prostate cancer progresses despite castrate levels of testosterone, it is known as castration-resistant prostate cancer.22 Previously, this was termed hormone refractory or androgen-independent prostate cancer. Castration resistant more accurately describes the cancer because it may continue to respond to treatments inhibiting the androgen pathways such as enzalutamide or abiraterone. Further, androgens remain a growth signal for the cancer and androgen deprivation therapy is continued throughout the treatment course of castrate-resistant prostate cancer.

**Enzalutamide**

Despite initial responses to androgen deprivation therapy and first-generation antiandrogens, disease resistance eventually develops. Enzalutamide is a second-generation antiandrogen that is effective in castrate-resistant prostate cancer, even when first-generation antiandrogens have failed.23 This may be because enzalutamide prevents the androgen receptor from entering the cell nucleus, further inhibiting androgen signaling. Enzalutamide improves overall survival in castrate-resistant prostate cancer compared to placebo.10,11 Primary adverse effects include fatigue, diarrhea, hot flashes, and musculoskeletal pain.33 A rare incidence of seizures was also noted. Enzalutamide is effective in patients that have failed previous chemotherapy, or in patients that are chemotherapy naive.24 Like other therapies for castrate-resistant prostate cancer, androgen deprivation therapy is continued. Enzalutamide is a strong CYP3A4 inducer and a moderate CYP2C9 and CYP2C19 inducer. Enzalutamide is known to decrease exposure and effect of multiple CYP enzyme substrates, including midazolam (CYP3A4 substrate), warfarin (CYP2C9 substrate), and omeprazole (CYP2C19 substrate).

**Abiraterone**

Despite androgen deprivation therapy with GnRH agonists, direct antagonists, or orchietomy. Androgen synthesis can continue to occur in the periphery (namely the adrenal glands) or within the tumor. The family of cytochrome P450 of enzymes plays a critical role in the synthesis of androgens. CYP17A1 inhibition prevents the conversion of pregnenolone to DHEA, a requisite precursor for testosterone. Abiraterone acetate is a potent and specific inhibitor of CYP17A1 resulting in further reduction of testosterone when combined with continued androgen deprivation. Inhibition of CYP17A1 results in mineral corticoid excess, which contributes to the primary adverse effects of abiraterone. These include fluid retention, hypokalemia, and hypertension.24 Less common significant adverse effects include hepatotoxicity. Abiraterone should be administered on an empty stomach either 2 hours after or 1 hour before a meal, as food significantly increases absorption. Abiraterone is effective in castration-resistant prostate cancer in chemotherapy naïve patients, as well as in patients with disease progression on docetaxel, not previously treated with abiraterone.25,26,34

Androgen synthesis inhibitors, such as aminoglutethimide 250 mg orally every 6 hours or ketoconazole 400 mg orally three times a day, can provide symptomatic relief for a short time in approximately 50% of patients with progressive disease despite previous androgen- ablation therapy.26 Adverse effects during aminoglutethimide therapy occur in approximately 50% of patients. Central nervous system effects that include lethargy, ataxia, and dizziness are the major adverse reactions. A generalized morbilliform, pruritic rash has been reported in up to 30% of patients treated. The rash is usually self-limiting and resolves within 5 to 8 days with continued therapy. Adverse effects from ketoconazole include diarrhea, transient rises in liver and renal function tests, and hypoadrenalism. Additionally, ketoconazole is a strong inhibitor of CYP1A2 and CYP3A4. Absorption of ketoconazole requires gastric acidity; therefore, ketoconazole should not be administered with H₂-blockers, proton pump inhibitors, or antacids. Ketoconazole should be combined with replacement doses of hydrocortisone to prevent symptomatic hypoadrenalism.

**Zoledronic Acid and Denosumab**

Skeletal metastases from hematogenous spread are the most common sites of distant spread of prostate cancer. Typically, the bone lesions are osteoblastic or a combination of osteoblastic and osteolytic. Bisphosphonates may prevent skeletal-related events and improve bone mineral density. Zoledronic acid at a dose of 4 mg every 3 weeks reduces the incidence of skeletal-related events (such as the need for palliative radiation or pathologic fracture) by 25% compared with placebo.35

Denosumab, a monoclonal antibody targeted against the receptor activator of nuclear factor kappa-B (NF-κB), also

</tbody>
</table>

Today he presents to the clinic with bone pain and a serum PSA of 67 ng/mL (67 mcg/L).

**Why was bicalutamide discontinued on 10/2/14?**

**How would you characterize the patient’s disease?**

**What treatments are options for him?**
increases the incidence of skeletal-related events in patients with castrate-resistant prostate cancer with bone metastasis. Denosumab is a subcutaneous injection administered at a dose of 120 mg every 4 weeks. While it may cause a higher incidence of hypocalcemia compared to zoledronic acid, it also provides greater protection against skeletal-related events, such as fracture. Similar to zoledronic acid, patients should be counseled to take calcium and vitamin D supplementation. Both denosumab and zoledronic acid also associated with a low but significant rate of osteonecrosis of the jaw. Dental procedures should be avoided while receiving these agents and dental screening prior to initiation is recommended.

**Chemotherapy with docetaxel and prednisone improves survival in patients with castrate-resistant prostate cancer.**

Docetaxel 75 mg/m² every 3 weeks combined with prednisone 5 mg twice a day improves survival in hormone-refractory metastatic prostate cancer. The most common adverse events reported with this regimen are nausea, alopecia, and bone marrow suppression. In addition, fluid retention and peripheral neuropathy, known effects of docetaxel, are observed. Docetaxel is hepatically eliminated; patients with hepatic impairment may not be eligible for treatment with docetaxel because of an increased risk for toxicity.

The combination of estramustine (280 mg three times a day, days 1 to 5) and docetaxel 60 mg/m² on day 2 every 3 weeks also improves survival in hormone-refractory metastatic prostate cancer. Estramustine causes a decrease in testosterone and a corresponding increase in estrogen; therefore, the adverse effects of estramustine include an increase in thromboembolic events, gynecomastia, and decreased libido (Table 92–7). Estramustine is an oral capsule and should be refrigerated. Calcium inhibits the absorption of estramustine. Although both the docetaxel–prednisone and the docetaxel–estramustine regimens are effective in hormone-refractory prostate cancer, the docetaxel/prednisone regimen reported similar efficacy without the cardiovascular adverse effects associated with estramustine. In addition, androgen deprivation is continued when chemotherapy is initiated.

The regimen of mitoxantrone plus prednisone has been shown to be effective in reducing pain from bone metastasis and was a standard therapy before the development of docetaxel and prednisone. Now, therapy with mitoxantrone is relegated to a salvage therapy after failure of other therapies.

**Chemotherapy with cabazitaxel and prednisone improves survival in patients with castrate-resistant prostate cancer who have either progressed or are intolerant to docetaxel.**

Cabazitaxel is an antimicrotubule taxane with demonstrated activity in docetaxel-resistant cell lines and animal models of human cancer. A partial explanation is that docetaxel is a substrate for P-glycoprotein multidrug resistance transporter while cabazitaxel has low affinity. In patients previously treated with docetaxel and prednisone, treatment with cabazitaxel 25 mg/m² every 3 weeks with prednisone 10 mg/day significantly improved progression-free survival and overall survival compared with mitoxantrone and prednisone. Neutropenia, febrile neutropenia, neuropathy, and diarrhea are the most significant toxicities. Hypersensitivity reactions may occur, and premedication with an antihistamine, a corticosteroid, and an H₂ antagonist is recommended. Cabazitaxel is extensively hepatically metabolized and should be avoided in patients with hepatic dysfunction (Table 92–8).

**Immunotherapy with sipuleucel-T improves survival in patients with castrate-resistant prostate cancer with minimally symptomatic disease.**

Sipuleucel-T is a patient-specific anticancer vaccine. Patients eligible for treatment first undergo leukapheresis to collect dendritic cells, which are sent to a central processing laboratory. These are then cultured and stimulated with a fusion protein of prostatic phosphatase and granulocyte macrophage colony-stimulating factor. The cultured cells are then returned and injected into the patient. This procedure is performed three times—at 0, 2, and 4 weeks. Treatment is well tolerated with common adverse effects of moderate and transient chills, fever, and transient influenza-like symptoms. Although disease progression was not improved by sipuleucel-T, overall survival was significantly improved from 21.7 months with placebo to 25.8 months with sipuleucel-T. Because disease progression was not slowed by sipuleucel-T, it does not offer significant relief from disease-related symptoms. In symptomatic patients, or those with rapidly progressing disease an alternative treatment that delays tumor progression is more appropriate.

**Radium-223**

Radium-223 is an alpha particle emitting, calcium-mimetic, radiopharmaceutical that provides significant palliation to patients with castrate-resistant prostate cancer with bone metastasis. Radium is taken up into the osseous metastatic loci of prostate cancer, where it emits primarily alpha irradiation. Alpha irradiation, as opposed to beta, consists of higher energy, dispersed into a smaller radius of approximately 1 cell length. Radium-223 results in lower rates of myelosuppression compared to alpha emitting radiopharmaceuticals. When given to patients with a high bone disease burden and limited visceral

### Patient Care Process

**Patient Assessment:**
- Obtain complete past medical history, family history, and social history.
- Obtain complete list of any concomitant prescription and over-the-counter medications; be sure to include herbal, vitamin, and mineral supplements.
- Verify completion of prostate cancer workup and staging.

**Therapy Evaluation:**
- Using information obtained, identify appropriate treatment options.

**Care Plan Development:**
- Discuss the benefits and risks of appropriate treatment options with the health care team and patient.
- If drug therapy is selected, review patient medical history for drug–drug and drug–herbal interactions.
- Initiate therapy.

**Follow-up Evaluation:**
- If patient is asymptomatic, monitor PSA and circulating androgens for castration level of testosterone. If patient is symptomatic, monitor symptoms for improvement or worsening.
- Monitor for any new symptoms and adverse events from therapy.

### OUTCOME EVALUATION

Monitoring of prostate cancer depends on the stage of the cancer. When definitive, curative therapy is attempted, objective parameters to assess tumor response include assessment of the tumor size, evaluation of involved lymph nodes, and the response of tumor markers such as PSA to treatment. Following definitive therapy, the PSA level is checked every 6 months for the first 5 years and then annually.23 Local recurrence in the absence of a rising PSA may occur, so the DRE and radiologic studies are also performed. In the metastatic setting, clinical benefit responses can be documented by evaluating performance status changes, weight changes, quality of life, and analgesic requirements, in addition to the PSA or and radiologic studies to objectively measure tumor response.

### Abbreviations Introduced in This Chapter

- **BPH** Benign prostatic hyperplasia
- **CAB** Combined androgen blockade
- **DES** Diethylstilbestrol
- **DHT** Dihydrotestosterone
- **DRE** Digital rectal examination
- **FSH** Follicle-stimulating hormone
- **GnRH** Gonadotropin-releasing hormone
- **IM** Intramuscular
- **LH** Luteinizing hormone
- **LHRH** Luteinizing hormone–releasing hormone
- **NCI** National Cancer Institute
- **PSA** Prostate-specific antigen

INTRODUCTION

Skin cancer is the most prevalent of all malignancies occurring in humans, and in the United States, it accounts for more than 50% of all cancers. The most common cutaneous malignancies are basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and malignant melanoma (MM). BCC and SCC are categorized as nonmelanoma skin cancer (NMSC). It is estimated that more than 3.5 million cases (in more than 2 million people) of BCC and SCC and more than 100,000 cases of melanomas are diagnosed in the United States each year. NMSC and MM differ with regard to prognosis, metastatic potential, mortality, curability, and treatment options.

RISK FACTORS

Environmental

The risk factors for developing MM can be categorized as environmental factors and host factors. Exposure to ultraviolet radiation (UVR) from the sun is recognized as one of the primary triggers for skin carcinogenesis. UV radiation (specifically UVB) is absorbed by DNA in the cells in the epidermal layer and may induce DNA damage. Gene mutations, such as UV-induced mutation to the p53 tumor suppressor gene, may occur, resulting in dysregulation of apoptosis, expansion of mutated keratinocytes, and initiation of skin cancer. Other mechanisms of UV radiation–induced DNA damage include the generation of reactive oxygen species, which create breaks in DNA, leading to genetic mutations and skin cancer. It is estimated that 65% to 90% of MMs are attributable to UV exposure, particularly when a person has a history of intense and blistering sunburns in childhood. If a person experienced more than one severe sunburn in childhood, the risk of developing melanoma is increased two-fold. Exposure to sources of artificial UV radiation such as tanning beds has also been linked to increased risk of skin cancer.

Host Factors

Host risk factors for developing MM include individuals with phenotypic characteristics of red hair, light skin, blue eyes, sun sensitivity, and freckling. Family history of MM in a first-degree relative is another risk factor for developing MM, with a twofold likelihood compared with patients with no family history. In individuals without a family history of MM (sporadic...
Patient Encounter, Part 1

A 55-year-old woman presents to her dermatologist with a pigmented skin lesion on her left shoulder that she noticed had enlarged and changed color recently in the past few months.

**History:** She has the lesion since youth, and it was measured at 3 mm. She noticed the change in color and size in the past few months.

The woman reports being a “sun worshiper” all her life; she spends her weekends outdoors or at the pool and vacations at the beach. She notes that she burns initially and then eventually tans with excessive freckling. She reports using an indoor tanning bed 3 to 5 days a week for the past 20 years. She does not use sunscreen or practice sun protection measures.

**What are this patient’s risk factors for developing malignant melanoma?**

**What primary prevention measures are recommended to prevent skin cancer?**

**What is the recommendation to detect melanoma early in a patient?**

---

### PRIMARY PREVENTION OF SKIN CANCER

UVR exposure from the sun is the major cause of NMSC and MM. Primary prevention strategies for skin cancer aim at educating people against excessive exposure to the sun and are spearheaded by the American Academy of Dermatology, American Cancer Society, Environmental Protection Agency, and Centers for Disease Control and Prevention. The aims of these programs are to increase public awareness about the harmful effects of sun exposure and the risk of skin cancer, change attitudes about the social norms related to sun protection and tanned skin, and decrease the incidence of skin cancer and deaths related to this malignancy. The National Council on Skin Cancer Prevention recommends a variety of simple strategies to minimize exposure to UV rays:

- Seek shade when outdoors, especially between the hours of 10 AM and 4 PM when UV rays are most intense.
- Wear hats with a broad enough brim to shade the face, ears, and neck.
- Wear protective clothing (especially tightly woven apparel) that covers as much as possible the arms, legs, and torso.
- Cover skin with a sunscreen lotion with a skin protection factor (SPF) of at least 30, protecting against UV radiation (both UVA and UVB).
- Apply sunscreen 15 minutes before going outdoors and reapply sunscreens every 2 hours (especially if sweating or swimming).
- Avoid intentional tanning and tanning beds.
- Take extra caution near water, sand, and snow.

The use of chemical sunscreen is only one of many strategies, and it should not be the sole agent used for cancer prevention. Sunscreen protective agents have been proven only to reduce the risk of actinic keratosis (AK) and SCC. There is no convincing evidence that sunscreen application has protective effect against BCC or MM.

### SECONDARY PREVENTION OF SKIN CANCER

Secondary prevention of skin cancer involves early detection of premalignant cancers for early intervention with the hope that it will reduce mortality and increase cure. Regular screening for melanoma either by skin self-examination or total skin examination performed by health care providers consistently identify smaller and thinner lesions in high-risk patients. However, recommendations for melanoma screening are conflicting because there are no randomized, controlled, prospective melanoma trials demonstrating that routine screening reduces mortality.

### PATHOPHYSIOLOGY

MM is a cancer that arises from melanocytes, which are cells that synthesize melanin and contribute to hair and skin pigmentation. The overwhelming majority of MMs originate from the skin, although they may also arise less commonly from mucosal epithelial tissues such as the conjunctiva, oral cavity, esophagus, vagina, female urethra, penis, and anus. Exposure to UVR is an important factor in MM development. MM may occur in individuals with either inherent genetic susceptibility or low genetic susceptibility for melanocyte proliferation. The distinguishing characteristic is that MM may develop with less solar damage and on intermittent sun exposed body sites such as the trunk for individuals with high genetic susceptibility. Conversely, in individuals with low genetic susceptibility, melanoma occurs with chronic UV exposure on commonly exposed areas such as the face and neck.

### Genetic Pathway to the Development of Melanoma

Recent advances in molecular profiling and genome sequencing have enabled the identification of oncogenic mutations that drive MM progression. Much attention has been focused on the BRAF melanoma oncogene and its role in MM. BRAF is a serine/threonine protein kinase that is a member of the RAF kinase...
family, which is a part of the RAF/MEK/ERK serine threonine cascade (also known as ERK/MAP kinase pathway or "classical" MAPK pathway).11 Mutations in BRAF activates the ERK/MAP pathway and thus trigger melanocyte proliferation and clonal expansion. BRAF mutation is found in approximately one half of all MM, and BRAF mutant melanomas tend to occur on intermittent sun-exposed skin areas, skin phenotypes that have poor UV protection (eg, pale skin, poor tanning response, red hair, and freckling), and younger individuals (younger than 55 years) with lower cumulative UV exposure.12 There are more than 50 mutations in BRAF described, but the valine to glutamic acid (BRAF V600E) substitution accounts for over 75% of all BRAF mutations. Furthermore, this V600E mutation is the most common BRAF mutation in MM.11 Potent and selective BRAF kinase inhibitors are now a mainstay for treating BRAF mutation positive metastatic MM.

CLINICAL PRESENTATION, DIAGNOSIS, AND STAGING

There are four major subtypes of cutaneous MM: superficial spreading, nodular, lentigo maligna melanoma, and acral lentiginous (Table 93–1). They each vary in clinical and growth characteristics.13,14

Data from Surveillance, Epidemiology, and End Results (SEER) show that 84% of diagnosed MM are locally confined, 9% are diagnosed after the cancer has spread regionally, 4% are diagnosed with distant metastasis, and the remaining 3% are not staged.15 **KEY CONCEPT** Once skin cancer is diagnosed, the cancer is staged to determine if the cancer is confined to the original tumor site or has spread to other sites, such as the lymph nodes, liver, brain, lungs, or bone. The purpose of staging is to determine prognosis, categorize patients with regard to metastatic potential and survival probability, and aid in clinical decision making. As with most solid tumors, the tumor, node, metastasis (TNM) classification is used to stage MM.16 Staging of solid tumors is described in Chapter 88.

**KEY CONCEPT** Determination of lymph node status is important in melanoma staging because it is an independent prognostic factor, and it provides guidance for therapy decisions. For patients with MM that are at risk of spreading to the lymph nodes, a sentinel lymph node (SLN) biopsy is performed. The SLN, the first lymph node to receive lymph draining from the tumor, is identified by injecting a radioactive material, technetium-99m-labeled radiocolloids, and vital blue dye into the skin next to the tumor and tracing the flow of lymph from the tumor site to the nearest lymph node chain. Once the SLN is located, it is removed and analyzed for the presence of MM cells. If it is positive for the presence of MM, then the whole lymph node basin in that area is dissected; this is also known as lymphadenectomy. An SLN biopsy is the initial procedure to assess the status of lymph node involvement to prevent the morbidity associated with a total lymphadenectomy.

In addition to the stage of the disease and the status of disease involvement in the lymph nodes, other prognostic factors for outcome in MM include primary tumor thickness (Figure 93–1), the presence of ulceration in the primary melanoma, mitotic activity, the presence of tumor infiltrating lymphocytes (TIL), and gender. Tumor thickness is defined as thin (less than 1 mm), intermediate (1–4 mm), and thick (more than 4 mm). The 10-year survival rate is 92% for thin tumors and 63% to 80% for intermediate tumors and decreases further to 50% in patients with thick tumors.16 Ulceration is defined as the lack of an intact dermis overlying the primary tumor on histologic evaluation. Survival rates for patients with an ulcerated melanoma are proportionately lower than those with a nonulcerated melanoma of equivalent thickness, but the survival rate is similar for a nonulcerated melanoma of the next highest level of thickness. The male sex is associated with poor prognosis and adverse outcome in MM.17

Skin Examination

The ABCDE acronym is a helpful mnemonic for recognizing the signs and symptoms of early MM (Figure 93–2). It was devised in 1985 by clinicians working in the Melanoma Clinical Cooperative Group at New York University School of Medicine and is used to educate health care professionals who are not dermatologists in differentiating common moles from cancer.7 It is also a useful tool to educate patients to assess pigmented lesions and screen for suspicious moles. This may help identify the MM in its early stage when it is curable. Not all MMs, including nodular melanoma, have all ABCDE characteristics, and it is not meant to provide a comprehensive list of all MM features. The characteristics for each of the letters are described in the Clinical Presentation and Diagnosis box. It should be noted that evolution of a lesion is one of the most important warning signs of danger in the assessment of moles for MM.

TREATMENT

Early diagnosis of skin cancer is the key to improved prognosis. On presentation to a clinician’s office, patients may offer a history of a new growth or an area of irritation. Conversely, the skin cancer may have been present for years undetected by the patient. The definitive diagnosis of any suspected cutaneous malignancy should be confirmed by a biopsy before treatment.

The modality of treatment for skin cancer depends on the size, location, and stage of the tumor; the age of the patient; and the type of skin cancer. Treatment options for skin cancer include surgery, radiation, chemotherapy, immunotherapy, and targeted therapy.

**Desired Outcome**

- The primary goals of therapy for MM are to completely eradicate the tumor and minimize the risk of tumor recurrence and metastasis. Secondary goals of therapy include preserving normal tissue, maintaining function, and providing optimal cosmetic outcomes. Patients with local disease MM (stages I and IIA) are curable with surgical resection of the tumor. Thus, the aim is to diagnose patients at the earliest stage to increase the probability of cure. Patients with regional disease (stages IIB, IIC, and III) have a high recurrence risk, and the goal of therapy is to prevent relapse of the disease. Disseminated, metastatic MM is not curable, and the goal of therapy is local control of the disease and palliation of symptoms.

The outcome of patients diagnosed with MM depends on the stage of the disease at diagnosis. The overall 5-year survival rate for patients with localized disease (stages I and IB) is the best at 89% to 95%.18 For patients with stage IIA to IIIA disease, the 5-year survival rate ranges from 63% to 79%.16 In patients with more advanced regional metastatic disease (stage IIIB to IICC), the 5-year survival rate ranges from 24% to 59%. Patients with stage IV distant metastatic disease have the worst 5-year survival rate at only 7% to 19%.16

**TREATMENT OPTIONS FOR MALIGNANT MELANOMA**

**Surgery**  
**KEY CONCEPT** The primary treatment modality for local/regional (stage I to III) MM is surgical excision of the tumor and a lymphadenectomy for patients with positive lymph nodes. The goals of therapy are to optimize local control, achieve potential cure, and minimize morbidity. Achieving adequate surgical margins for the primary tumor is important in preventing local recurrence and improving overall survival. The thickness of the tumor dictates the extent of the surgical margin. The most common first site of recurrence in primary melanoma after excision of the tumor is in the lymph nodes. **KEY CONCEPT** For patients with metastatic MM, surgical excision is not curative. The primary goal

**FIGURE 93–2.** ABCDE features of early melanoma. (Images courtesy of the Skin Cancer Foundation, New York, www.skincancer.org.)
Immunotherapy  
This includes patients with bulky metastasis. The relationship between melanoma and the immune system was also established after spontaneous regression of melanoma was observed, and spontaneous serologic and cellular immunity can be documented in a high proportion of patients with advanced melanoma. Strategies to enhance patients’ immune response for the treatment of MM have focused on cytokine therapy, immune-modulating therapy, adoptive T-cell therapy, and vaccines. Interferon-α-2b Interferon-α-2b (IFN-α-2b) has diverse mechanisms of action, including antiviral activity, impact on cellular metabolism and differentiation, and antitumor activity. The antitumor activity is attributable to a combination of direct antiproliferative effect on tumor cells and indirect immune-mediated effects. IFN and pegylated IFN (peginterferon-α-2b) are both approved by the FDA as adjuvant therapy for patients who are free of disease after curative surgical resection but are at high risk of MM recurrence. This includes patients with bulky disease or regional lymph node involvement such as stage IIB, IIC, or III disease. The optimum dose, schedule, and duration of IFN-α-2b in high-risk melanoma remain to be defined. A recent meta-analysis of clinical trials of IFN in patients at high risk of recurrence after surgical resection showed improvements in relapse-free survival and overall survival. However, IFN is associated with...
Clinical Presentation of MM

Patients with skin cancer generally present with a lesion that may be located anywhere on the body. The most common sites are the head, neck, trunk, and extremities. Changes in any characteristics of a lesion are important danger warning signals. Abnormal presentations of a mole or lesion indicate the need for further assessment.

- **Asymmetry**: Half the lesion does not mirror the other half
- **Border**: Sharp, ragged, uneven, and irregular borders
- **Color**: Multiple colors of various hues of light brown, dark brown, black, red, blue, or gray
- **Diameter**: Larger than 6 mm or the size of a pencil head eraser
- **Evolving**: Significant change in shape, size, symptoms, surface, or shades of color

Other signs and symptoms to monitor for in a lesion, in addition to ABCDE, include:

- Sudden or continuous enlargement of a lesion or elevation of a lesion
- Changes in the skin surrounding the nevus
- Redness, swelling, itching, tenderness, or pain
- Ulceration: friability of the lesion with bleeding or oozing. This is a danger signal

Less Common Sites and Manifestations of MM

It is important to examine these sites for “hidden” MM:

- Nailbed
- Mucosal tissue
- Scalp
- Eye

In the nailbed, a black streak or wide variegated brown streak, elevation of nailbed, skin next to nail becomes darker, nail looks deformed or is being destroyed; size of nail streak increases over time.

### Diagnostic Tests

- Dermoscopy
- Biopsy

### Staging Tests (Depending on Patient’s Presentation)

- Baseline chest radiography
- LDH level
- CT of chest, abdomen, pelvis
- SLN biopsy

**KEY CONCEPT** The status of the SLN is one of the most powerful independent prognostic factors predicting survival. It also provides the clinician with guidance for therapy decisions and accurate staging.

- PET
- MRI

---

substantial toxicities, and the decision for IFN therapy should be made on an individual basis after explaining to the patient the potential benefits and side effects of the therapy. The duration of high-dose IFN is for 1 year if in stage IIb to III, or peginterferon-α-2b for up to 5 years in stage III when the decision has been made to initiate IFN; low-dose or intermediate-dose IFN is not recommended (Table 93–2). Encouragement to participate in clinical trials is also reasonable for eligible patients.

HDI has substantial side effects that can be divided into acute and chronic manifestations and categorized into four major side effect groups: constitutional, neuropsychiatric, hematologic, and hepatic. Patients should be educated on the side effects to expect and counseled of the interventions available to minimize the toxicities. Peginterferon-α-2b has a longer duration of action than IFN-α-2b and may be administered once a week. The side effects are similar to IFN-α-2b, although the incidence may be less. The monitoring recommendations for peginterferon-α-2b are the same as for IFN.

**Interleukin 2** Interleukin-2 (IL-2) therapy is approved by the FDA for the treatment of metastatic MM. IL-2 indirectly causes tumor cell lysis by proliferating and activating cytotoxic T lymphocytes (CTLs). The overall objective response rate for patients with metastatic MM receiving high-dose IL-2 is 16%, with a complete response in 6% of patients and a partial response in 10% of patients. The median duration of response is 8.9 months for all responding patients and 5.9 months for patients with a partial response. The median duration of complete response has not been reached but is at least 59 months. Disease progression is not observed in any patient responding for longer than 30 months. The data are encouraging because for the small number of patients who responded to therapy, the effect is of a long duration, and some patients may be considered to be cured of the disease. (Refer to Table 93–2 for dosing.)

High-dose IL-2 therapy is associated with significant severe toxicities and morbidity. This treatment option is generally only considered in patients with good performance status who will have a better chance of tolerating and completing the therapy. With the availability of new therapies, IL-2 is no longer the primary option for patients with metastatic melanoma. Table 93–3 lists the most common side effects experienced by patients receiving IL-2 therapy and recommendations for management. All clinicians involved with the care of patients receiving IL-2 should be well educated on the monitoring and management of IL-2–specific side effects.

**Immune Checkpoint Inhibitors**

**Ipilimumab**

T-cell activation involves two different signals: (a) the binding of the T-cell receptor to a peptide presented by the major histocompatibility complex on the antigen-presenting cell (APC) and (b) the interaction of a costimulatory receptor (CD28) on the T-cell surface with a costimulatory ligand (B7) on the APC. The costimulatory molecules enhance the immune response by promoting T-cell activation and proliferation.

CTLA-4 is expressed in CD4+ and CD8+ T cells and regulatory T cells. It is a member of the immunoglobulin (Ig) super family. After T-cell activation occurs, CTLA-4 migrates to the surface of the T cell, where it has higher affinity for the B7 ligand.
than CD28 and preferentially binds to B7. This results in an inhibitory signal to the T cell and causes a downregulation on the immune response; in other words, CTLA-4 acts as a “brake” on the activation of the immune system.33

Ipilimumab is a fully human monoclonal IgG1 specific for CTLA-4. It has a high affinity for CTLA-4 and impedes binding of CTLA-4 to B7, preventing downregulation of the immune response. This results in increased proliferation of activated T cells and increases the interactions of T cells and cancer cells.33 Ipilimumab was approved by the FDA for the treatment of unresectable or metastatic melanoma based on a phase III study demonstrating improved survival.34 Pooled analysis of long-term survival in advanced melanoma patients found median overall survival to be 13.5 months with ipilimumab treatment-naive group compared to 10.7 months in previous treated group; 3-year survival rates were 26% and 20%, respectively.35 Common side effects may include pruritus, rash, gastrointestinal upset, and fatigue. Because T-cell activation can lead to enterocolitis, hepatitis, dermatitis including toxic epidermal necrolysis, neuropathy, and endocrinopathy, both providers and patients are enrolled in the FDA Risk Evaluation and Mitigation Strategy (REMS) that includes a communication plan.36 No formal studies have been done to assess cytochrome P-450 (CYP) interactions, and none are expected. Corticosteroids are the treatment of choice for ipilimumab-induced adverse events. The administration of steroids to treat the side effects did not appear to result in decreased effectiveness of ipilimumab. Interestingly, there may be a correlation between immune-related adverse events and treatment success.37 (see Table 93–4 for adverse effects and their management).

► Nivolumab

Many tumor cells express programmed death-ligand 1 (PD-L1) that can interact with programmed death-1 (PD-1) receptor on T cells and B cells to diminish the body’s immune response. Nivolumab is an IgG4 fully humanized antibody that targets PD-1 to interfere with the binding with PD-L1 and thus allow T cells to remain active to mount an immune response. The FDA-approved indication includes unresectable and metastatic MM following ipilimumab and, if BRAF V600 mutation positive, a BRAF inhibitor. Patient with confirmed, unresectable, previously treated stage III or IV melanoma without BRAF mutation in a phase III trial showed an overall rate of survival at 1 year of 72.9% in the nivolumab group compared to 42.1% in the dacarbazine group.38 Common side effects may include rash, purities, peripheral edema, and cough while rare but serious adverse events may include ventricular arrhythmia, infection, hepatotoxicity, and neuropathy. No formal studies have been done to assess CYP interactions.39

► Pembrolizumab

Pembrolizumab (previously known as lambrolizumab) is an IgG4 engineered humanized antibody that is also a PD-1 inhibitor. The FDA approved indication includes unresectable
and metastatic MM following ipilimumab and, if BRAF V600 mutation positive, a BRAF inhibitor. A study of patients with measurable metastatic locally advanced unresectable melanoma with adequate organ function and performance score found that overall response rate from investigator-assessed immune evaluation Criteria in Solid Tumors (RECIST) confirmed response rate was 38%. Common side effects may include arthralgia and constipation/diarrhea while rare but serious adverse events may include colitis, hepatitis, pancreatitis, pneumonitis, and hypophysitis. No formal studies have been done to assess cytochrome p450 interactions.

### RAF-MEK-ERK Pathway Targeted Therapy

**Vemurafenib**

Vemurafenib is an intermediary in signal transduction through the RAF-MEK-ERK (MAPK) pathway. Activation of BRAF is associated with downstream activation of ERK, elevation of cyclin D1, and an increase in cellular proliferation. BRAF is mutated in approximately 50% of melanomas, and over 75% of these mutations are the BRAF V600E mutation. Vemurafenib is an oral competitive small molecule serine threonine kinase inhibitor that functions by binding to the adenosine triphosphate binding domain of mutant BRAF. Vemurafenib selectively targets the mutated BRAF V600E isoform and was approved by the FDA for unresectable stage IIIC or metastatic melanoma that is BRAF V600 mutation positive. The Cobas 4800 BRAF V600 Mutation Test is the companion FDA-approved diagnostic tool used to test for the BRAF V600 Mutation (see Table 93–2 for dosing).

A phase III clinical trial compared vemurafenib with dacarbazine in patients with previously untreated, unresectable stage IIIC or metastatic melanoma possessing the BRAF V600E mutation. Data analysis at 6 months showed that overall survival was 84% and median progression-free survival (PFS) was 5.3 months for patients receiving vemurafenib compared with 64% overall survival and 1.6 months PFS for patients receiving dacarbazine. Common side effects associated with vemurafenib may include photosensitivity, rash, arthralgia, and alopecia. Rare but serious side effects may include prolonged QT interval, foot-hand syndrome, vision changes, and SCC though the latter can be excised without discontinuation of the agent. Vemurafenib is metabolized by CYP3A4 and thus may interact with its inducers or inhibitors. It may increase the serum concentration of substrates of CYP1A2 and 2D6. It may decrease the serum concentration of substrates of CYP3A4.

**Dabrafenib**

Similar to vemurafenib, dabrafenib is also a selective inhibitor of BRAF V600E kinase. The FDA-approved indications include monotherapy for unresectable and metastatic MM with BRAF V600E mutation and combination therapy with trametinib for unresectable and metastatic MM with BRAF V600E or V600K mutation. Dabrafenib is unique in its activity to treat melanoma

metastasis in the brain. A phase I trial (BREAK-I) showed patients with asymptomatic untreated brain metastasis (3 mm size or smaller) decreased brain tumor size in nine out of ten patients with BRAF V600 mutation and previously untreated brain metastasis, with four patient achieving complete elimination. A phase II trial (BREAK–MB) showed that investigator-assessed intracranial response rate in untreated compared to previously treated but relapsed BRAF V600E patients were 39% and 31%, respectively.11 Common side effects may include hypoglycemia, arthralgia, and neutropenia while rare but serious adverse events may include prolong QT interval, serious febrile reactions, uveitis, iritis, and SCC. Similar to vemurafenib, SCC can be excised without discontinuation of the agent. Dabrafenib is metabolized by CYP3A4 and 2C8 and thus may interact with its inducers or inhibitors. Dabrafenib may need to interrupt or discontinue therapy if symptoms are severe.

Trametinib

Trametinib is a MEK 1/2 kinase inhibitor that works directly downstream of BRAF in the MAPK pathway. The FDA approved indications include monotherapy or combination therapy with dabrafenib for unresectable and metastatic MM with BRAF V600E or V600K mutation. Patients in a Phase III trial with metastatic melanoma with a BRAF V600E or V600K mutation showed a response of median PFS of 4.8 months with trametinib compared to PFS of 1.4 months with chemotherapy (dacarbazine or paclitaxel).42 Common side effects may include dry skin and nail changes while rare but serious adverse events may include
vision changes and rhabdomyolysis. No formal studies have been done to assess CYP interactions.\(^2\)

**Dabrafenib and Trametinib Combination Therapy**

Favorable synergistic effects have been found when comparing BRAF and MEK inhibitor combination to BRAF inhibitor monotherapy. A Phase III trial comparing dabrafenib and trametinib to dabrafenib alone in patients with previously untreated, unresectable stage IIIIC or metastatic melanoma and either BRAF V600K or V600E mutation found an estimated median PFS of 9.3 months in the former versus 8.8 months in the latter.\(^3\) In another phase III trial comparing dabrafenib and trametinib to vemurafenib alone in patients with metastatic melanoma and either BRAF V600K or V600E mutation found median overall survival to be 17.2 months in the vemurafenib group and was not reached for the combination group. The rate of overall survival at 12 months was 72% in the combination group compared to 65% in the vemurafenib group.\(^4\)

Treatment options for metastatic MM include immunotherapies; ipilimumab, nivolumab, or pembrolizumab; targeted therapies; dabrafenib in combination with trametinib or vemurafenib monotherapy, or a clinical trial. Only patients determined to have mutated BRAF V600 isoform can be effectively treated with vemurafenib, dabrafenib, and/or trametinib. Even though ipilimumab and BRAF inhibitors (for BRAF V600 mutation positive patients) are indicated before treatment with pembrolizumab or nivolumab, the latter two drugs have been shown to have higher response rate and less toxicity compared to ipilimumab and are considered part of first-line therapy. Trametinib monotherapy is only recommended for BRAF V600 mutation positive patients who cannot tolerate BRAF inhibitor monotherapy.\(^5\)

### OUTCOME EVALUATION

After diagnosis and treatment of skin cancer, the next phase of management is appropriate follow-up with the purpose of detecting recurrent disease or new MMs.\(^6\)

Recurrence of MM occurs after complete resection in 30% of patients diagnosed with stage I to III disease, and 80% of the patients develop recurrence within 3 years of their diagnosis of primary MM. Among patients whose melanoma recurred, the site of recurrence is local in 20% to 28% of patients; in 26% to 60%, recurrence is in regional lymph nodes; and 15 to 50% experience distant recurrence. The rate of recurrence detection by patients is reported to be 33% to 99%; thus, patients should be educated on how to perform self-examination of the skin and lymph nodes and the importance of ongoing sun protection measures.\(^7\)

Patients who received immunotherapy for stage III or IV MM may experience fatigue and other chronic side effects. Develop a plan to order laboratory tests such as liver function tests, thyroid-stimulating hormone, and white blood cell count at baseline and on a weekly or monthly basis as indicated. Monitor and evaluate patients for side effects of IL-2, IFN, immune checkpoint inhibitors, and MAPK inhibitors and educate patients on what to expect and how the side effects will be managed. Assess patients’ psychological, physical, and social functioning. Counsel patients to contact the hospital’s social service department or the American Cancer Society for assistance in dealing with the disease emotionally and recommend that patients consider attending support group meetings or talking to a counselor if or before they become overwhelmed with the diagnosis.

### NONMELANOMA SKIN CANCER

#### EPIDEMIOLOGY AND ETIOLOGY

Nonmelanoma skin cancer (NMSC) accounts for more than half of all newly diagnosed cancers in the United States each year, and it was estimated that more than 3.5 million new cases of BCC and SCC (in more than 2 million people) would be diagnosed in 2011.\(^1\) The true prevalence of NMSC may be underestimated because it is treated in outpatient settings, and no formal reporting to cancer registries is required. The incidence rate of NMSC is increasing worldwide with a yearly rise of 3% to 8% since 1960.\(^6\) BCC is the most common form of NMSC and comprises 75% of NMSC with SCC accounting for 20%.\(^4\) The majority of NMSCs are curable, and the mortality rate is low; cure rates approach 98%, and the overall 5-year survival rate is greater than 95%.\(^5\) Metastasis occurs in fewer than 0.1% of BCCs compared with an average of 3.6% of SCCs. Seventy-five percent of all NMSC deaths are attributed to SCC.\(^7\) NMSC is associated with considerable morbidity related to functional and cosmetic deformity. In addition, it is an economic burden to the health care system because costs associated with NMSC treatment are estimated at approximately $426 million per year.\(^8\)

### RISK FACTORS

The risk of developing NMSC is multifactorial (Table 93–5). The most important risk factor for NMSC is UV radiation exposure, and data from epidemiologic studies indicate that greater cumulative lifetime sun exposure is associated with a higher risk of developing SCC, but intermittent and childhood sun-exposure correlates more with BCC.\(^6\) Most cases of BCC are sporadic; however, it occurs frequently in the rare individuals with hereditary disorders such as basal cell nevus syndrome (also known as Gorlin syndrome). It is also common in patients with genetic syndromes such as XP. The patched gene (PTCH), a tumor-suppressor gene, has been shown to be mutated in 68% of sporadic BCCs.\(^8\) There is clear evidence linking defects of the immune system to the development of NMSC. For example, it is observed that patients receiving chronic immunosuppressant therapy for organ transplantation have a 65-fold increase in developing SCC and 10-fold increase in developing BCC.\(^8\)
PATHOPHYSIOLOGY

NMSCs arise from epidermal keratinocytes and involve primarily squamous cells and basal cells of the epidermis and dermis skin layers. BCCs arise from interfollicular basal cells or keratinocytes in hair follicles or sebaceous glands.\(^4^6\)

CLINICAL PRESENTATION AND PROGNOSIS

BCC is characterized as circumscribed or diffuse, and within these two groups, it is further classified according to type, degree of differentiation, and depth of invasion (see Table 93–1).\(^1^4\) Nodular BCC is the most common type of BCC followed by superficial BCC. The morpheaform BCC is the most aggressive subtype.\(^1^3\) BCC has indolent growth characteristics with a very low metastatic and mortality rate.\(^4^6\) Paradoxically, BCCs can cause extensive local destruction and significant disfigurement. Approximately 80% of BCCs occur on the head and neck. Superficial BCC occurs predominantly on the trunk. Early-stage BCC is usually small, translucent or pearly with raised telangiectatic edges.\(^4^6\) BCC may also appear as raised, yellowish-reddish lesions with a border resembling a string of pearls and telangiectasia. Dermatoscopy may distinguish between a benign and malignant lesion; however, clinical examination is usually sufficient for diagnosis of BCC. Depending on the size of the tumor, subtype, and treatment planned, a biopsy may be needed.

SCC usually presents on sun-exposed sites because of UVR damage to the skin. Unlike BCC, SCCs are preceded by premalignant lesions such as leukoplakia, actinic keratosis (AK) (a small papule that appears on areas of sun damage on the skin), or SCC in situ (Bowen disease).\(^4^6\) The rate of AK progression to SCC is 1% to 10% in 10 years and may be higher if a patient has more than five AKs.\(^4^6\) Patients with a Bowen lesion present with slowly enlarging erythematous scaly or crusted plaques and have a 3% to 5% risk of progressing to SCC. A typical SCC lesion has an adherent crust and ill-defined edges; the first sign of malignant SCC is induration of the lesion. The rate of metastasis for SCC is 2% to 6% and may be as high as 10% to 14% in high-risk sites such as the ear and lip and 30% in the genital area.\(^4^6\) Metastasis most commonly presents 1 to 2 years after diagnosis of the primary SCC with 80% of metastasis involving the regional lymph nodes.\(^4^6\)

Risk factors for NMSC are outlined in Table 93–5. If a patient possesses these factors, he or she is at high risk for disease recurrence and subsequent metastasis. Patients with NMSC have a 10-fold increased risk of developing subsequent NMSC compared with the general population.\(^4^6\)

Staging for NMSC uses the TNM staging system recommended by the American Joint Committee on Cancer. It is seldom done for patients with BCC because nodal and visceral metastasis is rare for this disease.\(^4^6\)

TREATMENT

**Nonpharmacologic Therapy**

**Surgery**

Surgery is the primary treatment modality for all patients diagnosed with either BCC or SCC. Full-thickness ablative procedure in the form of surgical excision of the tumor along with a margin of normal tissue surrounding the tumor is the preferred method for high-risk tumors. Obtaining negative surgical margins is critical for cure and decreasing the risk of tumor recurrence. A margin of 4 to 5 mm in well-defined BCC and SCC ensures peripheral clearance in 95% of cases. Depending on the tumor size, degree of differentiation, and invasion of surrounding structures, larger margins of resection may be necessary.\(^4^6\)

The two most common surgical techniques used are electrodesication and curettage (ED&C) and Mohs micrographic surgery (MMS). The indications of each of these procedures are described below.

Low-risk tumors defined as small, well-differentiated, and slow growing can be treated with superficial ablative techniques, including ED&C and cryotherapy.\(^4^6\) ED&C is a simple, cost-effective technique that uses repeated cycles of using a curette to cut through malignant tissue followed by electrodesiccation, which involves the application of high voltage, low current to the skin, causing drying or desiccation of the tissue. ED&C is most appropriate for well-defined superficial lesions that are not located in areas with increased risk for metastasis. The disadvantage of this technique is that histologic confirmation of complete tumor removal is not possible.\(^4^6\) This procedure is not recommended for treatment of recurrent disease, tumors of the face, and high-risk tumors.\(^3^8\)

UVA, ultraviolet A.

Data from Refs. 46 and 48.
For high-risk NMSC or for tumors located in cosmetically or anatomically sensitive areas, MMS is the procedure of choice. The goal of this therapy is complete removal of the cancer with preservation of as much surrounding normal tissue as possible. MMS involves careful dissection, staining of frozen sections, and anatomic mapping of the tumor specimen. Sections are assessed immediately under the microscope by the surgeon, and the process is repeated until a tumor-free margin is attained. MMS cures 93% of primary NMSC and 90% to 94% of recurrent disease compared with 92% and 77% cure rate with standard excision for primary and recurrent disease, respectively.49

Cure rates for all modalities decrease with the presence of high-risk features but are still superior with MMS.49 Cryotherapy is a procedure used primarily for smaller, low-risk NMSCs with clearly defined margins. It involves delivering liquid nitrogen at subzero temperatures as a spray or with a supercooled metal probe to destroy the malignant tissue in a single cycle or multiple cycles.48 This technique can achieve comparable results to conventional surgery for well differentiated, not too large, superficial tumors in older patients with BCC.48 The procedure is contraindicated in the hair-bearing scalp, upper lip, ear, and nasal entrance for SCC may provide the best possible because the tumor is inoperable or surgery would lead to unacceptable cosmetic or functional impairment.49 Radiation to the lip, ear, and nasal entrance for SCC may provide the best cosmetic and functional result. On the other hand, some patients may develop dyspigmentation, radiodystrophy, or telangiectasia at the site of radiation, resulting in poorer cosmetic outcomes. Radiation is contraindicated in treating BCC that recurred after radiotherapy. It should be used with caution in patients younger than 65 years because latent NMSC can develop after 15 to 20 years of radiation exposure.48

► Radiation

Radiation is not standard therapy for the treatment of skin cancer; however, there are circumstances in which radiation may be preferred. It may be offered to patients in whom surgery is not possible because the tumor is inoperable or surgery would lead to unacceptable cosmetic or functional impairment.49 Radiation to the lip, ear, and nasal entrance for SCC may provide the best cosmetic and functional result. On the other hand, some patients may develop dyspigmentation, radiodystrophy, or telangiectasia at the site of radiation, resulting in poorer cosmetic outcomes. Radiation is contraindicated in treating BCC that recurred after radiotherapy. It should be used with caution in patients younger than 65 years because latent NMSC can develop after 15 to 20 years of radiation exposure.48

► Photodynamic Therapy

Photodynamic therapy (PDT) involves the topical application of a photosensitizing agent that is activated after exposure to a light source and causes tumor cell damage and death. The photosensitizer is converted to protoporphyrin IX after it is preferentially taken up by active tumor cells. Damage to cell membranes, organelles, and surrounding vasculature occurs when protoporphyrin IX is activated after exposure to a light source. Protoporphyrin IX has absorption bands at 408, 510, 543, 583, and 633 nm; therefore, blue light (corresponding to 408-nm band) and red light (corresponding to 633-nm band) are the most commonly used light source.49 Blue light is used for superficial lesions because of its shorter wavelength and because it does not penetrate the skin as well as red light.48

δ-Aminolevulinic acid (ALA) and methyl aminolevulinate (MAL) are two photosensitizing agents that have FDA approval for the treatment of AK (see Table 93–6 for dosing).29 PDT has also been shown to be effective in the treatment of SCC in situ, but it is not indicated for SCC because of its extensive invasiveness and metastatic potential.29 In patients with superficial BCC, MAL-PDT may be considered when surgery may result in suboptimal cosmetic outcomes or complications.29 For patients with nodular BCC, MAL-PDT may be considered but not ALA-PDT.29,48

Pharmacologic Therapy

► Fluorouracil

Nonsurgical treatment is used frequently for superficial NMSCs. Topical 5-fluorouracil has been used for the treatment of dermatologic disorders for approximately 45 years, and it has FDA approval for the treatment of AK and superficial BCC. Fluorouracil is available as solution and cream with strengths ranging from 1% to 5%. There is also a microsphere-encapsulated 0.5% cream that has reduced systemic absorption with enhanced skin retention to reduce systemic side effects. The microsphere formulation is applied only once a day, providing patient preference and convenience over the twice-daily application with the other formulations. The optimal strength of fluorouracil is still under investigation, but the FDA has approved 2% to 5% cream or solution and 0.5% microsphere formulation for AK. For superficial BCC, only the 5% strength is FDA approved for this indication. The most common side effects with topical fluorouracil are expected to occur within the initial 5 to 10 days of treatment, and it presents as erythema, irritation, burning sensation, pruritus, and pain along with hypo- or hypopigmentation. Patients also experience inflammatory reactions that include crust, edema,
and oozing. If the reactions are severe, the fluorouracil strength or frequency of application may be reduced. To reduce inflammation, topical steroids may be used concurrent with fluorouracil application and for 1 to 2 weeks after treatment.\(^29\) Caution should be used in administering fluorouracil to patients with dihydouracil dehydrogenase deficiency, an enzyme critical in the metabolism of fluorouracil, because increased toxicity may be observed.

▶ **Imiquimod**

Imiquimod is an immune-modulating agent that works by stimulating innate and cell-mediated immune responses. It has FDA approval for the treatment of AK and for when surgical procedure is not appropriate for superficial BCC located on trunk, neck, or extremities and when follow-up is assured. Imiquimod has been shown to have complete clearing of AK in 50% of patients and partial clearing in 75% of patients with AK compared with 5% for those treated with placebo. Cure rates for imiquimod 5% in patients with superficial BCC are greater than 90%. The response rate is much lower for nodular BCC at 75%; therefore, it should be used in these patients only if they are not able to undergo surgery, radiation, or cryotherapy and the tumor is small and in a low-risk area. Imiquimod is not recommended for the treatment of invasive SCC, but data for SCC in situ showed a 93% cure rate; thus, it may be considered for this patient population.

Imiquimod is available in 3.75% strength, which may be applied daily on larger areas of skin, the balding scalp, or the full face, and 5% strength, which may be used on areas of skin that are 25 cm\(^2\) or smaller (see Table 93–4). Imiquimod should be applied before bedtime and left on the skin for 6 to 10 hours. The most common side effects with imiquimod involve the area of application and present as erythema, pruritus, a burning or stinging sensation, and tenderness. Less commonly, hypopigmentation, fever, diarrhea, and fatigue may also occur. Temporal discontinuation of imiquimod and application of topical steroids may be necessary to alleviate the irritation symptoms. Imiquimod may be resumed at a decreased frequency after the symptoms have resolved.\(^{29}\)

▶ **Vismodegib**

Genetic alterations in hedgehog signaling pathway cause loss of function of patch homolog 1 (PTCH1), which normally acts to inhibit signaling activity of Smoothened, a transmembrane protein involved in Hedgehog signal transduction. Vismodegib is a first-in-class, oral small molecule inhibitor of the Hedgehog signaling pathway; it binds to and inhibits Smoothened (SMO). Vismodegib is approved by the FDA for the treatment of adults with metastatic BCC or locally advanced BCC that has recurred following surgery or who are not candidates for surgery or radiation.

### OUTCOME EVALUATION

BCC and SCC have excellent outcomes, with cure rates approaching 98%.\(^{47}\) Recurrence of NMSC is around 30% to 50% during a 5-year follow-up, and 70% to 80% of recurrence develops within the first 2 years after initial therapy.\(^47\) Therefore, it is crucial to advise patients to schedule routine follow-up visits with their dermatologist and to educate them about the value of sun protection and total-body skin self-examination.\(^29\)

Patients receiving topical agents such as fluorouracil or imiquimod should be educated to wash the treatment area with mild soap and water before applying the cream, use gloves to apply enough to cover the area with a 1-cm margin, and wash their hands thoroughly after each application. They should avoid sun exposure and be counseled to monitor for side effects such as pain, itching, and inflammation. They should consult their dermatologist if the side effects are intolerable.

**Patient Care Process**

**Patient Assessment:**
- Take a thorough medication history with particular attention to nonprescription or herbal medications.
- Assess patient sun exposure and advise patient regarding sun exposure prevention.

**Therapy Evaluation:**
- Determine the optimal treatment regimen for the patient incorporating diagnosis, stage, and mutation status.
- Verify regimen doses with a standardized reference and assess for dose adjustment based on height, weight, and body surface area and organ dysfunction (renal or hepatic).
- Assess appropriateness of supportive care for the regimens including need for prophylactic antiemetics.

**Care Plan Development:**
- Enroll patient in REMS program if they will receive ipilimumab.
- Provide patient education regarding common toxicities associated with immunotherapy such as rash, diarrhea, and hepatotoxicity.
- Provide patient education regarding common toxicities associated with targeted therapy such as hypoglycemia, arthralgia, and neutropenia.
- Advise patients receiving targeted therapies of the risk of new skin cancers.

**Follow-up Evaluation:**
- Schedule regular laboratory tests and skin exams to monitor for toxicities.
- Monitor patient for to therapy.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Demonstrate understanding of the etiology and risk factors associated with the development of ovarian cancer.
2. Justify the risk and benefits of the surgical and chemoprevention options available for decreasing the potential risk of developing ovarian cancer.
3. Interpret and understand the utility of the screening tests and serologic markers for diagnosing ovarian cancer.
4. Distinguish the nonspecific physical signs and symptoms of ovarian cancer.
5. Recommend the appropriate surgical and chemotherapy treatment options for newly diagnosed, persistent, and recurrent ovarian cancer patients.
6. Discuss the role of consolidation treatment for improving overall survival for ovarian cancer patients.
7. Compare and contrast chemotherapy options for women with recurrent platinum-resistant ovarian cancer.

INTRODUCTION

Ovarian cancer is relatively uncommon but is the most incurable of the gynecologic cancers. Ovarian cancer is often denoted as the “silent killer.” The primary reason for the high mortality rate associated with ovarian cancer is the nonspecific symptoms and difficulty for early detection or screening that result in patients presenting with advanced disease. The majority of ovarian cancers are of epithelial origin. Each time ovulation occurs, the epithelium of the ovary is broken followed by occurrence of cell repair. The incessant ovulation hypothesis proposes that the increasing number of times the ovary epithelium undergoes cell repair is associated with the increasing risk of mutations and ultimately ovarian cancer. Although the majority of patients will achieve a complete response (CR) to primary surgery and chemotherapy, disease recurs in more than 50% of patients in the first 2 years after completion of primary treatment.

Ovarian cancers often cause metastasis via the lymphatic and blood systems to the liver, and/or lungs. Common complications of advanced and progressive ovarian cancer include ascites and small bowel obstruction (SBO), which often are associated with the end of life.

EPIDEMIOLOGY AND ETIOLOGY

In 2015, there were an estimated 21,290 new cases of ovarian cancer diagnosed with an associated 14,180 deaths. Ovarian cancer remains the number one gynecologic killer and the fifth leading cause of cancer-related death in women. Despite great efforts and extensive research, addition of new agents and routes of administration, there has been little change in the mortality rate associated with ovarian cancer over the past five decades. Again, this high mortality rate associated with ovarian cancer can be attributed to its insidious onset of nonspecific symptoms, resulting in the majority of patients not presenting until the cancer has progressed to stages III to IV disease.

As with many other disease states, a significant risk factor associated with ovarian cancer is aging. Risk of ovarian cancer increases from age 40 to 79 years, with the mean age at diagnosis being 63 years and the majority of women being diagnosed between 55 and 64 years.

Ovarian cancer is a sporadic disease; fewer than 10% of ovarian cancers can be attributed to heredity. The majority of cases of ovarian cancer occur sporadically, thus making it difficult to screen and prevent. Although hereditary accounts for fewer than 10% of all ovarian cancer cases, when there is a family history, it appears to be an important risk factor in the development of ovarian cancer in some patients. If one family member has a diagnosis of ovarian cancer, the associated risk is about 9%, but this risk increases to greater than 50% if there are two or more first-degree relatives (ie, mother and sister) with a diagnosis of ovarian cancer or multiple cases of ovarian and breast cancer. Both breast cancer activator gene 1 (BRCA1) and breast cancer activator gene 2 (BRCA2) mutations have been associated with ovarian cancer. However, BRCA1 is more prevalent, being associated with 90% of hereditary and 10% of sporadic cases of ovarian cancer. Hereditary breast and ovarian cancer (HBOC) syndrome is one of the two different forms of hereditary ovarian cancer and is associated with germline mutations in BRCA1 and BRCA2. The hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome is a familial syndrome with germ-line mutations causing defects in enzymes involved in DNA
Screening and Prevention

- **Screening**

  Pelvic examinations are effective for detecting obvious tumors present with a sensitivity of 67% for detecting all tumors; however, minimal or microscopic disease cannot be detected on physical examination. Pelvic examinations are noninvasive and well accepted, but they do not usually detect ovarian cancer until it is in advanced stage. Transvaginal ultrasound (TVUS) is a component of current screening practices. Typically, it is used in combination with cancer antigen-125 (CA-125) or could be used as a single modality. TVUS releases sonic sound waves that create an image of the ovary to evaluate the size and shape and detect the presence of cystic or solid masses. Limitations of this technique are lack of specificity and an inability to detect peritoneal cancer or cancer in normal size ovaries. Most prevention clinics use this multimodality approach to screen high-risk women and recommend yearly ultrasound in combination with CA-125 blood test every 6 months.

  - **Serum CA-125 is the most extensively evaluated tumor marker for ovarian cancer.** Because CA-125 is a nonspecific marker, it is not a standard recommendation for routine screening for prevention of ovarian cancer. Unfortunately, CA-125 is nonspecific, and elevated levels can be associated with a number of other gynecologic and GI-related diseases. CA-125 levels in a woman without ovarian cancer are static or tend to decrease over time, but levels associated with malignancy continue to rise.

  - **Prevention**

    **Ovulation** is considered a hostile event to the ovarian epithelium, making it more susceptible to damage and cancer. Interventions or conditions that limit the number of ovulations in a woman’s reproductive history, including multiparity, have a protective effect.

  - **Chemoprevention** Investigational chemoprevention strategies used for ovarian cancer include oral contraceptives (OCs), aspirin and nonsteroidal anti-inflammatory agents, and retinoids, although none of these is currently accepted as standard treatment for the prevention of ovarian cancer. The theory that OCs reduce the number of ovulatory events is a basic explanation of its protective effect. Recent studies have suggested that progestin-induced apoptosis of the ovarian epithelium is responsible for the chemopreventive effect of OCs. The theory is that cells that have genetic damage but are not yet neoplastic have an increased chance of undergoing apoptosis. OCs decrease the relative risk to less than 0.4% in women that use OCs for longer than 5 years.

Patient Encounter 1, Part 1

The patient is a 66-year-old active woman, who has been in good health up until recently (about 6 weeks or so). At Thanksgiving, she mentioned to her daughter that she has had not been able to have a bowel movement in over 6 days despite use of OTC laxative medications. The following Monday she saw her gastroenterologist that completed CT scan that suggests minor colitis but no obvious reason for inability to have bowel movement. One week later, her symptoms persisted, so her physician did an exploratory laparoscopic surgery, which came back positive for an abdominal mass and thickening of the peritoneal lining and mass on right ovary extending to outside of colon wall which was removed by general surgeon and required temporary ostomy. Of note, she has been married for 41 years with only one sexual partner in her lifetime. They have three children who are all grown adults. Her first menses was when she was 11 years old and menopause was at age 54 years. She has had infrequent alcohol on social occasions only and denies any tobacco use.

**Based on the results from exploratory surgery, what additional diagnostic tests would be recommended to complete her workup?**

**In the context of this patient, discuss why ovarian cancer is often denoted the “silent killer” and what needs to be done for earlier diagnosis of ovarian cancer.**

**Compare and contrast the treatment options for RH after her initial surgery.**

- **Screening and Prevention**

  - **Patient Encounter 2**

    A 37-year-old professional, single woman who has been in good health, presents to your clinic complaining of constipation and abdominal bloating. She explains to you that she is concerned about her cancer risk because her 64-year-old mother was recently diagnosed breast cancer and then last month, her step-sister was diagnosed with stage I ovarian cancer and underwent TAH-BSO and had genetic testing completed that revealed she was **BRCA1** positive. She is requesting to check her CA-125 level today in clinic.

    **Explain the association between hereditary and ovarian cancer risk.**

    **Discuss why monitoring CA-125 is not used as a screening tool for ovarian cancer.**

    **Describe the potential advantages and disadvantages of using oral contraceptives for prevention of ovarian cancer for this patient.**
Nonsteroidal anti-inflammatory agents, aspirin, and acetaminophen have been suggested for use in the prevention of different cancers, especially hereditary nonpolyposis colon cancer. Although observational studies have linked these to a reduction of ovarian carcinoma risk, evidence is still lacking. Potential mechanisms include effects on normal ovulation shed and inhibition of ovulation. Other pharmacologic interventions that have been suggested but are still being evaluated include vitamin A, lutein, and other carotenoids. The protective effect of these agents is associated with inhibition of cell growth as well as promotion of cellular differentiation.

**Prophylactic Surgery** Surgical strategies are also used in the prevention of ovarian cancer. The goal is to remove healthy, at-risk organs and ultimately reduce the risk of developing cancer. These surgeries include prophylactic bilateral salpingo-oophorectomy (BSO) or tubal ligation (Figure 94–1).

Prophylactic oophorectomy should be considered in any woman with a high risk of developing ovarian cancer. The criteria for defining high risk includes any woman with two or more first-degree relatives with epithelial ovarian carcinoma; a family history of multiple occurrences of nonpolyposis colon cancer, endometrial cancer, and ovarian cancer; and a family history of multiple cases of breast and ovarian cancer. Patients undergoing prophylactic oophorectomy need to be made aware that complete protection is not guaranteed. Although a 67% reduction in risk has been shown, a potential 2% to 5% risk of peritoneal carcinomatosis remains.

**Tubal ligation** is another procedure that has shown potential for risk reduction. However, it is not recommended as a sole procedure in prophylaxis. The protective effect may be attributable to limiting exposure of the ovary to environmental carcinogens. A case-control study conducted by Narod and colleagues found that a history of tubal ligation in BRCA-positive women was associated with a statistically significant 63% reduction in risk.

**Genetic Screening** Genetic screening is another option available for high-risk patients. Patients can be screened for genes such as BRCA1 and BRCA2 or other genes such as those associated with HNPCC or the HBOC syndrome. Patient and family counseling and genetic counseling should be available for the patient and family to prepare and deal with the health and psychosocial implications of the genetic test results. Before this decision, the potential preventive options should be discussed, such as prophylactic BSO and/or total hysterectomy. Cancer risk and patient’s health need to be balanced, but typically surgery can be held off until after the childbearing years.

**PATHOPHYSIOLOGY**

The three current theories are the incessant ovulation hypothesis, the pituitary gonadotropin hypothesis, and the chronic inflammatory processes hypothesis. The incessant ovulation hypothesis proposes that the pathogenesis of ovarian cancer is connected to continual ovulation. Ovulation is considered a “hostile” event to the ovaries, perhaps with not enough time for adequate repair. Each time ovulation occurs, the ovary epithelium is disrupted, and cell damage occurs. Thus, repeated ovulations may lead to a greater number of repairs of the ovarian epithelium and increase the possibility of aberrant repairs, mutation, and carcinogenesis.

The pituitary gonadotropin hypothesis associates the disease with elevations in gonadotropin and estrogen levels. This leads to an increase in the number of follicles and therefore an increased risk of malignant changes. Finally, the chronic inflammatory processes may be involved with various environmental carcinogens to cause cancer.

The three major pathologic categories of ovarian tumors include sex-cord stromal, germ cell, and epithelial. About 85% to 90% of ovarian cancers are of epithelial origin. Epithelial ovarian tumors are composed of cells that cover the surface of the ovary such as serous, mucinous, endometrioid, clear cell, and poorly differentiated adenocarcinomas. Germ cell tumors involve the precursors of ova with the most common type being dysgerminoma, which are most commonly diagnosed in women younger than the age of 40 years and generally have a better prognosis. Sex-cord stromal tumors are indolent tumors that produce excess estrogen and androgens but also have a better overall prognosis. Although the histologic type of the tumor is not a significant prognostic factor, it is important to know the histopathologic grade. Undifferentiated tumors are associated with a poorer prognosis than lesions that are considered to be well or moderately differentiated.

**TREATMENT**

**Desired Outcomes**

Health care providers use a multimodality approach, including surgery and chemotherapy, in initial treatment of patients with ovarian cancer with a curative intent, or restoring a normal life span. Although the majority of patients initially achieve a CR, disease will recur within the first 2 years in more than 50% of patients. CR to treatment is defined as no evidence of disease can be detected by physical examination or diagnostic tests and patient has a normalized CA-125.

The stage of disease at the time of diagnosis is the most important prognostic factor affecting overall survival in ovarian cancer patients. The estimated 5-year survival rates of patients with localized, regional, distant, and unstaged ovarian cancer are 92.7%, 71.1%, 30.6%, and 26%, respectively. The histology of the disease is another predominant prognostic factor influencing treatment outcomes. Clear cell and undifferentiated tumors do not respond as well to chemotherapy. The extent of residual disease and tumor grade are also predictive of response to chemotherapy and overall survival. There are other prognostic factors that may predict how well a patient will respond to adjuvant chemotherapy.

The treatment goals shift when a patient presents with recurrent ovarian cancer. The desired outcomes focus on relief of
Clinical Presentation and Diagnosis of Ovarian Cancer

General
Ovarian cancer typically has delay in diagnosis due to the common nonspecific signs and symptoms often initially suggesting GI-related complications. By the time symptoms become unrelenting and bothersome, patients most likely have advanced stage disease.

Symptoms
Patients may experience episodes or persistent symptoms such as abdominal pain, constipation or diarrhea, flatulence, urinary frequency, or incontinence.

Signs
The degree of abdominal swelling secondary to fluid accumulation may present like “pregnant abdomen” and irregular vaginal bleeding.

Laboratory Test
- CA-125. The normal level is less than 35 U/mL (35 kU/L).
  - Note: This test is associated with a lack of specificity.
  - CA-125 can be elevated in a number of other states such as different phases of the menstrual cycle, endometriosis, and nongynecologic cancers.
- NOTE: It is important to rule out other cancers associated with the abdominal cavity.
- Carcinoembryonic antigen (CEA). CEA is a marker for colon cancer. A normal value is less than 3 ng/mL (3 mcg/L).
- CA-19–9 is a marker for many GI tumors such as cholangiocarcinomas.

Chemistries with Liver Function Tests (LFTs)
- LFTs and serum creatinine might be suggestive of extent of disease. The majority of this information is needed to determine if patient is a surgical candidate. Laboratory study results should be within normal limits.

Complete Blood Count (CBC)
- Abnormalities in CBC are not associated with ovarian cancer; however, this information is needed to determine if patient is a surgical candidate. Laboratories should be within normal limits.

Other Diagnostic Tests
To characterize local disease, one or both of the following are completed:
- TVUS
- Abdominal ultrasound
To evaluate the extent of disease, only one of the following is completed:
- CT scan
- MRI
- PET scan
Chest x-ray is also often done as part of clearance for surgery. Ovarian cancer is usually confined to the abdominal cavity, but spread can occur to the lung and liver and less commonly to the bone or brain. Disease is spread by direct extension, peritoneal seeding, lymphatic dissemination, or bloodborne metastasis. Lymphatic seeding is the most common pathway and frequently causes ascites.

Nonpharmacologic Therapy
**KEY CONCEPT** Surgery is the primary treatment intervention for ovarian cancer.25–27 A total hysterectomy with BSO (TH-BSO) (see Figure 94–1), omentectomy, and lymphonectomy (or lymph node dissection) is the standard initial surgical treatment of ovarian cancer.25 The objective of the surgery is to debulk the patient to less than 1 cm of residual disease remains. Residual disease less than 1 cm correlates with better CR rates to chemotherapy and better overall survival compared with patients with bulky residual disease (larger than 1 cm).24,27 Indeed, the size of residual tumor masses after primary surgery is found to be another important prognostic factor in patients with advanced ovarian cancer.27

A thorough exploratory laparotomy is essential for the accurate staging of the patient.25–27 **KEY CONCEPT** Ovarian cancer is staged surgically using the International Federation of Gynecology and Obstetrics (FIGO) staging algorithm. For certain patients with limited stage disease, surgery may be curative.

Other surgical procedures have been evaluated to improve overall survival. Debunking surgery is intended to relieve symptoms associated with complications such as SBO and help improve the patient’s quality of life but does not have a curative intent. Interval debunking that is completed after two to three cycles of chemotherapy has not translated to an improved survival benefit. Often debated, the benefit of the “second-look laparotomy” to evaluate residual disease after the patient has completed chemotherapy remains controversial because it has been difficult to establish any impact on patients’ overall survival. It has questionable benefit because although approximately 40% of patients with advanced disease have a negative second look, 50% still relapse.2 The role of laparoscopic surgery is somewhat controversial for initial surgery but is more often considered in debulking of recurrent or advanced disease when the intent is palliative rather than curative.25

Pharmacologic Therapy
**First-Line Chemotherapy**

**KEY CONCEPT** After initial surgery, the gold standard of care is six cycles of taxane/platinum-containing regimen for patients with advanced ovarian cancer.28–30 Patients with limited disease, ie, stage IA, will have observation alone after surgery
Most often, paclitaxel is the taxane agent used in combination with carboplatin as the preferred platinum agent. Depending on patients’ preexisting comorbidities and how well they tolerate chemotherapy regimens, substitution with docetaxel or cisplatin might be considered. The route of administration should also be discussed. Although intravenous (IV) administration is often used, intraperitoneal (IP) administration has been shown to improve overall survival and should be considered for first-line treatment; however, patient selection for IP therapy is critical (Table 94–1). Close monitoring of organ function, nausea/vomiting, myelosuppression, and neuropathies is necessary for all taxane/platinum regimens (Table 94–2).

### Intraperitoneal Chemotherapy

For more than four decades, numerous investigators have evaluated the IP route for administration of chemotherapy; however, it was not until the third report of an improvement in overall survival that brought its use to the forefront in the first-line setting. The principal theory supporting IP administration is to increase drug concentration in the site of disease, specifically the abdominal cavity. Patient characteristics greatly influence response and tolerability of IP chemotherapy. To be selected to receive IP chemotherapy for first-line treatment of ovarian cancer, the patient should have tumor optimally debulked and no bowel resection with primary surgery, normal renal and liver function, younger age, and no significant comorbidities.

When IP therapy is administered, the placement of an IP catheter should occur at the time of surgery unless otherwise contraindicated. During IP administration, chemotherapy is delivered to the peritoneal space in 1 L of normal saline (NS) that has been warmed followed by another liter of NS to enhance drug distribution as tolerated. The current standard IP regimen includes the administration of paclitaxel IV on day 1 followed by cisplatin IP on day 2 and then paclitaxel IP on day 8 given on a 21-day cycle for a total of six cycles (see Table 94–2). The most common toxicities associated with IP administration include abdominal pain, myelosuppression, neurotoxicity, and catheter-related infections. The substitution of carboplatin IP in place of cisplatin remains investigational and should not be recommended outside a clinical trial protocol.

### Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy is first-line treatment for patients who are poor surgical candidates or patients with bulky or significant tumor burden. For patients who are poor surgical candidates because of significant comorbidities, a combination of taxane with platinum agent is administered every 21 to 28 days as tolerated with the intent to relieve symptoms and...
### Table 94–1

**Summary of First-Line Chemotherapy Regimens for Advanced Ovarian Cancer**

**Gold standard first-line chemotherapy after initial surgery for treatment of ovarian cancer:**
Paclitaxel 175 mg/m² IV infused over 3 hours + carboplatin AUC = 5 IV infused over 1 hour. Regimen is given once every 21 days × 6 cycles
{+/− bevacizumab 7.5 mg/kg once every 3 weeks × 6 cycles followed by additional 12 cycles after completion of primary chemotherapy}

**Alternative first-line regimen: Paclitaxel IV with substitution of carboplatin IV with cisplatin IP and addition of paclitaxel IP therapy:**
Patient selection is critical; must have optimally debulked disease (< 1 cm) and no significant comorbidities; younger patients tolerate better Day 1: paclitaxel 135 mg/m² IV infused over 24 hours + day 2: cisplatin 100 mg/m² IP infused over 1 hour + day 8: paclitaxel 60 mg/m² IP infused over 1 hour. Regimen is given once every 21 days × 6 cycles

**Alternative first-line regimen: Dose density. Consider for patients with optimal debulking, no comorbidities, good performance status:**
Paclitaxel 80 mg/m² IV infused over 1 to 3 hours once a week with carboplatin AUC = 6 IV infused over 1 hour on day 1 only of 21-day cycle.

**Alternative first-line regimen: Substitution of cisplatin in place of carboplatin. Consider for patients experiencing difficulty with maintaining platelet counts:**
Paclitaxel 135 mg/m² IV infused over 24 hours + day 2: cisplatin 75 mg/m² IP infused over 4 hours. Regimen is given once every 21 days × 6 cycles

**Alternative first-line regimen: Substitution of docetaxel in place of paclitaxel. Consider for patients with preexisting or increased risk of neuropathies:**
Docetaxel 75 mg/m² IV infused over 1 hour + carboplatin AUC = 5 IV infused over 1 hour. Regimen is given once every 21 days × 6 cycles

AUC, area under the curve; IV, intravenous.

### Table 94–2

**Summary of Chemotherapy Agents Used for First-Line Treatment of Advanced Ovarian Cancer**

**Mechanism of Action of First-Line Agents**

**Platinum analogues:** Produce intra- and interstrand cross-links and DNA adducts to disrupt DNA replication

**Taxanes agents:** Stabilize microtubules and prevents depolymerization of tubulin

slow progression of disease. In some cases, especially in elderly patients, single-agent carboplatin is used as palliative treatment instead. Chemotherapy alone has not been curative for patients with advanced ovarian cancer.\textsuperscript{25}

In patients with bulky disease or significant tumor burden, neoadjuvant chemotherapy can be used to decrease tumor burden to increase the likelihood of optimal tumor debulking during surgery.\textsuperscript{31} Typically, three cycles of the standard combination taxane/platinum regimen is administered once every 21 days. After surgery, patient will receive another three to six cycles depending on their response to chemotherapy.

### Consolidation and Maintenance Chemotherapy

Consolidation chemotherapy is the addition of cycles of the taxane/platinum regimen or the addition of single-agent platinum or single taxane after completion of first-line chemotherapy.\textsuperscript{36} If the tumor has a partial response (PR) to first-line chemotherapy evident by a significant decline in CA-125 by greater than 30% presurgery level and/or tumor regression or decrease in size, then cancer is still considered taxane/platinum sensitive. Additional cycles of chemotherapy are given until CR is achieved (see Figure 94–2). In 2014, bevacizumab was finally approved to be added to the primary treatment and as consolidation treatment for ovarian cancer based on the improved overall survival observed in the ICON-7 study.\textsuperscript{37}

Maintenance chemotherapy is similar to consolidation chemotherapy except maintenance chemotherapy is given to patients who have achieved a clinically CR.\textsuperscript{38} Maintenance chemotherapy is used to hopefully extend progression-free and overall survival by eliminating any microscopic disease present after completion of primary chemotherapy.

For an extensive description of the common agents used in first-line, consolidation, and maintenance chemotherapy of ovarian cancer, please see Chapter 88. A brief overview of the regimens is provided in Table 94–1 and adverse effects are provided in Table 94–2.

### Recurrent Chemotherapy

In the recurrent setting, platinum sensitivity of the tumor is assessed first. If recurrence occurs in less than 6 months or disease progresses while the patient is receiving a platinum-based regimen, the cancer is considered platinum resistant (see Figure 94–2). These parameters are also used to determine if tumors are taxane sensitive or resistant. However, patients resistant to paclitaxel may still respond to docetaxel.\textsuperscript{39} If the treatment goal is palliative care, then often single therapy will be used, but curative care typically is an aggressive combination regimen (see Figure 94–2 and Table 94–3). Sometimes an investigational agent may achieve responses equivalent or surpassing standard therapy, and should be considered for most patients.

\textsuperscript{a}Platinum resistance = disease progression while on platinum agent or recurrence within 6 months of completion of platinum-based therapy.\textsuperscript{36}

\textsuperscript{b}See Table 94–2 for specific monitoring parameters.

ANC, absolute neutrophil count; AUC, area under the curve; IV, intravenous; PO, oral; PPE, palmar-plantar erythrodysesthesia.
Platinum Sensitive

In patients who experienced a CR to first-line chemotherapy and have had greater than a 6-month platinum-free interval, retreatment with a platinum-containing regimen is appropriate. The combination of carboplatin with gemcitabine, liposomal doxorubicin, or paclitaxel for the treatment of platinum-sensitive recurrent ovarian cancer with a curative intent is recommended. However, in patients who are unable to tolerate additional combination chemotherapy regimens, carboplatin alone or any one of the second-line agents would be appropriate.

Platinum Resistant

Recurrent or persistent ovarian cancer after platinum-based regimens has a discouraging prognosis. Second-line agents have not been successful to date, but any active agent that has not been used during initial treatment is available to use.

| Docetaxel          | 75 mg/m² IV over 1 hour every 21–28 days vs. 30–40 mg/m² IV over 1 hour once every week | 22                | Neutropenia (DLT), hyperlacrimation, fluid retention, nail disorders, myelosuppression | 1. Premedicate for hypersensitivity reactions with dexamethasone  
2. Use with caution in liver dysfunction. Patients with bilirubin greater than the ULN and/or liver transaminases greater than 1.5 times the ULN should not receive docetaxel  
3. Do not give if the biliary tract is obstructed  
1. Use with caution in renal or liver dysfunction. No specific guidelines available |
| Gemcitabine        | 800 mg/m² IV infused over 30 minutes once a week on days 1, 8, and 15 followed by 1 week of rest | 13.9–27            | Myelosuppression (DLT), flulike symptoms, headache, somnolence, nausea/vomiting, stomatitis, diarrhea, constipation, rash | 1. Give proper dosing for liver dysfunction; total bilirubin 1.2–3 mg/dL (21–51 μmol/L); reduce dose by 50%; total bilirubin ≥ 3 mg/dL (51 μmol/L); reduce dose by 75%  
2. Do not give if total bilirubin is > 5 mg/dL |
| Liposomal doxorubicin | 40 mg/m² IV infused over 3 hours cycle 1 and 2, then infused over 1 hr; thereafter repeat every 28 days | 12.3–18           | Myelosuppression, stomatitis, mucositis, alopecia, flushing, shortness of breath, hypotension, headaches, cardiotoxicity, hand–foot syndrome |
| Topotecan          | 1.5 mg/m² IV infused over 30 minutes on days 1, 2, 3, 4, and 5; repeat every 21 days OR 4 mg/m² IV infused over 30 minutes once a week for 3 consecutive weeks followed by 1-week rest | 6.5–17            | Myelosuppression (DLT), nausea/vomiting, diarrhea, stomatitis, abdominal pain, alopecia, AST/ALT elevation | 1. Give proper dosing for renal dysfunction; CrCl 40–60 mL/min (0.67–1.00 mL/s); no dosage adjustment needed; CrCl 20–39 mL/min (0.33–0.66 mL/s); reduce dose by 50%  
2. Do not give if CrCl < 20 mL/min (0.33 mL/s) |
| Altretamine        | 260 mg/m² PO daily for 14–21 days; repeat every 28 days             | 9.7               | Nausea/vomiting, diarrhea, abdominal cramping, myelosuppression | 1. Monitor for potential CYP450 drug interactions  
2. Use with caution in renal dysfunction; CrCl ≥ 51 mL/min (0.84 mL/s); no dose adjustment; CrCl 30–50 mL/min (0.50–0.83 mL/s); reduce dose by 25%; CrCl < 30 mL/min (0.50 mL/s); do not give  
3. Use with caution in liver dysfunction; no specific guidelines available |
| Capecitabine       | 1800–2500 mg/m² PO as divided dose twice daily for 14 consecutive days followed by 1 week of rest | 29                | Myelosuppression, hand–foot syndrome, nausea/vomiting, edema, stomatitis, diarrhea, cardiotoxicity, rash | 1. Monitor for PPE and recommend regular use of lotions on hands and feet  
2. Use with caution in renal dysfunction; CrCl ≥ 51 mL/min (0.84 mL/s); no dose adjustment; CrCl 30–50 mL/min (0.50–0.83 mL/s); reduce dose by 25%; CrCl < 30 mL/min (0.50 mL/s); do not give  
3. Use with caution in liver dysfunction; no specific guidelines available |

(Continued)
Patient Encounter 1, Part 2: Completion of Primary Treatment

Your patient completed six cycles of paclitaxel 175 mg/m² IV plus carboplatin AUC 6 IV. Her CT scan findings suggest minimal residual disease and CA-125 has decreased but still above the normal range (38 U/mL [38 kU/L]) upon completion of her chemotherapy. She feels great and has no obvious symptoms of ovarian cancer at this time.

Discuss the advantages and disadvantages of treatment options for consolidation treatment with chemotherapy versus bevacizumab for this patient.

Describe the role of second-look surgery for this patient.

In addition, appropriate diagnostic scans (ie, CT scan, MRI, or PET scan) should be evaluated once every three cycles. Patients should also have routine physical examinations with each cycle of chemotherapy to evaluate for any physical toxicity associated with chemotherapy such as neutropenias, fluid retention, palmar-plantar erythrodysesthesia, myelosuppression, or nausea/vomiting.

Unfortunately, most patients will eventually progress through all chemotherapy options, and supportive care measures should be provided to maintain patient comfort and quality of life. Common complications while developing a plan for treatment of advanced or progressive ovarian cancer include ascites, uncontrollable pain, and SBO. Precaution should be used in removal of ascites because of the potential complications associated with rapid fluid shifts. Liberal use of opioids to control pain is appropriate as ovarian cancer patients cope with PD and approaching end of life. Appropriate bowel regimens with laxatives and stool softeners should be used to prevent constipation. However, when a patient with a well-controlled bowel regimen presents with new onset of constipation, additional workup is required before altering the bowel regimen. In ovarian cancer patients, SBO is a common complication of progressive disease.

In general, laxatives should not be used in patients with SBOs. Before treating constipation, patients should have a physical examination and abdominal x-ray to rule out SBO. Often, palliative surgery is required to correct SBO and alleviate patient pain. Patients should not eat any solid or liquids until resolution of SBO. If inoperable SBO exists, then parenteral nutrition can be considered but weighed against ultimate treatment objectives. Overall, providing any measures needed to maintain patient comfort is the priority for patients with progressive ovarian cancer.

Acute Leukemia

INTRODUCTION

The acute leukemias are hematologic malignancies of bone marrow precursors characterized by excessive production of immature hematopoietic cells. This proliferation of “blast” cells eventually replaces normal bone marrow and leads to the failure of normal hematopoiesis and the appearance in peripheral blood as well as infiltration of other organs. These blast cells proliferate in the marrow and inhibit normal cellular elements, resulting in anemia, neutropenia, and thrombocytopenia. Leukemia also may infiltrate other organs, including the liver, spleen, bone, skin, lymph nodes, testis and central nervous system (CNS). Virtually anywhere there is blood flow, the potential for extramedullary (outside the bone marrow) leukemia exists.

Acute leukemias are classified according to their cell of origin. Acute lymphocytic leukemia (ALL) arises from the lymphoid precursors. Acute nonlymphocytic leukemia (ANLL) or acute myelogenous leukemia (AML) arises from the myeloid or megakaryocytic precursors. As a result of clinical trials defining various prognostic (risk) factors that helped guide treatment modifications, the outcomes of acute leukemias, especially ALL, has improved dramatically over the past 30 years. Risk-based treatment strategies that consider multiple phenotypic and biological risk factors and attempt to match the aggressiveness of therapy with the presumed risk of relapse and death are now the standard of care. Despite the overall success in treating patients with acute leukemias, the long-term survival for patients who relapse remains dismal.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Leukemia is a relatively uncommon disease. The current overall age-adjusted annual incidence of acute leukemia in the United States has remained relatively stable at 10 per 100,000 in children and 1 to 2 per 100,000 in adults. In 2015, it is estimated that there will be 54,270 new cases of leukemia, or 3.1% of all new cancer cases.

In the pediatric population, leukemia is a common cancer, accounting for almost one-third of all childhood malignancies. ALL accounts for 75% to 80% of all cases of childhood leukemia, whereas AML accounts for no more than 20%. Males generally are affected more often than females in all but the infant age group, and its incidence is higher in whites than among other racial groups.

The incidence of AML in children is bimodal: It peaks at 2 years of age, decreases steadily thereafter to age 9 years, and then increases again at around age 16. The average age of diagnosis for AML is about 65 years and is a result of an increasing incidence of AML with age.

Etiology

The causes of the acute leukemias is unknown; multiple influences related to genetics, socioeconomics, infection, environment, hematopoietic development, and chance all may play a role. Table 95–1 lists the major conditions that have been associated with the acute leukemias. In most cases, however, there is no identifiable cause of the leukemia.

Although leukemia is rarely a hereditary disease, some genetic associations are evident. For example, among identical twins, the concordance for ALL in the initially unaffected twin is 20% to 25% within 1 year. Although the incidence in fraternal twins is much less, there is still a fourfold increase in the risk of leukemia in the initially unaffected twin compared with the normal population. One explanation for this association may be a shared placental circulation, which allows for transmission of disease from one twin to the other. Additionally, leukemia is known to have an increased incidence in several chromosomally abnormal populations. Patients with Down syndrome have a 20 times
increased risk of developing leukemia compared with the rest of the population. Patients with Klinefelter syndrome and Bloom syndrome also have an increased incidence of leukemias.

Exposure to environmental agents such as agricultural chemicals, pesticides, and radiation have also been periodically associated with leukemia, but none is conclusively related to the development of leukemia. An increased frequency of ALL is associated with higher socioeconomic status. It is postulated that less social contact in early infancy and thus a late exposure to some common infectious agents may have some impact.

Risk factors for the development of AML include exposure to environmental toxins, Hispanic ethnicity, and genetics. Of greater concern is the increased prevalence of AML as a secondary malignancy, resulting from chemotherapy and radiation treatment for other cancers. Alkylating agents, such as ifosfamide and cyclophosphamide, and topoisomerase inhibitors, such as etoposide, are linked to an increased risk of AML and myelodysplastic syndrome (MDS).

**PATHOPHYSIOLOGY**

Hematopoiesis is defined as the development and maturation of blood cells and their precursors. In utero, hematopoiesis may occur in the liver, spleen, and bone marrow; after birth, this process occurs exclusively in the bone marrow. All blood cells are generated from a common hematopoietic precursor, or stem cell. These stem cells are self-renewing and pluripotent and thus are able to commit to any one of the different lines of maturation that give rise to platelet-producing megakaryocytes, lymphoid, erythroid, and myeloid cells. The myeloid cell line produces megakaryocytes, natural killer (NK) cells, and dendritic cells. In contrast to the ordered development of normal cells, the development of leukemia seems to represent an arrest in differentiation at an early phase in the continuum of stem cell to mature cell.

Both AML and ALL are presumed to arise from clonal expansion of these “arrested” cells. As these cells expand, they acquire one and often more chromosomal aberrations, including translocations, inversions, deletions, point mutations, and amplifications. The translocation t(12;21) or TEL-AML1 is found in approximately 25% of cases of pediatric ALL and is associated with a favorable prognosis. This translocation is uncommon in adults. Another example is the t(9;22) translocation (Philadelphia chromosome, Ph+), which results in the BCR-ABL fusion protein. This translocation produces a novel kinase that leads to uncontrolled proliferation, survival, and self-renewal of cells. It is uncommon in childhood ALL and commonly found in adult ALL, especially in older patients.

Patients with MDS or AML as a secondary neoplasm are often characterized by having had prior alkylator-based or etoposide-based chemotherapy. Patients who have received treatment for Hodgkin disease or solid tumors are most at risk for this problem because they often treated with these agents. Patients with MDS have an abnormal bone marrow and a variety of cytopenias involving one or more of their marrow cell lines. They are at high risk of converting to overt leukemia over time. A variety of complex cytogenetic findings and monosomies of chromosome 5 or 7, and 11q23 translocations are often present in this population.

**Leukemia Classification**

Classification methods for leukemia have evolved from simple schemes that were largely phenotypic and considered only age, gender, white blood cell (WBC) count, and blast morphology to now-complex methods that include biological features such as cell-surface receptors, DNA content (ploidy; more or less than normal chromosomal DNA content), and a variety of cytogenetic abnormalities.

For all newly diagnosed patients with leukemia, an aspirate of the liquid marrow and a bone marrow core biopsy are obtained. Analysis of the leukemic cell surface markers (immunophenotyping) establish three types of ALL, pre-B, mature B, and T-cell precursor ALL. There are eight subtypes of AML (M0 to M7) as classified by the French-American-British (FAB) scheme (Tables 95–2 and 95–3).

**Immunophenotyping** by flow cytometry has taken on an increasingly important role in the diagnosis of leukemia. Owing to the ease of application, sensitivity, and quantifiable results, flow cytometry is the preferred method for leukemic lineage as well as prognostic assignment. This approach takes advantage of the development of diagnostic monoclonal antibodies (MAbs) to many cell-surface antigens that are differentially expressed during hematopoietic differentiation. The antigens are referred to as antibody cluster determinants (CDs) that define cells at various stages of development and can easily separate ALL from AML and T-cell from pre-B-cell ALL. The combined approach of flow cytometric identification and cytogenetic DNA content, much of which is also revealed by flow cytometry and fluorescent in situ hybridization (FISH; microscopic, fluorescence identification of chromosomal features) has facilitated diagnosis and delineation of specific subtypes of the acute leukemias. Common immunophenotypic markers seen in AML and ALL are provided in Table 95–4.

**Prognostic Factors**

**Key Concept** The goal of treatment is to match treatment to risk and minimize overtreatment or undertreatment. Patients with leukemia are sorted into prognostic categories based on clinical and biological features that mirror their risk of relapse. Risk assessment is an important factor in the selection of treatment. Age, WBC, leukemic cell-surface markers, DNA content, and specific...
cytogenetic abnormalities predict response to therapy and are used to assign risk and associated treatment.4 On the basis of these prognostic variables, patients are assigned to standard-, high-, or very-high-risk groups that determine the aggressiveness of treatment.

**Table 95–3**

**WHO Classification of AML and Related Neoplasms**

| AML with recurrent genetic abnormalities: | AML with t(8;21)(q22;q22); RUNX1-RUNX1T1 |

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CD, cluster determinants.

An 8-year-old boy presents to the pediatric emergency department with his father with a history of aches, chills, and fevers for the past 4 to 5 days. He has had several colds over the past few weeks that do not seem to be improving. He has also had diffuse body and bone pain in his legs over the past couple of weeks. Physical examination reveals pallor, cervical lymphadenopathy, and hepatosplenomegaly. Electrolytes and uric acid are within normal limits. A complete blood count (CBC) shows a normochromic, normocytic anemia with a hemoglobin of 7.0 g/dL (70 g/L, 4.34 mmol/L; reference range, 11.7 to 15.7 g/dL, 7.26 to 9.74 mmol/L), hematocrit of 21% (0.21; reference range, 35%–47% or 0.35–0.47), and WBC count of 4.1 × 10⁹/mm³ (4.1 × 10⁹/L). The differential on the WBC count reveals 65% (0.65) lymphocytes (reference range, 20%–40% or 0.2–0.4), 13% (0.13) neutrophils (reference range, 55%–62% or 0.55–0.62), and 22% (0.22) lymphoblasts (normal amount, 0%). Flow cytometry from the peripheral blood is consistent with pre–B-cell ALL.

**What information is consistent with the diagnosis of ALL?**

**What are the prognostic factors for this patient?**

**What is the role of flow cytometry in identifying ALL?**

---

22, t(9;22)(q34;q11.2), is a high-risk feature, which is present in about 3% of children but is much more common in adults with ALL. This translocation results in a novel tyrosine kinase that drives cell proliferation.⁷,⁸

Among children younger than 1 year of age, as many as 70% possess a poor prognostic genotype represented by the presence of the MLL (11q22) gene rearrangement. This finding is rare among older patients. Leukemias with the MLL gene rearrangement are highly resistant to the key antileukemic drugs such as glucocorticoids and L-asparaginase.⁹

The DNA content of blast cells, hyper-, hypo-, or diploid, corresponding to increased, decreased, or normal chromosome numbers, has been considered prognostic. Lower risk patients with hyperdiploidy (greater than 50 chromosomes per leukemic cell) generally include approximately 25% of children who have B-cell lineage ALL.¹⁰ These children are between the ages of 1 and 9 years, but the higher risk patients with normal diploidy (50 chromosomes) generally are older. Hypodiploid ALL with less than 44 chromosomes occurs in 1% to 5% of pediatric patients with ALL and is an independent risk factor for poor prognosis with declining prognosis with decreased chromosome number.¹⁰

Patients with cell-surface markers indicating that the blasts are early in the B-cell lineage (CD markers) are considered favorable and standard risk, whereas those with mature B-cell and T-cell blasts are considered high risk. T-cell ALL is found in approximately 15% of childhood ALL. Compared with B-lineage ALL, T-cell ALL is relatively resistant to different classes of drugs, including methotrexate and cytarabine.

Patients completing induction treatment and in apparent remission still harbor malignant cells in their bone marrow even though they appear disease free by peripheral blood and bone marrow morphology. Assuming that most patients present with about a 10³ to 10⁴ leukemic cell burden at diagnosis, at least 10⁹ cells remain after initial treatment. These residual leukemic cells are below the limits of detection using standard morphologic examination. Measurement of this population of cells has become an increasingly significant prognostic factor and a determinant of the aggressiveness of postinduction therapy. Through flow cytometric analysis and polymerase chain reaction, it is possible to detect one leukemic cell among 10⁹ normal cells, representing a 100-fold greater sensitivity than morphologic examination.¹¹,¹²

**Minimal residual disease (MRD) is a quantitative assessment of subclinical remnant of leukemic burden remaining at the end of the initial phase of treatment (induction) when a patient may appear to be in a complete morphologic remission. This measure has become one of the strongest predictors of outcome for patients with acute leukemia. The elimination of MRD is a principal objective of postinduction leukemia therapy. Several studies in children, in whom ALL is common, have evaluated disease levels at the end of induction and correlated these values with event-free survival (EFS). For a patient with detectable MRD less than 0.1% at the end of induction, EFS is 88% at 3 years. Conversely, a patient with high MRD (greater than 1%) has a 3-year EFS of only 30%.¹³ Assessment of MRD is also emerging as an important indicator of disease recurrence in the adult population and in patients with AML.**

### Prognostic Factors in AML

The major prognostic factors in newly diagnosed AML are age, subtype, chromosome status, ethnicity, and body mass index.

Older adults with AML (greater than 60 years), compared with younger patients with the same disease, have a dismal prognosis and represent a distinct population in terms of disease biology, treatment-related complications, and overall survival (OS). These older patients have a higher incidence of unfavorable chromosomal abnormalities, such as aberrations of chromosomes 5, 7, or 8, FLT₇ internal tandem duplication (ITD) and fewer abnormalities that are associated with a more favorable outcome, such as t(8;21) or inv(16) (Table 95–6).¹⁴,¹⁵

Recent studies suggest that ethnicity may be an important predictor of outcome in children with AML. Investigators found that African Americans treated with chemotherapy had a significantly worse outcome than whites, perhaps suggesting race-related pharmacogenetic differences. Body mass index may also affect the prognosis of children with AML. Underweight patients and
overweight patients were less likely to survive than normal weight patients because of a greater risk of treatment-related deaths. Current clinical trials in adults and pediatrics strongly suggest that patients with detectable MRD at the end of induction therapy or consolidation is strongly associated with the risk of relapse.\textsuperscript{14}

**TREATMENT**

**Desired Outcome**

The primary objective in treating patients with acute leukemia is to achieve a continuous complete remission (CCR). Remission is defined as the absence of all clinical evidence of leukemia with the restoration of normal hematopoiesis. For both ALL and AML, remission induction is achieved with the use of myelosuppressive chemotherapy that initially induces a state of bone marrow aplasia as the leukemic cells die followed by a slow return and proliferation of normal cells. After this period, hematopoiesis is restored. Failure to achieve remission in the first 7 to 14 days of therapy is highly predictive of later disease recurrence. This again represents the growing importance of MRD in prognosis and treatment.

**Nonpharmacologic Therapy**

This year, roughly 1.6 million people will be diagnosed with cancer in the United States and Canada. With improvements in detection and treatment, approximately two-thirds of those diagnosed with the disease can expect to be alive in 5 years. With improving longevity, the cumulative adverse effects of both the disease and treatment are becoming an increasingly important issue. “Late-effects” data show that both adult and pediatric cancer survivors are at greater risk for developing second malignancies, cardiovascular disease, diabetes, and osteoporosis than those in the general population. With respect to the growing population of pediatric cancer survivors, data confirm that they are eight times more likely than their siblings to have a severe or life-threatening chronic health condition. For example, the survivors of pediatric ALL have an increased risk of obesity, osteopenia, and associated comorbidities. Thus, it is important to provide supportive care and intervention and counseling related to nutrition, smoking cessation, and exercise as a part of their active treatment. Health care professionals should think beyond the immediate treatment-related issues of their patients and provide appropriate, active assistance to promote healthy lifestyles and encourage patients to take active roles in pursuing general preventive health strategies.\textsuperscript{15}

**Pharmacologic Therapy: ALL**

The treatment for ALL consists of four main elements: remission induction (the initial tumor reduction leading to morphologic remission), CNS-directed treatment, intensive postremission consolidation regimens, followed by a prolonged maintenance phase (Table 95–7).

**Remission Induction**

The initial treatment for acute leukemias is called induction. The purpose of induction is to induce a remission, a state in which there is no identifiable leukemic cells in the bone marrow or peripheral blood with light microscopy. Current induction therapy for ALL typically consists of vincristine, L-asparaginase, and a steroid (prednisone or dexamethasone). An anthracycline is added for higher risk patients. Although induction treatment produces 95% CR in children, it declines to no more than 60% in patients older than 60 years of age.

Adults, unlike children, are universally considered to be at high risk for relapse; therefore, their induction regimens include an anthracycline (daunorubicin or doxorubicin) in addition to the standard steroid and vincristine treatment that have been the backbone of treatment for this disease for the last 40 years.\textsuperscript{16,17}

---

**Patient Encounter 1, Part 2**

The patient is admitted to the pediatric oncology service. A bone marrow biopsy and aspirate is done, which shows 85% replacement with precursor B-cell blasts. FISH analysis performed on the peripheral blood is positive for the BCR/ABL translocation (Ph\textsuperscript{+}) in 5.5% of the cells examined. He is started on intravenous hydration with sodium bicarbonate and allopurinol. A diagnostic lumbar puncture (LP) is performed, which is negative for CNS leukemia. During the LP, the patient receives IT cytarabine.

**What is the role of CNS prophylaxis for this patient?**

**What is the BCR/ABL translocation?**

**How does the presence of this chromosomal abnormality change this patient’s risk status?**

Clinical Presentation and Diagnosis of ALL

**General**
- Typically, patients have symptoms for 1 to 3 months before presentation. These include fatigue, fever, and pallor, but patients generally are in no obvious distress.

**Symptoms**
- The patient may present with weakness, malaise, bleeding, and weight loss.
- Neutropenic patients are often febrile and highly susceptible to infection.
- Anemia usually presents as pallor, tiredness, and general fatigue.
- Patients with thrombocytopenia usually present with bruising, petechiae, and ecchymosis.
- Patients often present with bone pain secondary to expansion of the marrow cavity from leukemic infiltration.
- CNS involvement is common at diagnosis.

**Signs**
- Temperature may be elevated secondary to an infection associated with a low WBC count.
- Petechiae and bleeding are indicative of thrombocytopenia.
- Patients may present with organ involvement, such as peripheral adenopathy, hepatomegaly, and splenomegaly.
- T-lineage ALL may present with a mediastinal mass.

**Laboratory Tests**
- CBC with differential is performed.
- The anemia is usually normochromic and normocytic. Approximately 50% of children present with platelet counts of less than 50 × 10^9/mm^3 (50 × 10^9/L). The WBC count may be normal, decreased, or high. About 20% of patients have WBC counts over 100 × 10^9/mm^3 (100 × 10^9/L), which places them at risk for leukostasis.
- Uric acid is increased in approximately 50% of patients secondary to rapid cellular turnover.
- Electrolytes: Potassium and phosphorus often are elevated. Calcium usually is low.
- Coagulation disorders: Elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia.

**Other Laboratory Tests**
Flow cytometric evaluation of bone marrow and peripheral blood is performed to characterize the type of leukemia as well as to detect specific chromosomal rearrangements. The bone marrow at diagnosis usually is hypercellular, with normal hematopoiesis being replaced by leukemic blasts. At diagnosis, a LP is performed to determine if CNS leukemia is present.

Dexamethasone often replaces prednisone as the steroid of treatment because of its longer half-life and better CNS penetration. Although dexamethasone possesses more favorable pharmacologic characteristics than prednisone, its use may be associated with more aseptic osteonecrosis of the femoral and humoral heads as well as an increase in life-threatening infections and septic deaths.

**CNS Prophylaxis**

Leukemic invasion of the CNS is considered to be an almost universal event in patients even in those whose cerebrospinal fluid (CSF) cytology shows no apparent disease. Thus, all patients with ALL and AML leukemia receive intrathecal (IT) chemotherapy. Although this is often referred to as “prophylaxis,” it more realistically represents treatment. CNS prophylaxis relies on IT chemotherapy (eg, methotrexate, cytarabine, and corticosteroids), systemic chemotherapy with dexamethasone and high-dose methotrexate, and craniospinal irradiation (XRT) in selected high-risk patients. Cranial radiation use diminished substantially after the efficacy of IT treatment was evident, and the toxicities associated with radiation; learning disabilities, growth retardation, and secondary malignancies (particularly with the use of 6-mercaptopurine), were recognized. IT therapy has replaced cranial XRT as CNS prophylaxis for all except the very high-risk patients and those with T-cell ALL who are at higher risk of CNS disease.

Inexplicably, the treatment of CNS leukemia has not impacted the OS of adults as it has for childhood ALL. With IT chemotherapy alone, the incidence of CNS relapse in adults is 9% to 13% compared with less than 3% in children.

**Postremission Consolidation Regimens**

**Consolidation** After completion of induction and restoration of normal hematopoiesis, patients begin consolidation. The goal of consolidation is to administer dose-intensive chemotherapy in an effort to further reduce the burden of residual leukemic cells. It is in this and subsequent treatment phases that the remaining leukemic burden is eliminated. Several regimens use agents and schedules designed to minimize the development of drug cross-resistance. Studies have demonstrated that consolidation is an effective strategy in the prevention of relapse in children with ALL, but its benefits in adults are less clear.

In children, the intensity of the consolidation treatment is now determined not only by the child’s risk classification but also by the degree of cytocrviewer during induction (MRD). Patients who respond slowly to induction therapy (as determined by bone marrow examination early in induction) are at higher risk of relapse and are treated with more aggressive regimens.

**Delayed Intensification** The Berlin-Frankfurt-Munster (BFM) Study Group introduced a treatment element called delayed intensification (or reinduction) therapy. This therapy consisted of repetition of the initial remission induction therapy administered approximately 3 months after remission. This, similar to consolidation, has been adopted as a component of treatment for children by virtually all institutions.

Intensification regimens may vary in their aggressiveness and the drugs they use depending on the patient’s risk group and immunophenotype. For example, the use of high-dose methotrexate (5 g/m^2) appears to improve outcome in patients with T-cell ALL. The use of intensive asparaginase treatment in T-cell ALL patients also has improved outcomes significantly.

**Maintenance**

The purpose of maintenance therapy is to further eliminate leukemic cells and produce an enduring CCR. The two most important agents in maintenance chemotherapy are a combination of oral methotrexate and 6-mercaptopurine. Improved outcome is associated with increasing 6-mercaptopurine doses to the limits of individual tolerance based on absolute neutrophil count (ANC). The benefit of adding intermittent “pulses” of vincristine and a steroid (usually dexamethasone) to the antimetabolite backbone remains unclear, but it is common practice in most modern treatment regimens. The goal is to induce a moderate immunosuppression and leukemic cell kill. 6-Mercaptopurine is a key agent in maintenance therapy. It has a complex metabolism and is initially cleared by thiopurine methyltransferase (TPMT). TPMT activity is variable with about 90% of patients having normal activity, about 10% having intermediate activity, and fewer than 1% having very low or no activity. These enzymatic polymorphisms are inherited in an autosomal recessive fashion and have a profound influence on 6-mercaptopurine tolerance.6-8,21

TPMT screening is recommended for children starting therapy with 6-mercaptopurine. Children who possess alleles that have diminished activity require 6-mercaptopurine dose reductions of 50% to 90% to prevent severe immunosuppression and infection. Despite these reductions, these children have equivalent OS when compared with those receiving full-dose 6-mercaptopurine. The optimal duration of maintenance therapy in both children and adults is unknown, but most regimens are given for 2 to 3 years; extension of the regimen beyond 3 years has not shown any additional benefit.

**ALL in Infants and Young Children**

Infants and children younger than 1 year of age account for approximately 5% of all children with ALL and have the worst outcome of any group with this disease. These patients have several poor prognostic features at diagnosis, including hyperleukocytosis, hepatomegaly, splenomegaly, and CNS leukemia.9

A characteristic finding in up to 70% in this group is a chromosomal translocation involving the MLL gene located at 11q23. There are multiple possible rearrangements of this gene with other chromosomes, and all confer a poor prognosis. In vitro, blasts of these patients showed greater drug resistance to prednisolone and L-asparaginase than from other patients, although they are more sensitive to cytarabine.22 Based on this information, several studies are testing the efficacy of intensified chemotherapy that includes high-dose cytarabine. Another achievement is the prevention of CNS relapse using IT cytarabine in conjunction with high-dose systemic cytarabine. This combination has eliminated the need for cranial XRT in this young population. Even with major advances in cure rates for the general pediatric ALL population, in whom survival is 80% or more, the long-term survival of infants is only about 40% (Tables 95–8).

**ALL in Adolescents and Young Adults**

As noted previously, age is an important prognostic factor in ALL. Adolescents and adult patients have generally been shown to have poorer survival than children. However, the group of patients between late adolescence and age 30 years (adolescents and young adults) have a substantially better outcome than older adult patients, most likely because of the use of using

---
pediatric ALL regimens. Retrospective studies show that survival is improved from 30% to 40% with standard adult therapy to as high as 65% with pediatric protocols. The reasons for this are not entirely clear, and multiple factors are likely to play a role. Among the likely explanations is that pediatric protocols use more aggressive and prolonged postremission consolidation therapy before maintenance. Other proposed explanations are the potential differences in disease biology in this versus older age patients, more intense CNS prophylaxis, and the greater degree of social support and better compliance fostered in a pediatric environment. Current and planned trials are focusing on the potential of extending this treatment approach to patients age 40 years and possibly older.

**ALL in Adults**

The incidence of ALL in adults ages 30 to 60 years is only 2 per 100,000 persons per year compared with almost 10 per 100,000 in children. The conventional risk factors such as high WBC counts, older age, and CNS disease hold true in adults as in children. However, the significance of cytogenetic and molecular markers that are so important in children seems to be less predictive of outcome in adults. An exception is the adverse prognostic factor, the presence of the *BCR-ABL* translocation (Ph¹) just as in childhood ALL. This occurs in 15% to 30% of adults and is even more common in patients older than 60 years of age. The use of imatinib or dasatinib, both potent inhibitors of the Ph¹-associated *BCR-ABL* tyrosine kinase, has now become a standard of practice for all patient groups with Ph¹ disease. Results show that the combination of these agents with conventional chemotherapy improves remission rates as well as OS compared with the use of conventional chemotherapy alone.

Currently, the induction and consolidation regimens in adults is similar to the regimens in pediatric patients, but the more aggressive postinduction regimens are not as well tolerated in this population, particularly in elderly patients (age greater than 60 years) and are associated with a much higher incidence of toxicity and treatment-related deaths. Some investigators are studying “moderate-dose” consolidation regimens that are better tolerated, although long-term efficacy data is lacking. Even though remissions are achieved in 80% to 90% of adult patients, 5 years disease-free survivals are only in the 30% to 40% range. Among elderly patients, the outcome is even poorer with no more than 20% having long-term survival.

**Relapsed ALL**

Relapse is the recurrence of leukemic cells at any site after remission has been achieved. Bone marrow relapse is the major form of treatment failure in 15% to 20% of patients with ALL. Most relapses have the same immunophenotype and cytogenetic changes seen of the original disease. Extramedullary sites of relapse include the CNS and the testicles. Extramedullary relapse, although once common, has decreased to 5% or less because of effective prophylaxis. Site of relapse and the length of the first remission are important predictors of second remission and OS. Marrow relapses occurring less than 18 to 24 months into first remission are associated with a poor survival, but longer periods of remission (greater than 36 months) have a much higher chance of survival. Treatment strategies for relapsed ALL include chemotherapy or allogeneic hematopoietic stem cell transplant (allo-HSCT). Even though patients undergoing allo-HSCT are less likely to relapse, treatment-related toxicity leads to a higher incidence of morbidity and mortality compared with chemotherapy alone. Clofarabine, a next-generation deoxyadenosine analogue, has shown considerable activity in children and adults with refractory acute leukemias. Of interest, this is the only anticancer drug to receive primary indication for use in pediatrics in the past 10 years.

**Treatment of AML**

As with ALL, the primary aim in treating patients with AML is to induce remission and thereafter prevent relapse. Treatment of AML is conventionally divided into two phases: induction and consolidation. The prognosis of children with AML has improved dramatically over the past 30 years. Rates of complete remission as high as 80% to 90% and overall survival rates of 60% now are reported. This improvement is a result of better understanding of the biology of AML and the development of molecular targets that are used in combination with conventional chemotherapy. The current induction therapy for AML usually consists of a combination of cytarabine, daunorubicin, and etoposide. The second phase of treatment for AML is called consolidation. The purpose of this phase is to further enhance remission with more cytoreduction.

**Remission Induction**

The goal of induction chemotherapy in AML is essentially identical to that in ALL—“empty” the bone marrow of all hematopoietic precursors and allow repopulation with normal cells. The combination of an anthracycline (eg, daunorubicin, doxorubicin,
Clinical Presentation and Diagnosis of AML

General
- Patients may have symptoms of AML for 1 to 3 months before presentation. These include fatigue, fever, and pallor, but patients generally are in no obvious distress.

Symptoms
- The patient may present with weakness, bone pain, malaise, bleeding, and weight loss.
- Neutropenic patients are often febrile and highly susceptible to infection.
- Anemia usually presents as pallor, tiredness, and general fatigue.
- Patients with thrombocytopenia usually present with bruising, petechiae, and ecchymosis.
- Chloromas (localized leukemic deposits named after their color) may be seen, especially in the periorbital regions and as skin infiltrates.
- Gum hypertrophy is indicative of AML M4 and AML M5 subtypes.
- Disseminated intravascular coagulation may be present in all AML subtypes, but is common in AML M3 and is associated with generalized bleeding or hemorrhage.
- Lymphadenopathy, massive hepatosplenomegaly, and bone pain are not as common in AML as in ALL.

Signs
- Temperature may be elevated secondary to an infection associated with a low WBC count.
- Petechiae and bleeding are indicative of thrombocytopenia.

Laboratory Tests
- CBC with differential is performed.
- The anemia is usually normochromic and normocytic.
- Approximately 50% of children present with platelet counts of less than $50 \times 10^3$ mm$^{-3}$ ($50 \times 10^3$/L).
- The WBC count may be normal, decreased, or high. About 20% of patients have WBC counts of over $100 \times 10^3$ mm$^{-3}$ ($100 \times 10^3$/L), which places them at risk for leukostasis.
- Uric acid is increased in approximately 50% of patients secondary to rapid cellular turnover.
- Electrolytes: Potassium and phosphorus are often elevated. Calcium is usually low.
- Coagulation disorders: Elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia.

Other Diagnostic Tests
Flow cytometric evaluation of bone marrow and peripheral blood to characterize the type of leukemia, as well as to detect specific chromosomal rearrangements. The bone marrow at diagnosis usually is hypercellular, with normal hematopoiesis being replaced by leukemic blasts. The presence of greater than 20% blasts in the bone marrow is diagnostic for AML. At diagnosis, a LP is performed to determine if CNS leukemia is present. The CNS is involved at diagnosis in approximately 15% of patients.

Postremission Chemotherapy
In AML, postremission chemotherapy is often referred to as consolidation therapy. Several cycles of intensive postremission chemotherapy combining non–cross-resistant agents given every 4 to 6 weeks substantially improves DFS. Without postremission treatment, all patients would relapse within several weeks. This is analogous to the consolidation and other phases of postremission chemotherapy in ALL. The use of high-dose cytarabine in postremission therapy seems to be important for improving survival, but the most effective dose has yet to be determined. Although the optimal number of courses remains to be determined, at least four are probably required.

Allogeneic Hematopoietic Stem Cell Transplantation
Hematopoietic stem cell transplantation (HSCT) is the most effective treatment for AML. Its promising benefit must be weighed against the potential risk of transplantation related sequelae. HSCT has become a less attractive option as the results of increasingly intensive chemotherapy and postrelapse salvage therapy have improved.

The availability of HLA-matched sibling donors determines whether patients undergo HSCT as postremission treatment. To facilitate this process, it is important to obtain HLA typing on all younger patients and siblings shortly after diagnosis. Patients who do not have an HLA-matched sibling proceed to postremission therapy with chemotherapy alone.

Complications and benefits of allogeneic HSCT are described in Chapter 98. Transplant-related mortality following matched-sibling allo-HSCT is 20% to 30% in most series. Complications from transplantation increase with age; therefore, patients older than 60 years of age are uncommonly considered to receive a myeloablative allo-HSCT. Because the average age of AML patients is 65 years, most patients with this disease are not candidates for this form of therapy. For older patients up to 70 years of age, a reduced-intensity (mini or nonmyeloablative allogeneic) transplant may be an option. These transplants use less intensive preparative regimens and rely on the allogeneic graft-versus-leukemia (GVL) effect to eliminate their disease.

The role of HSCT, particularly whether it should be performed during the first CR or reserved for second remission, remains
the most controversial issue in pediatric AML. In certain institutions, HSCT is often reserved for patients that are considered high risk. Some types of AML patients may be curable with conventional-dose chemotherapy alone.

**Autologous Hematopoietic Stem Cell Transplantation**

Because the majority of AML patients lack a HLA-identical donor, investigators began to consider the use of the patient’s own bone marrow, obtained while in CR, as a source of hematopoietic regeneration. However, relapse continues to be a problem secondary to the presence of residual disease in the graft. Despite the reduced morbidity and mortality associated with auto-HSCT, this type of transplant does not compare favorably to standard postremission chemotherapy.

► **CNS Therapy**

The prevalence of CNS disease at diagnosis of AML is approximately 15%. Features associated with the risk of CNS leukemia include hyperleukocytosis, monocytic, or myelomonocytic leukemia (FAB M4 or M5), and young age. Adequate CNS prophylaxis is an essential component of therapy. Studies have shown that patients with CNS disease at diagnosis can be cured with IT therapy alone without the use of cranial XRT. In most cases, IT cytarabine with or without methotrexate and systemic high-dose cytarabine provide effective treatment.

**AML in Infants**

AML in infants younger than 12 months of age shows clinical and biological characteristics different from those of older children. The disease phenotype is more commonly monoblastic or myelomonoblastic (M4, M5), and the patients usually present with hyperleukocytosis. Extramedullary involvement is common, often involving skin and other organs. As in infant AML, there is a high incidence of translocations involving the MLL gene in infant AML. The number of infant AML trials reported is limited, but the EFS of this population is similar to that of older children with AML. This is in marked contrast to the outcomes for infants with ALL for whom the EFS is much lower than in older children.

**AML in the Elderly**

AML is the most common acute leukemia in the elderly. Compared with younger patients with the same disease, older adults have a poor prognosis and represent a distinct population with regard to the biology of their disease. Older adults have a lower incidence of favorable chromosomal aberrations and a higher incidence of unfavorable aberrations. Fms-like tyrosine kinase 3 (FLT3), which is an AML oncogene plays an important role in AML pathogenesis and was associated with a poor outcome. FLT3-ITD is common in adults, but is only found in 12% of the pediatric population. The elderly also have a much higher incidence of comorbidities, such as type 2 diabetes, obesity, and other physiologic limitations. Thus, the poor prognosis of AML in the elderly is only partly the result of unfavorable biology.

In older adults, in contrast to children, AML is more likely to arise from a proximal bone marrow–stem cell disorder, such as MDS, or present as a secondary, prior treatment-related leukemia. These forms of AML are notoriously poorly responsive to conventional chemotherapy and thus have a lower CR rate and poorer survival.

As previously noted, age is an important prognostic factor. Older adults are not as tolerant of or as responsive to remission induction and consolidation chemotherapy as younger patients. Furthermore, long-term survival for patients older than 60 years is only 5% to 15% compared with 30% DFS for younger adults.

**Relapsed AML**

Even though 75% to 85% of patients with AML achieve a remission, only about 50% survive. Patients who relapse usually respond poorly to additional treatment and have a shorter duration of remission. This is probably related to drug resistance induced during induction and certain chromosomal abnormalities.

Even though there is no standard therapy for relapse, most studies have shown that high-dose cytarabine-containing regimens have considerable activity in obtaining a second remission. Cytarabine has been used in combination with mitoxantrone, etoposide, fludarabine, 2-chlorodeoxyadenosine, and (more recently) clofarabine. The targeted immunotherapy agent gemtuzumab has induced remissions who have recurrent CD33+ AML alone or in combination with standard chemotherapy.

After a patient has achieved a second remission with conventional chemotherapy, allo-HSCT is the therapy of choice. For patients without an HLA-matched sibling, a matched unrelated donor (MUD) or cord blood transplant may be a reasonable alternative. The combination of myeloablative high-dose chemotherapy and the GVL effect is thought to offer the best chance of survival in AML.

**Complications of Treatment**

► **Tumor Lysis Syndrome**

Tumor lysis syndrome (TLS) is an oncologic emergency that is characterized by metabolic abnormalities resulting from the death of blast cells and the release of large amounts of purines, pyrimidines, and intracellular potassium and phosphorus. Uric acid, the ultimate breakdown product of purines, is poorly soluble in plasma and urine. Deposition of uric acid and calcium phosphate crystals in the renal tubules can lead to acute renal failure. Many patients with acute leukemia, especially those with a high tumor burden, are at risk for TLS during the first several days of chemotherapy. Measures to prevent TLS include aggressive hydration, alkalinization to help solubilize uric acid, and allopurinol to reduce uric acid production. Hyperhydration and alkalinization is generally an effective method of dealing with this issue. However, on some occasions, the use of rasburicase is indicated. Rasburicase is a urate oxidase that catalyzes the oxidation of uric acid to allantoin, which is much more soluble than uric acid and excreted more easily. Given its high cost, rasburicase generally is restricted to patients with high WBC counts (greater than 50 × 10⁹/L, 50 × 10³/µL) and uric acid levels greater than 8 mg/dL (476 µmol/L).

► **Infection**

Infection is a primary cause of death in acute leukemia patients. Both the disease and aggressive chemotherapy cause severe myelosuppression, placing the patient at risk for sepsis.

The therapy for AML is extremely myelosuppressive. Children with AML have a 10% to 20% induction mortality rate secondary to infection and bleeding complications. Therefore, patients receiving induction therapy usually are hospitalized for the first 4 to 6 weeks of therapy. The induction therapy for ALL is far less myelosuppressive, and these patients recover their neutrophil counts quicker and usually do not require prolonged hospitalizations.

It is important to recognize that symptoms and signs of infection may be absent in a severely immunosuppressed or neutropenic patient. Fever (greater than 38.3°C [100.9°F]) in a
neutropenic patient is a medical emergency. Because the progression of infection in neutropenic patients can be rapid, empirical antibiotic therapy should be administered quickly when fever is documented. Currently, the most commonly used initial antibiotic agent is cefepime, a fourth-generation cephalosporin that has good antipseudomonal coverage as well as adequate coverage against *Streptococcus viridans* and pneumococci. Disseminated fungal infections most commonly caused by Candida and Aspergillus species can be life threatening in children with AML. From the results of clinical trials in adults, many pediatric institutions recommend antifungal prophylaxis with voriconazole, posaconazole, micafungin, or caspofungin. Fluconazole and itraconazole are not considered ideal, because they are not effective against aspergillus species and other molds. Trimethoprim–sulfamethoxazole is started in all patients with any acute leukemia for the prevention of *Pneumocystis jiroveci* pneumonia (PJP). Patients normally continue this therapy for 6 months after completion of treatment. The use of additional antibiotic prophylaxis is not encouraged because of concerns for antibiotic resistance.

Of note is that up to 10% of patients seem to exhibit excessive myelosuppression with trimethoprim–sulfonamides (presumably the result of the antifolate trimethoprim in combination with other systemic cytotoxic agents). Changing to another antibiotic agent such as dapsone or inhaled pentamidine may help to alleviate this problem.

### Secondary Malignancies

Secondary malignancies are a risk of the successful treatment of a prior cancer or the use of cytotoxic agents in a variety of autoimmune diseases. The chemotherapy agents used, especially alkylating agents and topoisomerase II inhibitors, predispose patients to secondary hematopoietic neoplasms. As the aggressiveness of treatment and the number of survivors of AML increase, the risk of secondary neoplasms also may rise. There are two different types of second malignancies: acute leukemia, which is generally myeloid in origin, or MDS. There are also reports of secondary solid tumors, especially within regions of prior radiation exposure. The latency period between the end of treatment and the development of a secondary leukemia is generally in the range of 5 to 10 years. For those patients who develop secondary solid malignancies, the latency may be as long as 10 to 20 years.

The incidence of second cancers attributed to alkylators peaks 4 to 6 years after exposure and plateaus after 10 to 15 years. Higher cumulative doses and older age at the time of treatment are risk factors for this type of cancer. Epipodophyllotoxins (etoposide and others) can induce a second malignancy characterized by balanced chromosomal translocations and short latency periods (2–4 years). The risk of this leukemia is related to schedule (dose intensity) and the concomitant use of other agents (L-asparaginase, alkylating agents, and possibly antimetabolites). The prognosis for topoisomerase II inhibitor–related secondary leukemia is extremely poor. Only about 10% of these patients survive after salvage chemotherapy, and only 20% survive after HSCT.

Irradiating therapy is also a cause of secondary malignancies. These secondary tumors generally develop within or adjacent to the previous radiation field. These cancers often have a prolonged latency, typically 15 or more years, but shorter latencies (5–14 years) are known. Higher doses of radiation and younger age are associated with an increased risk of secondary malignancy.

Unlike children, adults may have other factors that predispose them to secondary malignancies. Lifestyle choices such as tobacco use, alcohol use, and diet have been implicated in influencing the development of secondary neoplasms in the adult population. Now that 80% or more of children survive their primary cancers, the incidence of secondary neoplasms may increase. Recognizing this potential, many treatment regimens for children are being modified appropriately to reduce exposure to alkylators, topoisomerase inhibitors, and radiation. Late effects clinics screen for secondary malignancies and other disease and treatment-related disabilities that accompany childhood cancer. Similar screening and educational opportunities are not as established in adult survivors.

### Late Effects

With increased success in pediatric clinical trials, the OS rate for pediatric cancers has increased markedly over the last 35 years. For some diseases (acute lymphoblastic leukemia, Wilms tumor, low-grade and common germ cell tumors), the OS rate is now at or above 80%. Despite this significant increase in survival, many patients, particularly pediatric cancer survivors, have disease-related or treatment-related disabilities. As many as 50% to 60% of these survivors are estimated to have at least one chronic or late-occurring complication of treatment. In leukemia, the intensified use of methotrexate may be responsible for some sporadic neurotoxicity seen in children and adults. Likewise, the use of pharmacologic doses of glucocorticoids has been associated with avascular necrosis of bone in older children and adults. High cumulative doses of anthracyclines can cause irreversible cardiomyopathy. Cranial XRT is now less frequently used for CNS leukemia prophylaxis but can cause neuropsychological and neuroendocrine abnormalities that may lead to obesity, short stature, or precocious puberty. As newer and more intensive treatments enter clinical trials, close observation for long-term side effects will assume even greater importance.

### Supportive Care

Because of the need for repeated venous access, a central venous catheter or infusion port is placed before starting treatment. These devices are useful not only for delivery of chemotherapy but also to support patients during periods of myelosuppression. Infection and bleeding complications are the primary causes of mortality in patients with leukemia.

Platelet transfusions are a common tool to prevent hemorrhage. Patients with uncomplicated thrombocytopenia can be transfused when the platelet count falls below 10 × 10^9/mm³ (10 × 10^9/L). Patients who are either highly febrile or actively bleeding may require transfusions at higher levels. Red blood cell transfusions generally are not necessary for a hemoglobin concentration greater than 8 g/dL (80 g/L, 4.97 mmol/L).

There is much controversy regarding the routine use of colony-stimulating factors (eg, granulocyte colony-stimulating factor [G-CSF] and granulocyte-macrophage colony-stimulating factor [GM-CSF]) in neutropenic patients. Even though several clinical trials have shown the time to ANC recovery is decreased with a colony-stimulating factor, none have demonstrated that CSFs statistically influence infection-related mortality. At present, the use of colony-stimulating factors (G-CSF most commonly) generally is limited to those chemotherapy regimens that place the patient at highest risk for prolonged neutropenia.

### OUTCOME EVALUATION

Developing strategies for the treatment and monitoring of acute leukemias begins with risk stratification. Understanding the likely risk of relapse determines the aggressiveness and length...

Continuous complete remission

Determine the significance of the presence MRD at the

end of induction.

Care Plan Development:

• Provide patient education on the potential side effects of
the drug therapy for acute leukemia.
• Address the importance of medication compliance.
• Discuss the warning signs to report immediately to the
health care provider (eg, fever, bruising, or bleeding).

Follow-up Evaluation:

• Follow-up with weekly CBCs and electrolytes to assess
the effectiveness of therapy for any adverse effects associated
with treatment.
• Provide education regarding the long-term sequelae
associated with the treatment for acute leukemia.

Therapy Evaluation:

• Evaluate the response to treatment by performing a bone
marrow and LP.
• Does the patient demonstrate any residual leukemia as
defined by the presence of blasts in the bone marrow or
‘CSF’?
• Determine the significance of the presence MRD at the
end of induction.

A clinician is generally charged with developing a plan to
educate patients and families about their drugs and doses.
This is a critical responsibility; it is imperative that the patients
and their families understand why they are receiving their medications
and how to take them. Frank, open discussion (with the
family or patient in possession of their prescriptions) go a long
way toward preventing errors that occur as a result of “assuming”
that they understand their medications. If modifications are
necessary secondary to toxicity or inadequate response, establish
a plan for treatment change. Remember that individual patients
often do not fit the “average” patient profile, and dose modifications
are frequently needed. The practitioner should be familiar
with dosing ranges, WBC count, and other parameters that
indicate appropriate treatment response. Based on response to
prior phases of treatment, the clinician should recognize potential
toxicities in subsequent phases of treatment with the same or
different drugs at similar or different doses.

REFERENCES

Patient Care Process

Patient Assessment:

• Based on the physical exam and review of systems does
the patient have the symptoms and physical findings of
acute leukemia?
• Review the medical history. Is the patient receiving any
medications that would be contraindicated or cause
adverse effects prior to starting induction therapy?
• Review the laboratory features especially serum
electrolytes and uric acid.
• Measure serum electrolytes and uric acid every 6 to 8 hours
during the first 3 to 4 days of therapy. Patient may require
frequent blood and platelet transfusions.

Therapy Evaluation:

• Evaluate the response to treatment by performing a bone
marrow and LP.
• Does the patient demonstrate any residual leukemia as
defined by the presence of blasts in the bone marrow or
‘CSF’?
• Determine the significance of the presence MRD at the
end of induction.

the effectiveness of therapy for any adverse effects associated
with treatment.
• Provide education regarding the long-term sequelae
associated with the treatment for acute leukemia.

Of therapy. Remission status and MRD after the induction phase
of treatment must be closely observed. Failure to obtain morphologic bone marrow remission by day 28 is a very adverse
diagnostic sign and dictates further induction treatment. For
those who have a morphologic remission, quantification of MRD
has become an increasingly important prognostic factor. Levels
of residual less than 0.01% appear to be associated with better
outcomes.

A clinician is generally charged with developing a plan to
educate patients and families about their drugs and doses.
This is a critical responsibility; it is imperative that the patients
and their families understand why they are receiving their medications
and how to take them. Frank, open discussion (with the

indicate appropriate treatment response. Based on response to
prior phases of treatment, the clinician should recognize potential
toxicities in subsequent phases of treatment with the same or
different drugs at similar or different doses.

INTRODUCTION

Several diseases comprise chronic leukemia. The two most common forms are chronic myelogenous leukemia (CML) and chronic lymphocytic leukemia (CLL). The slower progression of the disease contrasts it from acute leukemia, with the survival of chronic leukemia often lasting several years without treatment. This chapter covers CML and CLL. The chapter also discusses the hematologic cancer multiple myeloma.

CHRONIC MYELOGENOUS LEUKEMIA

CML is a hematologic cancer that results from an abnormal proliferation of an early myeloid progenitor cell. The clinical course of CML has three phases: chronic phase, accelerated phase, and blast crisis. Criteria for these phases is largely based on the percent blasts in the peripheral blood or bone marrow. Chemotherapy can be used to control white blood cell (WBC) counts in the chronic phase, but as CML slowly progresses, the cancer becomes resistant to treatment. Blast crisis resembles acute leukemia, and immediate aggressive treatment is required.

EPIDEMIOLOGY AND ETIOLOGY

It was estimated that 6660 new cases of CML would be diagnosed in 2015, accounting for 15% of all adult leukemias. The incidence of CML increases with age, the median age being 67 years. In most newly diagnosed cases, the etiology cannot be determined, but high doses of ionizing radiation and exposure to solvents such as benzene are recognized risk factors.

PATHOPHYSIOLOGY

Cell of Origin

CML arises from a defect in an early progenitor cell. The pluripotent (noncommitted) stem cell is implicated as the origin of the disease; therefore, multiple cell lineages of hematopoiesis may be affected, including myeloid, erythroid, megakaryocyte, and (rarely) lymphoid lineages. These cells remain functional in chronic phase CML, which is why patients in this phase are at low risk for developing infections.

Ph Chromosome

The Philadelphia chromosome (Ph) results from a translocation between chromosomes 9 and 22, leaving a shortened chromosome 22. The Ph results in the formation of an abnormal fusion gene between the breakpoint cluster region and the Abelson proto-oncogene (BCR-ABL), which encodes an overly active tyrosine kinase. The loss of control of tyrosine kinase activity causes abnormal cellular proliferation and inhibition of apoptosis. Molecular tools such as quantitative and qualitative polymerase chain reaction (Q-PCR) and fluorescence in situ hybridization (FISH) are used in detection and monitoring of CML.

TREATMENT

Desired Outcome

The primary goal in the treatment of CML is to eradicate the Ph positive clones. Elimination of the Ph is termed a complete cytogenetic response. International standardization of molecular
Clinical Presentation and Diagnosis of CML

Signs and Symptoms
- 30%–50% are asymptomatic at diagnosis
- Symptoms may include fatigue, fever, weight loss, and bleeding
- Organomegaly consisting of splenomegaly and hepatomegaly

Diagnostic Procedures
- Peripheral blood smear
- Bone marrow biopsy (percentage of blasts)
- Cytogenetic studies
- Molecular testing (Q-PCR and FISH to detect BCR-ABL transcripts)

Laboratory Findings
Peripheral blood smear
- Leukocytosis (most present with WBC count > 100 × 10^3/mm^3)
- Thrombocytosis (~50% of patients in chronic phase)
- Anemia
- Basophilia
- Presence of blasts

Bone marrow
- Hypercellularity with presence of blasts
- Cytogenetics including the presence of Ph

Poor Prognostic Factors
- Older age
- Splenomegaly
- High percent blasts in the blood
- High or low platelet count

response has been updated to reflect a percentage of BCR-ABL1 compared to control gene. A complete molecular response is undetectable BCR-ABL transcripts by the international scale. An early goal of therapy is to achieve a complete hematologic response or to normalize peripheral blood counts. A cure from CML can only come from complete eradication of the Ph clone.

General Approach to Treatment
There have been significant advances in the treatment of CML since the discovery of the Ph in 1960. The success of therapy is largely dependent on the clinical phase of the disease. Treatment decisions are based on patient’s age, phase of CML, and comorbidities. Nearly all patients with CML are initially treated with a tyrosine kinase inhibitor (TKI). Depending on the clinical phase, newer TKIs or omacetaxine may be options for patients who fail to respond or do not tolerate initial TKI therapy. Hydroxyurea may be used after diagnosis to rapidly reduce high WBC counts and prevent potentially serious complications (respiratory and neurologic) associated with large numbers of circulating neutrophils. Hydroxyurea, though, does not alter the disease process. TKIs can also reduce peripheral WBC counts over several weeks; therefore, many patients are started on a TKI alone. Although allogeneic stem cell transplant is the only curative therapy for CML, transplantation is reserved for patients with TKI resistance. Figure 96–1 illustrates one approach for clinically managing newly diagnosed CML patients.

Nonpharmacologic Therapy

Hematopoietic Stem Cell Transplantation
Allogeneic stem cell transplantation is the only curative treatment option for CML, however the TKIs have diminished the role of transplant. Allogeneic stem cell transplant may be considered for the rare patient with BCR-ABL mutations that are resistant to or who fail TKI therapy. Transplant should also be considered for patients who present in blast crisis or who progress on a TKI in accelerated phase or blast crisis. There are significant risks and long-term complications with allogeneic stem cell transplantation including early mortality and graft-versus-host disease. For patients who do not achieve a complete molecular response or have a relapse, the infusion of donor lymphocytes may place the patient back into a durable remission.

Pharmacologic Therapy (Table 96–1)
The treatment of CML has dramatically changed since the introduction of TKIs. Nearly all patients with CML are initially treated with a TKI. These oral agents do not cure CML but are able to produce long-term disease control in the vast majority of patients.

Imatinib mesylate (Gleevec)
Imatinib mesylate (STI-571; Gleevec) is a first-generation TKI and was the first TKI to show efficacy in the treatment of CML. Imatinib inhibits phosphorylation of various proteins involved in cell proliferation. In CML, imatinib works by binding to the adenosine triphosphate–binding pocket of BCR-ABL. The 8-year follow-up data show that the use of imatinib in chronic phase CML results in an overall survival of 85% and an estimated event-free survival of 81%. As expected with more aggressive disease, lower response rates are reported in accelerated phase and blast crisis. Disease progression is typically attributed to imatinib primary or secondary resistance. The ABL mutation T315I is one mechanism of secondary resistance that results in reactivation of BCR-ABL activity. The T315I mutation renders imatinib and the second-generation TKIs ineffective; therefore, alternative therapy with agents that overcome this mutation must be selected.

Imatinib may be used as first-line therapy in patients with CML. Standard dosing of imatinib is 400 mg/day in chronic phase CML. Studies have investigated the use of higher doses of imatinib in all phases of CML. Although these higher doses produced rapid responses compared to standard imatinib dosing, they were also associated with more serious adverse effects. Therapy with imatinib is generally well tolerated. Common side effects include myelosuppression (phase and dose related), rash, gastrointestinal disturbances, edema, fatigue, arthralgias, myalgias, and headaches. Congestive heart failure is a rare but serious side effect and requires careful monitoring in patients with preexisting cardiac conditions. Imatinib is metabolized by CYP450 3A4, and possible drug interactions include agents that inhibit or induce 3A4, such as erythromycin, ketoconazole, and phenytoin.
Imatinib 400 mg daily
or
Dasatinib 100 mg daily
or

### Advanced-Generation TKIs

There are four advanced-generation BCR-ABL TKI inhibitors. Key Concept: Dasatinib (Sprycel), nilotinib (Tasigna), bosutinib (Bosulif), and ponatinib (Iclusig) are advanced generation TKIs that may overcome imatinib resistance or intolerance. These inhibitors are anywhere from 10 to 325 times more potent than imatinib in inhibiting BCR-ABL and are able to overcome most BCR-ABL mutations that lead to imatinib resistance. Of the four, only ponatinib can overcome the T315I mutation. Dasatinib and nilotinib were initially indicated for use in CML when patients failed imatinib therapy. Their indication has now expanded to include first-line therapy based on results of trials comparing these drugs to imatinib. These study results suggest that dasatinib and nilotinib are comparable to, if not better than, imatinib in achieving faster and deeper cytogenetic and molecular responses. These studies suggest that fewer patients may progress to accelerated or blast phase on dasatinib or nilotinib compared to imatinib. Common side effects are similar to those of imatinib.
A significant and potentially severe side effect of pleural effusions has been reported with the use of imatinib and dasatinib but not with the use of nilotinib. Additional side effects include QT prolongation (dasatinib and nilotinib) and increases in indirect bilirubin (nilotinib). Bosutinib is used in the second-line treatment of CML when patients are resistant or intolerant to prior TKI therapy. Bosutinib overcomes most BCR-ABL domain mutations with the exception of the T315I mutation. Bosutinib is not recommended as first-line therapy since the Phase III trial comparing the efficacy of bosutinib to imatinib did not meet its primary endpoint of complete cytogenetic response at 12 months. The side effects of bosutinib appear to be less severe and less common than many of the other TKIs. Gastrointestinal disturbances and rash are some of the most common nonhematologic side effects.

Ponatinib is a third-generation multikinase inhibitor that overcomes the BCR-ABL domain mutation T315I. Ponatinib was initially approved for the treatment of patients in all phases that were resistant or intolerant to prior TKI therapy. In postmarketing analysis, an increase in serious arterial thrombotic events was shown in 24% of patients. The revised label indicates the use of ponatinib in patients harboring the T315I mutation or have failed multiple prior TKIs. Nonhematologic side effects include rash, dry skin, and abdominal pain. Rare yet serious adverse effects include liver failure and death, which are both black-box warnings.

**Omacetaxine Mepesuccinate**

Omacetaxine mepesuccinate (Synribo) is a semisynthetic formulation of homoharringtonine. Omacetaxine reversibly inhibits protein synthesis thereby causing cell death. Unlike TKIs, the mechanism of action affects both normal and malignant hematopoietic cells. Omacetaxine is a subcutaneous injection indicated for patients in chronic or accelerated phase CML who are resistant or intolerant to two or more TKIs. It may be used in patients with the T315I mutation. Nonhematologic adverse reactions include gastrointestinal disturbances, fatigue and hyperglycemia. Febrile neutropenia, infections, and cerebral hemorrhage are a few of the serious adverse reactions.

**OUTCOME EVALUATION**

Successful treatment for CML depends on the elimination of the Ph. Nearly all newly diagnosed CML patients will be placed on a TKI. First-line treatment options include imatinib, dasatinib, and nilotinib. Which agent to use depends on several factors, including mutational status, disease risk score, age, comorbid conditions, and medication safety profile. Patients should be counseled on the importance of medication adherence. Patients should understand that poorer outcomes may result if they are not adherent to daily TKI therapy. Historically, if patients fail to obtain a cytogenetic response within 6 to 12 months, a change in therapy is recommended. Research is evaluating the use of early molecular responses in the treatment management of CML. If TKI treatment failure occurs, patients should undergo BCR-ABL domain mutation testing. Second-line chronic phase CML therapy should be determined based on mutational analysis with second-generation TKIs (including bosutinib). These agents may also be used in patients who have accelerated phase CML. Ponatinib may be considered if the T315I mutational status is present with an understanding that it is associated with serious vascular effects. Omacetaxine, allogeneic stem cell transplantation and clinical trials are options for those patients that do not respond to a TKI.

Some patients will not respond to treatment and will progress to blast crisis where they will receive treatment for acute leukemia. Although its use is limited, allogeneic transplant offers the only cure for CML and may be useful in patients with advanced disease.

**Patient Encounter 1**

A 48-year-old man presents to his primary care physician with complaints of worsening fatigue and left upper quadrant pain. His medical history consists of type 2 diabetes managed with metformin and gastroesophageal reflux disease treated with omeprazole. A CBC is drawn and shows the following:

- **Total WBC:** 70 × 10^9/L (70 × 10^9/mm^3), (4% [0.04] blasts, 86% [0.86] segs, 10% [0.10] lymphs)
- **Hgb/Hct:** 8.3 g/dL (83 g/L; 5.15 mmol/L)/25% (0.25)
- **Platelets:** 489 × 10^9/L (489 × 10^9/mm^3)

The patient is referred to an oncologist for further workup. A bone marrow biopsy is performed and reveals hypercellular marrow with 5% (0.05) blasts. FISH analysis is positive for Ph.

**What information is suggestive of CML?**

**What are the first-line treatment options for chronic phase CML patient?**

**Which specific treatment do you recommend for this patient and why?**

**Identify your treatment goals for this patient.**

Assuming this patient has suboptimal response to your initial therapy, what would you recommend for second-line therapy?

**What factors may contribute to this patient’s having a suboptimal response?**

**CHRONIC LYMPHOCYTIC LEUKEMIA**

CLL is a cancer that results in the accumulation of functionally incompetent lymphocytes. CLL is usually considered an indolent, incurable disease, and treatment should only be initiated when patients have symptoms. However, a subset of patients will have aggressive disease, and these individuals need to be treated aggressively.

**EPIDEMIOLOGY AND ETIOLOGY**

CLL is the most common type of leukemia diagnosed in adults, accounting for 30% of all adult leukemias. It was estimated that in 2015, 14,620 new cases would be diagnosed in the United States. The median age at diagnosis is the sixth decade of life with the incidence increasing with age. The etiology of CLL is unknown, but hereditary factors may have a role, with family members of CLL patients having a twofold to sevenfold increased risk of CLL.

**PATHOPHYSIOLOGY**

**Cell of Origin**

CLL is characterized by small, relatively incompetent B lymphocytes that accumulate in the blood and bone marrow over time. The lack of apoptotic mechanisms leads to the persistence and accumulation of B lymphocytes. The exact cell of origin is controversial but has been described as an antigen-activated B
lymphocyte. Chromosomal abnormalities have been identified in 40% to 50% cases of CLL and often correlate with progressive disease. Numerous tyrosine kinases appear to be involved in CLL, including the activation of Bruton tyrosine kinase (BTK). Detection of some of these markers may predict clinical course and prognosis and may influence treatment decisions.

Clinical Course

**KEY CONCEPT** CLL can have a variable clinical course with survival ranging from months to decades. Low-risk disease is asymptomatic, and median survival times exceed 10 years. Intermediate risk is associated with lymphadenopathy and has median survival times of about 7 years. High-risk patients with anemia have median survival times of only 3 years. The typical low-risk patient is an asymptomatic elderly patient who is diagnosed on routine blood draw. The typical high-risk patient is a symptomatic middle-aged patient.

### PROGNOSTIC FACTORS

Two staging systems, Rai’s and Binet’s, have been developed to help practitioners determine the overall prognosis of patients with CLL. They are comparable systems and are useful to broadly determine good, intermediate, and poor prognostic disease. Risk stratification criteria included in these systems are lymphadenopathy, splenomegaly, hepatomegaly, and cytopenias. Increasingly, a number of biological markers of the disease such as deletions of chromosome 17p and 13q and mutational status of immunoglobulin heavy chain variable region gene (IgVH) are being used to predict the likely clinical course. These biological markers are not included in the Rai’s or Binet’s staging systems.

### TREATMENT

#### Desired Outcomes

The primary goals in the treatment of CLL are to provide palliation of symptoms and improve overall survival. Because the current treatments for CLL are not curative, reduction in tumor burden and improvement in disease symptoms are reasonable end points, particularly in older patients. A complete response (CR) to therapy can be defined as a resolution of lymphadenopathy and organomegaly, normalization of peripheral blood counts, and elimination of lymphoblasts in the bone marrow. Nonpharmacologic Therapy

**KEY CONCEPT** Asymptomatic early stage CLL can be observed without treatment until evidence of disease progression. Past studies with chlorambucil suggest that chemotherapy does not improve overall survival in early stage CLL although there is question whether this remains true with the development of newer therapies. In addition, deferring therapy until a patient becomes symptomatic does not alter overall survival. For this reason, the notion of “watch and wait” is considered reasonable for older patients with low risk disease. Several factors will influence this approach, including life expectancy, disease characteristics, and ability to tolerate therapy.

- **Hematopoietic Stem Cell Transplantation**

  The use of hematopoietic stem cell transplantation (HSCT) in CLL is limited. Allogeneic transplantation offers longer disease-free remissions than autologous transplantation but is associated with high treatment morbidity and mortality. Several factors must be considered before allogeneic stem cell transplantation. The lack of a donor, older age, and poor performance status make transplant an uncommon procedure in this population. Allogeneic transplantation remains an option for younger patients with aggressive disease who have failed prior therapies. Although its use is currently limited, HSCT may someday be an important component in achieving a cure for CLL.

#### Pharmacologic Therapy (Table 96–2)

- CLL treatment is typically initiated in the symptomatic patient. Numerous agents can be used as initial therapy in the treatment of symptomatic or advanced CLL. Many of the chemotherapy regimens have not been compared directly with one another, so

there is not one preferred regimen. Selection of the appropriate chemotherapy depends on the individual patient and practitioner’s preference. Figure 96–2 illustrates one approach for initial therapy in newly diagnosed patients with CLL.

**Cytotoxic Chemotherapy**

Historically, chlorambucil (Leukeran), an oral alkylating agent, was considered the standard treatment for CLL. Today, the treatment for CLL has changed with the development of the purine analogs. There are three purine analogs used in the treatment of CLL: fludarabine (Fludara), pentostatin (Nipent), and cladribine (Leustatin) with fludarabine being the most studied. **Fludarabine-based chemoimmunotherapy is commonly used as first-line therapy for younger patients with CLL.** Randomized clinical trials have shown that fludarabine is superior to chlorambucil in achieving higher response rates and producing a longer duration of response. Fludarabine is effective in previously untreated patients as well as patients who have chlorambucil-resistant disease. Although fludarabine is one of the most effective agents in the treatment of CLL, it is rarely used as a sole agent. Instead fludarabine is given in combination with other drugs to improve response rates.20,22

Fludarabine is associated with more toxicities than chlorambucil, including myelosuppression and prolonged immunosuppression.22 Resultant infectious complications may occur during the periods of prolonged immunosuppression. Clinicians should consider antibacterial and antiviral prophylaxis for *Pneumocystis* and varicella zoster when using fludarabine-based therapy.21 Today, chlorambucil remains a practical option for symptomatic elderly patients who require palliative therapy because of the ease of oral administration, low cost and limited side-effect profile.

Bendamustine (Treanda) is an alkylating agent used in the treatment of CLL. As first-line therapy for CLL, bendamustine was shown to have superior overall response rates, CRs, and longer progression-free survival than chlorambucil.22 Bendamustine is usually given in combination with rituximab as first-line therapy.20,22

**Monoclonal Antibodies**

**Combination chemoimmunotherapy with anti-CD20 monoclonal antibodies are widely used in the treatment of CLL.**

Rituximab (Rituxan) is a naked chimeric monoclonal antibody directed against the CD20 antigen on B-lymphocytes.20,22 Similar to other B-cell malignancies, CLL expresses CD20 antigens. Dose escalation studies suggest that higher doses are required than those used in non-Hodgkin lymphoma.24 The higher dose required in CLL is probably a combined effect of lower CD20 antigen expression and higher concentrations of soluble CD20 antigen than in non-Hodgkin lymphoma.24 Rituximab is given in combination with other therapies since these combinations result in higher CRs than rituximab alone.19 The most common side effects of rituximab include infusion reactions consisting of fever, chills, hypotension, nausea, vomiting, and headache.18 Premedication with diphenhydramine and acetaminophen is recommended to minimize infusion reactions.

Ofatumumab (Arzerra) and obinutuzumab (Gazyva) are two newer biologics in this class. Ofatumumab is a CD20 antigen-directed monoclonal antibody that is approved in CLL patients who fail fludarabine and alemtuzumab.25 Obinutuzumab is different than the other two having a higher binding affinity to the CD20 epitope and causing direct cell death.25 It is approved in combination with chlorambucil for the treatment of previously untreated CLL. Premedications are similar to rituximab with the addition of a corticosteroid to reduce the incidence of infusion reactions. The rate of infusion and titration depends on patient tolerability of the medication. Table 96-2 lists some of the adverse effects seen with the anti-CD20 monoclonal antibodies.

Alemtuzumab (Campath) is a humanized monoclonal antibody directed against the CD52 antigen.20 CD52 antigen is expressed on the majority of B and T lymphocytes. Alemtuzumab may be used as single agent or combination therapy in the treatment of CLL. Studies have shown alemtuzumab to be effective in fludarabine-resistant disease, in patients with the deletion of 17p, and as front-line therapy.22 Infusion-related reactions can be significant and typically occur with the initial dose and lessen in severity with subsequent doses. To limit acute allergic reactions, subcutaneous administration may be given instead of IV dosing.18,22 Premedication with oral antihistamines and acetaminophen is recommended. Alemtuzumab also suppresses the T cells, resulting in prolonged immunosuppression. Infectious complications may occur from the reactivation of
cytomegalovirus and herpes virus and from infection with *Pneumocystis*. These infections have been shown to occur with both the IV and subcutaneous routes of administrations. Patients should receive trimethoprim–sulfamethoxazole and acyclovir or an equivalent antiviral to prevent these infections.29,30

► Small-Molecule Inhibitors

An understanding of the B-cell receptor signaling pathways of CLL has led to the approval of newer oral targeted therapies.26 Ibrutinib (Imbruvica) is an inhibitor of BTK which is an essential enzyme in the B-cell receptor pathway. Ibrutinib has been shown to have an improved progression free survival, response rate and overall survival compared to ofatumumab in previously treated patients with CLL.27 Ibrutinib has also been studied in previously untreated patients with CLL and in patients with the del 17p.22

Idelalisib (Zydelig) targets phosphatidylinositol-3-kinase (PI3-K), an essential lipid kinase that is a regulator of the B-cell receptor pathway and involved in cellular survival and proliferation. Idelalisib has been studied as monotherapy as well as combination therapy with rituximab in patients with relapsed disease.28 Nonhematologic side effects for both drugs may be found in Table 96–2. Black-box warnings for idelalisib include hepatotoxicity, colitis, pneumonitis, and intestinal perforation.

► Chemoimmunotherapy

Chemoimmunotherapy is the standard for younger patients with symptomatic CLL. The regimen is often selected based on age and cytogenetics. Combination therapy generally consists of an anti-CD20 antibody in combination with chemotherapy. The combination of fludarabine, cyclophosphamide, and rituximab improves CR rates compared with fludarabine alone (70% vs 20%, respectively) but at the expense of increased infections.19,22 Rituximab is often added to bendamustine, lenalidomide, and alemtuzumab.22 A recent multiple-treatment meta-analysis was not able to show a significant survival benefit of one regimen compared to another.29

**OUTCOME EVALUATION**

Successful outcomes depend on the appropriate treatment selection for a specific patient. Risk-versus-benefit should be determined in the treatment of older CLL patients. Because CLL is incurable, watch and wait is a reasonable approach for those with indolent disease. Treatment can then begin when the patient becomes symptomatic. Aggressive chemoimmunotherapy with fludarabine is often reserved for younger patients with high-risk CLL, with the goal being prolonged disease-free survival. A desirable response to therapy includes a reduction in lymphocytes, decrease in stage of the disease, and resolution of symptoms.

**MULTIPLE MYELOMA**

Multiple myeloma (MM) is a malignancy of the plasma cell and is characterized by an abnormal production of a monoclonal protein in the bone marrow. Features of the disease include bone lesions, anemia, and renal insufficiency.30 Multiple myeloma is an incurable disease; however, advancements in the treatment of myeloma have significantly extended survival.

**EPIDEMIOLOGY AND ETIOLOGY**

Multiple myeloma (MM) is the second most common hematologic malignancy. It is estimated that approximately 26,850 new cases of MM would be reported in 2015, accounting for 1% to 2% of all cancers.2 The median age at diagnosis is 70 years, and fewer than 2% are diagnosed before the age of 40 years.30,31 The incidence of myeloma is highest in African Americans, lowest in Asians, and occurs more frequently in men than women.31 The etiology of MM remains largely unknown although a exposure to ionizing radiation and genetic factors have been implicated.31

**PATHOPHYSIOLOGY**

The pathogenesis of MM is quite complex with multiple-step models created to postulate the process. Myeloma must be distinguished from a condition called monoclonal gammopathy of unknown significance (MGUS), which is characterized by a monoclonal immunoglobulin without malignant plasma cells. Yearly, about 1% of patients with MGUS will develop MM. Chromosomal abnormalities and changes in gene expression lead to cell cycle dysregulation and appear to be involved early in the disease process.19 The pathophysiology of MM involves complex bone marrow microenvironment, and cytokine interactions. Interleukin-6, tumor necrosis factor, vascular endothelial growth factor, and stromal-derived factor-1 support the establishment and proliferation of myeloma cells.30,31 The understanding of these interactions has led to novel agents used in the treatment of MM.

**PROGNOSTIC FACTORS**

Prognostic factors for myeloma include tumor, treatment, and patient related factors. The International Staging System is used to predict outcomes after therapy. Staging is stratified based on the levels of serum β2-microglobulinemia and serum albumin. High β2-microglobulinemia and low albumin are poor prognostic factors and are indicative of high tumor load.22 Although cytogenetic abnormalities are not included in the International Staging System, many abnormalities are associated with poor outcomes. The Mayo Stratification for Myeloma and Risk-Adapted
Clinical Presentation and Diagnosis of Multiple Myeloma

### Signs and Symptoms
- “CRAB”
  - “C”—hyperCalcemia
  - “R”—Renal failure (serum creatinine > 2 mg/dL [177 μmol/L])
  - “A”—Anemia (fatigue)
  - “B”—Bone disease (pain, lesions, fractures)
- Weight loss
- Recurrent infections

### Diagnostic Procedures
- Laboratory
  - CBC, chemistry panel, β₂-microglobulin
  - Peripheral blood smear
  - Serum protein electrophoresis and immunofixation
  - Urine protein electrophoresis and immunofixation
  - Serum free light chains
- Radiologic evaluation (MRI, bone densitometry)
- Bone marrow biopsy
- Cytogenetic studies
- Molecular testing

### Laboratory Findings
- Peripheral blood
  - Monoclonal protein in serum (usually IgG or IgA)
  - High β₂-microglobulin
  - Low platelets and hemoglobin
  - High creatinine, urea, lactate dehydrogenase, C-reactive protein, and calcium
  - Rouleaux formation
- Urinalysis
  - Urinary free light chains (Bence-Jones Protein)
- Bone marrow
  - Plasma cells (10% or more)
  - Abnormal cytogenetics
- Radiologic findings
  - Bone lesions, fractures, osteoporosis

### Poor Prognostic Factors
- High serum β₂-microglobulin and low serum albumin
- Elevated C-reactive protein
- Elevated lactate dehydrogenase
- IgA isotype
- Low platelet count
- Chromosome 13 deletions and other cytogenetic abnormalities

Therapy classification incorporates tumor biology to stratify patients according to their disease risk. Chromosomal changes are being used to predict high-risk patients with perhaps the most important being deletions of the long arm of chromosome 13 and translocation of chromosomes 4 and 14. Older patients, renal impairment, and other comorbidities also predict for poorer outcomes.

### TREATMENT

#### Desired Outcomes
The primary goal in the treatment of MM is to prolong progression-free and overall survival while minimizing complications associated with the disease. A watch and wait approach is an option for asymptomatic patients (smoldering myeloma) who have no lytic lesions in the bone. When symptoms occur, treatment is required. The treatment of MM often includes induction, transplantation, and maintenance therapy. All patients should be evaluated early on to see if they are transplant eligible candidates. Autologous stem cell transplantation prolongs overall survival in patients who can tolerate high-dose chemotherapy. Regardless of transplant eligibility, all patients will be placed on initial induction therapy to reduce tumor burden. Maintenance therapy following transplant with immunomodulators or proteasome inhibitors is being used to prolong the duration of response. Almost all patients become refractory to initial treatment and require the use of salvage therapies.

---

**Patient Encounter 3**

A 58-year-old woman presents to her health care provider with complaints of extreme fatigue and severe right and left hip pain. Her past medical history includes controlled hypertension. Workup reveals:

**Radiology:** X-ray of right and left hips: Osteolytic lesions

**Labs:** Hemoglobin: 7.2 g/dL (72 g/L; 4.47 mmol/L); platelets: 220 x 10⁹/L (220 x 10³/mm³); corrected calcium: 11.8 mg/dL (2.95 mmol/L); serum creatinine: 1.8 mg/dL (159 μmol/L); serum IgG: 4200 mg/dL (42 g/L) (normal: 620–1500 mg/dL [6.2–15 g/L]; serum IgM: 80 mg/dL (8 g/L) (normal: 50–200 mg/dL [0.5–2 g/L]; bone marrow: 83% plasma cell infiltrates

**What information is suggestive of multiple myeloma?**

**What treatment options are available for this patient?**

**Assuming this patient is a candidate for autologous stem cell transplantation, what would be an appropriate induction regimen?**

**Assuming this patient is not a candidate for autologous stem cell transplantation, what would be an appropriate induction regimen?**

**What may be used for maintenance therapy after an autologous stem cell transplantation?**
illustrates possible treatment approaches for transplant-eligible and transplant-ineligible patients.

Nonpharmacologic Therapy

**Autologous Stem Cell Transplantation**

Autologous stem cell transplantation results in higher response rates and extends progression-free survival compared with those who receive conventional chemotherapy. Although these initial trials did not include the immunomodulators, stem cell transplant remains the standard of care and should be considered in all patients who can tolerate high-dose chemotherapy. High-dose melphalan is the most common preparative regimen. Two sequential transplants (tandem transplants) improve overall survival in patients who do not have a good partial response after one transplant. The use of maintenance therapy after autologous transplantation with lenalidomide or bortezomib may be used in select patients to extend progression-free survival. Since the studies supporting the use of transplant were conducted prior to the development of many of the novel agents used in the treatment of myeloma; the future role of stem cell transplantation may evolve.

Pharmacologic Therapy (Table 96–3)

Symptomatic MM requires treatment. There are five main classes of drugs used in the treatment of multiple myeloma: alkylating agents, anthracyclines, corticosteroids, immunomodulatory agents, and proteasome inhibitors. Drugs from these classes are used in combination and are the backbone for numerous chemotherapeutic regimens.

**Conventional-Dose Chemotherapy**

The use of conventional-dose chemotherapy with alkylating agents or anthracyclines has declined with the advent of immunomodulators and proteasome inhibitors. The combination of melphalan and prednisone (MP) was once the most common initial treatment combination for myeloma. Today, melphalan-based therapy may be considered as initial therapy in transplant-ineligible patients. Melphalan is toxic to progenitor cells and should be avoided in transplant eligible patients. The anthracycline doxorubicin is also incorporated into treatment regimens. Currently, the combination of doxorubicin, bortezomib, and dexamethasone may be selected for induction therapy in patients who are transplant eligible. This regimen minimizes the risk of secondary malignancies that are associated with chronic alkylating therapy.

**Immunomodulatory Drugs**

Thalidomide (Thalomid), lenalidomide (Revlimid), and pomalidomide (Pomalyst) are used in the treatment of MM. Depending on the agent, they may be used as monotherapy or combination therapy. The precise mechanism of action is unknown, but its antimyeloma activity may be attributable to its antiangiogenic and anticytokine properties. Response rates are improved when an immunomodulatory agent is added to a treatment regimen. Thalidomide and steroid combinations produce

DVT, deep venous thrombosis; IV, intravenous; PE, pulmonary embolism; po, oral; SC, subcutaneous; VAD, vincristine–dexamethasone.
If patients continue to have disease progression, another regimen may be utilized. 

• Monitor WBC count and signs of infection if the patient is receiving aggressive chemoimmunotherapy.

**Care Plan Development:**

• Address any concerns about the selected medication including cost and management of adverse effects.

• Supportive care medication such as remedications for the prevention of infusion reactions, prophylactic trimethoprim–sulfamethoxazole and an antiviral (acyclovir, famciclovir, or valacyclovir) may be recommended for certain medications.

Follow-up Evaluation:

• Asymptomatic patients will be routinely follow-up to determine when they require treatment.

• Routine follow-ups during and postchemotherapy will be needed to assess treatment efficacy.

**MULTIPLE MYELOMA**

**Patient Assessment:**

• Review medical history, including patient’s age, comorbid conditions and current medications to determine whether the patient is transplant eligible.

**Therapy Evaluation:**

• If patients continue to have disease progression or have relapsed disease, another regimen may be used.

• Monitor myeloma monoclonal protein in urine and serum, renal function, hemoglobin, and platelets.

• Assess safety of medications including the monitoring of peripheral neuropathy. Dose reduction may be necessary to prevent permanent neurologic damage.

• Supportive care including bisphosphonates, pain medications and prophylactic anticoagulation may be required depending on the medication selected.

**Follow-up Evaluation:**

• Frequent follow-up is needed to determine efficacy or if another regimen should be used.

• Maintenance therapy posttransplantation requires additional follow-up and monitoring of adverse effects.
myeloma. Low-dose dexamethasone with lenalidomide offers improved overall survival compared with high-dose dexamethasone. The combination of melphalan, prednisone, and lenalidomide (MPL) may be used as initial therapy in transplant ineligible patients. The response rate appears to be quite high at 81% with 24% achieving a CR. Lenalidomide lacks many of the common side effects seen with thalidomide. Significant adverse effects of lenalidomide include myelo-suppression and DVTs. DVT prophylaxis is recommended with lenalidomide–dexamethasone combinations. Stem cells should be collected shortly after starting lenalidomide because CD34-positive stem cell counts tend to decrease with prolonged lenalidomide exposure. Maintenance lenalidomide after stem cell transplantation has been associated with an increase in progression free survival, however, with an increase in the incidence of secondary malignancies.

Pomalidomide is the newest immunomodulatory agent used in the treatment of refractory or progressive MM. It was shown to increase PFS and OS when used in combination with dexamethasone in patients that were refractory to bortezomib and lenalidomide. Adverse effects for pomalidomide include myelo-suppression and an increase in infections.

**Proteasome Inhibitors**

Bortezomib (Velcade) and carfilzomib (Kyprolis) are proteosome inhibitors approved for the treatment of MM. Proteosome inhibitors induce myeloma cell death by modulating nuclear factor kappa-B products, including inflammatory cytokines and adhesion molecules that support myeloma cell growth. These drugs also disrupt the myeloma microenvironment by inhibiting the binding of myeloma cells to the bone marrow stromal cells. Bortezomib-based regimens are frequently used as induction therapy in transplant-eligible patients. The response rates have been reported as high as 97% in newly diagnosed myeloma. Bortezomib can also be given in combination with a corticosteroid and melphalan (MPB) in patients who are not transplant eligible. Superior response rates and survival are seen with the combination MPB compared MP. Side effects of bortezomib include fatigue, nausea, peripheral neuropathy, and hematologic effects. The incidence of DVT is lower than the immunomodulators; thus, bortezomib does not routinely require prophylactic anticoagulation. However, prophylactic acyclovir should be considered to reduce the risk of herpes zoster reactivations. Carfilzomib is a newer second-generation proteasome inhibitor that is used in the treatment of refractory MM. Studies are also examining carfilzomib as primary therapy in combination regimens with an immunomodulator and dexamethasone.

**Bisphosphonates**

Bone disease is a common manifestation of MM. Bisphosphonates should be initiated in symptomatic patients with bone lesions to slow osteopenia and reduce the fracture risk associated with the disease. Pamidronate 90 mg and zoledronic acid 4 mg have equivalent efficacy in the management of osteolytic lesions. The use of zoledronic acid decreases pain and bone-related complications and improves quality of life. Osteonecrosis of the jaw is a major concern with bisphosphonate therapy. Risk factors are unclear, but osteonecrosis of the jaw is more common in patients receiving IV administration of bisphosphonates and having dental procedures performed. It is recommended that patients have dental restoration work before starting bisphosphonate therapy. Several consensus guidelines have been published on the use of bisphosphonates and myeloma. Recommendations on the duration of therapy and which bisphosphonate to use have largely been left up to the practitioner.

**OUTCOME EVALUATION**

Newly diagnosed, asymptomatic patients with MM may be observed without treatment. This asymptomatic period may last for months to a couple years. All patients with MM become symptomatic, and when this occurs, treatment is required. All patients should be evaluated for an autologous stem cell transplant. For patients who are eligible for transplant, induction therapy often consists of thalidomide or lenalidomide, bortezomib, and dexamethasone. Maintenance therapy with an immunomodulatory agent may be used post-transplant. There are numerous treatment options for transplant ineligible patients including MPT, MPB, or MPL. Nearly all patients progress at some point, and second-line therapy usually includes bortezomib. Monthly bisphosphonates should be given to patients who have bone lesions with the hope of reducing pain and fractures.

**Abbreviations Introduced in This Chapter**

- CLL: Chronic lymphocytic leukemia
- CML: Chronic myelogenous leukemia
- CR: Complete response
- DVT: Deep venous thrombosis
- FISH: Fluorescence in situ hybridization
- HSCT: Hematopoietic stem cell transplantation
- MGUS: Monoclonal gammopathy of unknown significance
- MP: Melphan–prednisone
- MPB: Melphan–prednisone–bortezomib
- MPL: Melphan–prednisone–lenalidomide
- MPT: Melphan–prednisone–thalidomide
- Ph: Philadelphia chromosome
- Q-PCR: Qualitative and quantitative polymerase chain reaction
- TKI: Tyrosine kinase inhibitor
- WBC: White blood cell

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss the underlying pathophysiologic mechanisms of the lymphomas and how they relate to presenting symptoms of the disease.

2. Differentiate the pathologic findings of Hodgkin lymphoma (HL), follicular indolent non-Hodgkin lymphoma (NHL), and diffuse aggressive NHL and how this information yields a specific diagnosis.

3. Describe the general staging criteria for the lymphomas and how it relates to prognosis; evaluate the role of the prognostic systems such as the International Prognostic Score for HL, the Follicular Lymphoma International Prognostic Index, and the International Prognostic Index for diffuse, aggressive NHL.

4. Compare and contrast the treatment algorithms for early and advanced stage disease for HL.

5. Delineate the clinical course of follicular indolent and diffuse aggressive NHL and the implications for disease classification schemes and treatment goals.

6. Outline the general treatment approach to follicular indolent and diffuse aggressive NHL for localized and advanced disease.

7. Interpret the current role for monoclonal antibody therapy in NHL.

8. Assess the role of autologous hematopoietic stem cell transplantation for relapsed lymphomas.

INTRODUCTION

The malignant lymphomas are a clonal disorder of hematopoiesis with the primary malignant cells consisting of lymphocytes of B-, T-, or natural killer (NK) cell origin. Lymphoma cells predominate in the lymph nodes; however, they can infiltrate lymphoid and nonlymphoid tissues, such as the bone marrow, central nervous system (CNS), gastrointestinal (GI) tract, liver, mediastinum, skin, and spleen. An overview of the lymph node regions is depicted in Figure 97–1. There are two broad classifications of lymphoma, Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL), and both contain numerous histologic subtypes that are pathologically distinct disease entities.

The clinical course varies widely among histologies of lymphoma. More aggressive lymphoma subtypes are highly proliferating tumor cells that require aggressive therapeutic intervention with chemotherapy, radiation therapy, or both. By contrast, certain subtypes of NHL are characterized by a disease course that flares and remits intermittently over a period of years regardless of treatment.

HODGKIN LYMPHOMA

EPIDEMIOLOGY AND ETIOLOGY

Approximately 9050 new cases of HL were estimated to be diagnosed in the United States in 2015, with 1150 deaths attributed to the disease. The incidence of HL is bimodal, with its peaks occurring in the third decade of life and in patients older than 50 years of age. The precise cause of HL is unknown, but certain associations have been reported and provide insight about possible etiologic factors. Epstein-Barr virus (EBV) has been associated with HL, its viral genome is detected in Reed-Sternberg (RS) cells in up to 40% of cases in developed countries. Other viruses (cytomegalovirus, human herpes viruses, HIV, and adenoviruses) have been associated with HL; however, data is conflicting. Other possible risk factors identified include woodworking and a familial history of HL.

PATHOPHYSIOLOGY

Pluripotent stem cells in the bone marrow are able to differentiate to both lymphoid and myeloid progenitor cells. Lymphoid progenitor cells undergo normal gene rearrangement to yield either B-cell or T-cell lineage precursor cells. Normal maturation for naive B cells includes expression of cell surface antibody or the cells typically undergo apoptosis. These cells are differentiated from other B cells, such as memory cells, by virtue of cell surface antigen (CD5+ or CD5- and CD27+) and bound antibody (IgM+ and IgD+). When naive B cells recognize antigen with their cell surface antibody, they accumulate in the lymph nodes, spleen, or other lymphoid tissue. The DNA of these B cells is susceptible to three different types of genetic modification: receptor editing, somatic hypermutation, and class switching within the germinal center of the lymph node. Germinal centers are microanatomic structures located within lymph nodes that develop
with clonal B-cell expansion secondary to antigen stimulation. Under normal circumstances, these genetic changes allow for adaptation of the immune system to the repeated exposure to environmental antigens.

The pathophysiology of HL is defined by the presence of the RS cell in a grouping of lymph nodes. The RS cell is a morphologically large cell with a multinucleated structure possessing pronounced eosinophilic nucleoli, thought to be B-cell in origin. In the affected lymph nodes, the RS cells are contained within an inflammatory background that is believed to be essential for their survival.

RS cells have lost the expression of most B-cell markers. Common cell-surface antigens expressed by RS cells include CD30 and CD15, but other common B-cell antigens, such as CD20 are inconsistently expressed. The Janus kinase-signal transduction and transcription (JAK-STAT) signaling pathway has also been found to be active in HL. Additionally, the overexpression of nuclear factor kappa-B (NF-kB), a proliferative and antiapoptotic transcription factor nuclear factor is believed to contribute to the expansion and survival of RS cells.

HL is classified into disease subtypes based on the number and morphologic appearance of RS cells and the background cellular milieu. These are listed in the World Health Organization (WHO) classification of lymphoid neoplastic diseases in Table 97–1. Nodular sclerosing (70%) is the most common form of HL. It is more common in young adults and is marked by the presence of the RS variant cell, the lacunar cell. The second most common form of HL is the mixed-cellularity variant (20%), with others accounting for the remainder of cases. Factors identified as negative disease prognostic indicators are listed in Table 97–2.

### TREATMENT OF HL

**Desired Outcome**

Staging of HL with a standard classification is necessary to guide treatment. The extent and location of involvement, localized or disseminated extranodal disease, and B symptoms are factors in assignment of stage. The Cotswold staging system,
The principal goal in treating HL is to cure the patient of the primary malignancy. HL is sensitive to both radiation and chemotherapy, resulting in an 80% rate of cure with modern therapy. Treatment strategy is generally divided into approaches for early stage I/II localized disease and stage III/IV advanced disease. Patients with early stage I/II disease are further classified into favorable, unfavorable with bulky disease, and unfavorable with nonbulky disease. Regardless of stage, all patients are treated with curative intent. Other goals during treatment include:

- Complete resolution of disease symptoms
- Incorporation of supportive care measures to optimize quality of life during therapy
- Minimization of acute and long-term treatment-related toxicity

Clinical Presentation and Diagnosis of Malignant Lymphomas

**General**
Nonspecific; can range from an asymptomatic patient with a less aggressive lymphoma to a patient who is gravely ill with advanced disease.

**Symptoms**
- Lymphadenopathy, generally in the cervical, axillary, supravacular, or inguinal lymph nodes
- Splenomegaly
- Shortness of breath, dry cough, chest pressure (patients with mediastinal mass)
- GI complications (nausea, vomiting, early satiety, constipation, and diarrhea)
- Back, chest, or abdominal pain

**Signs**
- Fever
- Night sweats
- Weight loss greater than 10% within last 6 months
- Pruritus

**Laboratory Tests**
- LDH
- ESR
- Serum chemistries
- CBC with differential

**Other Diagnostic Tests**
- Physical examination with careful attention to lymph node inspection.
- Imaging—chest x-ray, chest CT, abdominal or pelvic CT; integrated PET and CT is recommended as part of the initial workup.
- Bone marrow biopsy.
- Biopsy of suspected lymph node(s)—either open lymph node biopsy (preferred) or core biopsy; fine-needle aspiration should only be performed if preferred biopsy methods are unobtainable.
- Hematopathology evaluation of biopsy specimen—morphologic inspection, immunohistochemistry for cell surface antigens to characterize lymphoma cells, cytogenetic analysis.

**Designations Applicable to All Stages**
- A: No symptoms
- B: Fever, night sweats, and weight loss
- X: Bulky disease: greater than one-third the width of the mediastinum or > 10 cm maximal dimension of nodal mass
- E: Involvement of a single extranodal site, contiguous or proximal to a known nodal site
- CS: Clinical stage
- PS: Pathologic stage

*Also used for non-Hodgkin lymphoma.*
Early Stage Disease

Favorable stage I/II HL. Patients with favorable disease have:

- 30 Gy of IFRT is the preferred treatment of patients with dose) of IFRT or two cycles Stanford V chemotherapy plus dacarbazine) plus 20 to 30 Gy (Gray, the absorbed radiation long-term toxicities

- For new cancers of the breast, lung, and stomach, as well as melanoma and new NHL, depending on the radiation field. Patients cured with radiotherapy are at increased risk for new cancers of the breast, lung, and stomach, as well as melanoma and new NHL, depending on the radiation field.

Nonpharmacologic Therapy

Radiation therapy is effective in the treatment of HL and has cured patients of their disease. Historically, patients with favorable early stage I/II disease were treated with radiation alone. However, long-term toxicities associated with this practice have precluded this approach. Current treatment strategies combine radiation with chemotherapy. This has been reported to reduce the irradiated volume and dose as well as the number of cycles of chemotherapy.

Historically in the treatment of HL, the radiation fields were large and often included the lungs, liver, heart, and breast. Today, the use of involved-field radiotherapy (IFRT) limits radiation to the involved area. In addition to the smaller radiation volumes, other organs such as the breast, heart, and lungs have reduced exposure.

Treatment with radiotherapy produces significant toxicity of acute and delayed onset. Acute effects of irradiation include nausea, vomiting, anorexia, xerostomia, pharyngitis, dry cough, fatigue, diarrhea, and rash. These effects are typically transient, resolving shortly after completion of treatment. Delayed effects from radiotherapy are concerning in as they may be permanent and present months to years after therapy. Pneumonitis, pericarditis, hypothyroidism, infertility (with pelvic field irradiation), coronary artery disease, deformities in bone and muscle growth, Lhermitte sign are not uncommon. Patients cured with radiotherapy are at increased risk for new cancers of the breast, lung, and stomach, as well as melanoma and new NHL, depending on the radiation field.

Pharmacologic Therapy

- **Early Stage Disease**

  **Key Concept**

  Initial treatment of HL includes combination chemotherapy, these regimens are effective and have acceptable long-term toxicities. Combined modality therapy of two to four cycles ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) plus 20 to 30 Gy (Gray, the absorbed radiation dose) of IFRT or two cycles Stanford V chemotherapy plus 30 Gy of IRFT is the preferred treatment of patients with favorable stage I/II HL. Patients with favorable disease have:

  - an erythrocyte sedimentation rate less than 50 mm/hour, no extralymphatic lesions, and one or two lymph nodes involved.
  - Restaging should occur after a minimum of two cycles of chemotherapy. IFRT should be initiated within 3 weeks for patients who achieve a complete response (CR) or a partial response (PR). After completion of IFRT, no further treatment is necessary for patients with a CR, further restaging is required for patients with PR to therapy.
  - ABVD or Stanford V followed by IFRT is recommended for patients with unfavorable, bulky disease. Four cycles of ABVD are given before restaging. For patients with a CR, IFRT is administered alone or in combination with two more cycles of ABVD. Patients with a PR will receive two additional cycles of chemotherapy. If there is response, patients then receive IFRT followed by end of treatment assessment to determine disease response. Patients with unfavorable, nonbulky disease receive ABVD for two cycles followed by interim staging. Two to four more cycles are recommended guided by the response to chemotherapy. The use of the Stanford V regimen should be considered for patients with mediastinal disease, bulky disease, B symptoms, or unfavorable nonbulky disease. A listing of chemotherapy regimens used in HL is presented in Table 97–4.

*Used for both Hodgkin lymphoma and non-Hodgkin lymphoma. IV, intravenous; po, oral; SCT, stem cell transplantation.
Patients with advanced disease can be further classified into two groups based on IPS. (see Table 97–2) Patients with three or fewer poor prognostic factors are considered to have favorable disease while patients with four or more factors have unfavorable disease. Patients who have at least four of the criteria may warrant more aggressive treatment.

Trials have focused on the use of multiagent chemotherapy for six to eight total cycles. The combination chemotherapy regimen MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) is of historical significance because it was the first chemotherapy regimen to cure HL in the 1960s. However, significant toxicity, including sterility and secondary leukemia led to the development of new regimens. ABVD was compared with MOPP or ABVD–MOPP alternating. This pivotal phase III trial comparing these regimens in patients with stage III/IV HL documented a higher CR in the ABVD arms. A recent update of the data shows superior 18-year freedom from progression in the ABVD arms compared to MOPP though a survival advantage has yet to be demonstrated. ABVD is now considered standard therapy for initial treatment of stage III or IV HL. Further information on ABVD may be found in Table 97–5.

Additional regimens such as Stanford V and BEACOPP were developed to improve the outcomes of patients with advanced HL. Except in patients with high risk disease (IPS greater than 3) the Stanford V regimen has demonstrated similar response rates to ABVD reported for event-free survival, overall survival, and toxicity. A dose-escalated regimen of BEACOPP (with colony-stimulating factor [CSF] support) was compared with a standard-dose BEACOPP and also COPP (cyclophosphamide substituted for mechlorethamine in MOPP) alternating with ABVD. The dose-escalated BEACOPP was superior to the other arms in both freedom from treatment failure and overall survival at 10 years. However, the escalated BEACOPP regimen is associated with more toxicity including infertility and more cases of secondary leukemia. Currently, neither BEACOPP regimen is widely used in the United States but is considered for advanced HL with a high number of poor prognostic factors.

Despite the high success rate in treating HL, approximately 5% to 10% of patients will be refractory to initial treatment and 10% to 30% will relapse after initial response. Patients relapsing after treatment should be offered additional therapy as durable responses have been reported. The duration of remission after chemotherapy remains a vital prognostic factor for likelihood of response to future treatment. For healthy patients, the definitive therapy after relapse is high-dose chemotherapy with autologous stem cell transplantation (SCT). This treatment offers a cure rate of approximately 40%.

Several studies have reported the importance of giving conventional chemotherapy before SCT. The purpose of the initial treatment after relapse is to decrease the tumor bulk before high-dose chemotherapy. The safety profile of autologous SCT continues to improve as refinements in supportive care are realized. Current estimates of mortality from autologous SCT for HL are approximately 5%. Morbidity commonly associated with preparative regimens in HL, aside from infectious and bleeding complications, includes the additive pulmonary toxicity of bleomycin coupled with carbustine, inducing potentially fatal pulmonary pneumonitis.

Patients who are not candidates for autologous SCT may receive standard salvage chemotherapy, such as etoposide, methylprednisolone, cytarabine, and cisplatin (ESHAP) or dexamethasone, cytarabine, and cisplatin (DHAP). Newer regimens such as GVD (gemcitabine, vinorelbine, and pegylated liposomal doxorubicin), IGEV (ifosfamide, gemcitabine, and vinorelbine) and GCD (gemcitabine, carboplatin, and dexamethasone) have also been effective for relapsed refractory HL. Brentuximab vedotin is a monoclonal antibody approved for the treatment of relapsed or refractory HL. It targets CD-30 and is linked to a microtubule-disrupting agent, monomethylauristatin E. This agent has been effective in heavily pretreated HL patients. Clinical trials are currently ongoing to further define the role of brentuximab.

*aSee dose adjustments (Chapter 88).*
NHL since 1998 that follows a dramatic increase that had nearly doubled the number of cases in the United States since 1950. The increase may be related to the development of aggressive NHL in patients with HIV, although the overall increase is independent of HIV disease, particularly for patients older than 65 years of age. The median age for diagnosis is 50 years, although children and young adults may also be affected. The etiology of certain aggressive NHL subtypes is related to specific endemic geographic factors. Follicular or low-grade lymphoma is more common in the United States and Europe and is relatively uncommon in the Caribbean, Far East, Middle East, or Africa. Follicular diffuse lymphomas of the GI tract are more prevalent in patients with celiac sprue, inflammatory bowel disease, or Helicobacter pylori infection. The incidence of Burkitt NHL is 7 cases per 100,000 people in Africa compared with 0.1 per 100,000 in the United States. Malaria or EBV is thought to contribute to the chronic B-lymphocyte stimulation that leads to malignant transformation in Burkitt NHL. EBV has been shown to transform lymphocytes in vitro to a monoclonal malignant population, which is believed to drive the development of disease in patients who are in a chronically immunosuppressed state. Patients with congenital diseases such as Wiskott-Aldrich syndrome, common variable hypogammaglobulinemia; X-linked lymphoproliferative syndrome. Environmental factors have been identified as contributing to the development of NHL. Certain occupations such as wood and forestry workers, butchers, exterminators, grain millers, machinists, mechanics, painters, printers, and industrial workers have a higher prevalence of disease. Industrial chemicals such as pesticides, herbicides, organic chemicals (eg, benzene), solvents, and wood preservatives are also associated with NHL.

**PATHOPHYSIOLOGY**

The pathophysiology of NHL is governed by numerous environmental and genetic events culminating with a monoclonal population of malignant lymphocytes. B cells represent the cells of origin in excess of 90% of cases. Figure 97–2 outlines normal B-cell

---

maturation with accompanying cell-surface antigens. Evolving data are correlating chromosomal mutations with specific disease subtypes. Cyto genetic abnormalities involving translocations of antigen receptor genes are prevalent in NHL. These include T-cell receptor genes in T-cell lymphomas and immunoglobulin genes in B-cell lymphomas. The principal defect appears to be an error in the assembly of the regulatory gene segment of an antigen receptor gene, resulting in inappropriate binding to an oncogene. This results in dysregulation of cell growth and proliferation, leading to the malignant clone of lymphocytes. Oncogenes identified in different lymphomatous diseases include c-myc, bcl-1, bcl-2, bcl-3, NF-xB, and bcl-6.9 Classic translocations for NHL include t(8;14) in Burkitt lymphoma, t(14;18) in follicular lymphomas, t(11;14) mantle cell lymphoma, and t(11;18)/(t(1;14) in mucosa-associated lymphoid tissue (MALT).

**KEY CONCEPT** Characterization of the morphology of the lymphocytes, the reactivity of the other cells in the lymph node, and the lymph node architecture are essential in obtaining a diagnosis and predicting disease course. The nodal presentation of NHL is divided into two main categories: follicular, corresponding to low-grade disease, and diffuse, corresponding to aggressive disease. A follicular disease pattern in the inspected lymph node is indicative of a more indolent or low-grade progression that has survival measured in years if left untreated. In contrast, a diffuse pattern of lymph node infiltration is a marker of highly aggressive disease, resulting in death within weeks to months if untreated. Follicular NHL is the most common indolent subtype, comprising 22% of NHL. Diffuse, large B-cell lymphoma is the most common aggressive histology, comprising 31% of NHL. The cells of origin for follicular NHL tend to be more mature, nondividing lymphocytes, whereas aggressive NHL is derived from rapidly dividing lymphoid precursors. A unique feature of the biology of NHL is that follicular low-grade histologies can undergo further malignant transformation, transforming further into a diffuse, large B-cell lymphoma population. This syndrome, called Richter transformation, may occur in up to 20% of follicular low-grade lymphoma patients and involves multiple genetic events, including abnormalities of chromosomes 11 and 12 and tumor suppressor genes. Richter transformation may also occur in patients with chronic lymphocytic leukemia, which results in a transformation to diffuse lymphoma.20

The classification of NHL has undergone several revisions as the histology, molecular biology, and clinical course have been more precisely defined. Classification schemes such as the Working Formulation categorize disease on aggressiveness into three categories: low grade—survival estimated in years without treatment, intermediate grade—survival estimated in months without treatment, and high grade—survival measured in days to weeks for untreated disease (Table 97–6). This scheme is limited in its clinical applicability because the large number of distinct diseases that are not categorized by this classification. The WHO has updated a classification scheme published in 1994 by the International Lymphoma Study Group called the Revised European American Classification of Lymphoid Neoplasms (REAL) that broadly categorizes histologic subtypes into B- and T-cell subtypes. This newer classification incorporates immunologic morphologic and genetic and clinical attributes of various NHL histologies.

Prognostic factors present at diagnosis have been identified for NHL. Age, the presence of B symptoms, performance status, number of nodal and extranodal sites, lactate dehydrogenase level, bulky disease (greater than 10 cm), advanced stage, and β₂-microglobulin concentration have been shown to be important prognostic features in NHL. Table 97–7 shows the International Prognostic Index (IPI), a predictive model for aggressive NHL to be treated with doxorubicin-containing chemotherapy regimens.21 This index is used as a tool to identify patients who may benefit from a more intense treatment regimen. Additionally, patients with diffuse aggressive B-cell lymphoma that is of germinal center type carry a better prognosis than other patients.22 A model similar to the IPI, the Follicular Lymphoma International Prognostic Index (FLIPI), is used to help guide treatment decisions in follicular lymphoma.23

**TREATMENT OF NHL**

**Desired Outcome**

Treatment of NHL depends primarily on histologic subtype (follicular low grade versus diffuse aggressive) and staging (local stage I/II versus advanced stage III/IV) to guide treatment with observation, chemotherapy, radiation, or chemotherapy and radiation. The Cotswold modification of the Ann Arbor staging system for HL is used in NHL as well.

Treatment goals depend on the patient’s specific subtype of NHL. For follicular low-grade NHL, the disease is considered to be incurable with standard therapies. Many patients with follicular lymphoma are older than 60 years of age, making allogeneic SCT impractical due to high treatment-related mortality for older patients.

**KEY CONCEPT** The treatment goals for low-grade NHL include:

- Observation of the disease until the patient exhibits obvious progression that limits functional capacity or is life threatening
- Treatment that induces remission with manageable toxicity
- Judicious selection of treatment options to avoid long-term toxicity
- Prevention of infectious complications

The intent of treatment for patients with aggressive histologies is cure of the malignancy. Some histologic subtypes exhibit an aggressive clinical course and are not considered to be curable. These patients are still treated with curative-intent chemotherapy or may be considered for a clinical trial.

Nonpharmacologic Therapy

For patients with low-grade follicular NHL, deferring initiation of therapy until progression of disease is a standard approach. The median survival time is 6 to 10 years. Some patients may be asymptomatic for several years after initial diagnosis, making observation a reasonable approach. Radiation therapy has a limited role in NHL relative to HL. NHL is more often a systemic disease, and radiation typically has been reserved for consolidation after chemotherapy in patients presenting with a large extranodal mass. However, IFRT without systemic therapy is a treatment option for patients with stage I/II follicular lymphoma.

For early-stage diffuse, aggressive NHL, combined-modality therapy was tested versus a longer course of chemotherapy. Overall survival favored the CHOP-radiation arm for 5 years (82% vs 72%). There was a trend toward increased toxicity, particularly hematologic and cardiac toxicity, in the CHOP alone arm. The results of this trial have established combined-modality therapy as first-line treatment for early stage NHL.

Pharmacologic Therapy

Follicular Low-Grade NHL

The management of low-grade lymphomas is an area of controversy, especially in patients presenting with early stage disease.

*The nodal map used in the Follicular Lymphoma International Prognostic Index is different than the nodal map used in conventional staging.*

Typical indications for treatment include cytopenias, recurrent infections, threatened end-organ function, disease progression over at least 6 months, or patient preference. In these patients, chemotherapy such as fludarabine or bendamustine is typically offered initially. In patients in whom a more rapid response is desired, such as patients with advanced disease, multiagent chemotherapy such as CVP (cyclophosphamide, vincristine, and prednisone) or CHOP may be used. These regimens, detailed in Table 97–8, have not been associated with an improvement in overall survival, making it impossible to select an unequivocal first-line regimen.25–27

Rituximab is also an integral component in drug therapy for this disease. Rituximab is a chimeric monoclonal antibody that binds specifically to CD20 expressed on B lymphocytes.28 NHL of B-cell origin expresses CD20 in greater than 90% of cases. The initial clinical experience with rituximab involved 166 patients with CD20+ low-grade lymphoma treated with four doses of 375 mg/m² of rituximab weekly.29 The overall response rate was 48%, with CR in 6% of patients. The median follow-up of 12 months demonstrated a median time to progression of 13 months. This established rituximab as a viable treatment option in patients with indolent follicular NHL, typically added to chemotherapy in most patients. Additionally, rituximab was examined as maintenance therapy administered every 8 weeks for 2 years after rituximab-containing multiagent chemotherapy. Compared with observation, rituximab increased 3-year PFS (74.9 vs 57.6 months).30

Other strategies for treatment of low-grade lymphomas include the combination of monoclonal antibodies directed against CD20 with a radiopharmaceutical attached and a new kinase inhibitor active against B-cells. Ibritumomab- yttrium 90 is a monoclonal antibody targeting CD20 that delivers radioactive yttrium. It is indicated for the treatment of relapsed follicular lymphoma or as consolidation after response to initial chemotherapy. Idelalisib is a small molecule that inhibits PI3Kδ kinase found in B-cells, inducing apoptosis and inhibiting chemotaxis. It was approved for follicular lymphoma based on a phase I study in patients who had failed multiple prior therapies. These heavily pretreated patients had an overall response
rate of 45%.

High-dose chemotherapy is being evaluated for low-grade follicular NHL, but its role is currently limited to clinical trials.

**Diffuse, Aggressive NHL**

*Key Concept* The mainstay of therapy for diffuse, aggressive NHL has been anthracycline-based combination chemotherapy, generally consisting of four or more drugs. Therapy options for intermediate- and high-grade NHL generally are segregated between localized (stage I/II) and advanced (stage III/IV) disease. Combined-modality therapy with an abbreviated course of CHOP and local radiation is considered a standard of care for stage I/II disease.

The standard therapy for disseminated disease since the 1970s has been CHOP. This regimen conferred a response of 50% to 60%, with long-term survival of approximately 30%. However, the 1980s were notable for the development of newer combination chemotherapy regimens that incorporated increasing numbers of agents with varying schedules. A phase III clinical trial compared CHOP to three more intensity regimens in patients with intermediate or high-grade NHL (Working Formulation Classification). There were no significant differences in response rate or overall survival between the groups. Severe toxicity and death were higher in the advanced-generation treatment programs relative to CHOP. This pivotal trial has cemented CHOP as first-line chemotherapy in diffuse NHL.

Rituximab is also routinely used to treat diffuse, aggressive NHL. Another study randomized patients 60 to 80 years of age with newly diagnosed disease to either CHOP for eight cycles or CHOP plus rituximab for eight cycles. Two-year follow-up showed rituximab improved CR (76% vs 63%) and median event-free survival (57% vs 38%) and long-term follow-up confirmed benefit was with an increase in 10-year survival (43% vs 27.6%). Similar findings have been reported in younger patients, making CHOP plus rituximab first-line therapy for advanced-stage diffuse, aggressive NHL (Table 97–9).

**Special Populations**

There are histologic subtypes of diffuse, aggressive NHL that respond less well to treatment with conventional regimens such as CHOP. Burkitt lymphoma, lymphoblastic lymphoma, mantle cell lymphoma, and primary CNS lymphoma are examples of disease that benefit from more intensive therapy. Regimens such as hyper-CVAD, which alternate cycles of hyperfractionated cyclophosphamide, doxorubicin, vincristine, and dexamethasone with high-dose cytarabine and methotrexate, may be substituted for CHOP.

Patients with CNS NHL have disease that is poorly responsive to therapy because of inadequate penetration of standard doses of chemotherapy across the blood–brain barrier. High-dose methotrexate, ranging from 2500 to 8000 mg/m² is a mainstay of therapy. Treatment may also include intrathecal chemotherapy. Drugs that are commonly instilled intrathecally include

methotrexate, cytarabine (conventional formulation and liposomal products), and corticosteroids.

The recent appreciation of H. pylori colonization and MALT has spurred the more aggressive treatment of this organism with antibiotics. In patients with localized disease, aggressive, combination therapy for H. pylori has been shown to induce MALT remission. Patients with advanced disease may require combination chemotherapy, such as CHOP.

Mantle cell lymphoma, which comprises 6% of NHL cases, is defined by a chromosomal translocation of (t(11;14)(q13;32). This translocation results in the overexpression of cyclin D1 coupled with NF-κB, which plays a critical role in intracellular protein regulation and protranscription factors leading to increased cell survival. Bortezomib, a proteasome inhibitor, disrupts the regulation and degradation of proteins required for cell cycle regulation. It is approved by the FDA for the treatment of patients with mantle cell lymphoma who have failed prior chemotherapy. A study conducted in 155 patients demonstrated that bortezomib resulted in 31% overall response rate with a median survival of 9.3 months. Bortezomib is well tolerated, with peripheral neuropathy, thrombocytopenia, neutropenia, and nausea reported most frequently.

With more than half of patients with NHL expected to relapse, salvage therapy plays a major role in the attempt to cure recurrence. Multiple drug regimens such as ESHAP and DHAP can induce a CR, but the long-term cure rate with these regimens is less than 10%. Salvage therapy can induce remissions with subsequent relapses; however, the chance for a CR and the duration of remission is further diminished.

High-dose chemotherapy with autologous SCT has been studied as an alternative to standard dose regimens in the setting of first relapse. The best-studied indication for SCT is for patients with intermediate- or high-grade disease that fails to respond to first-line therapy. A 3- to 5-year survival of greater than 40% is achieved in patients who have good performance and disease that demonstrates a significant response to one or two cycles of salvage chemotherapy. The procedure-related mortality rate has ranged from 5% to 10% in published reports. However, as with HL, with more broad application of peripheral blood stem cells and improved supportive care, the mortality rate continues to decline. The role of allogeneic SCT in this setting is limited because of donor availability, the older age of patients, and the high treatment-related morbidity and mortality. Additionally, outcomes between autologous and allogeneic transplant appear similar.

Patients with HIV-related lymphoma represent a therapeutic dilemma considering many have high-grade NHL. A common presentation is that of extranodal disease, frequently in the GI tract, CNS, or bone marrow. Therapy for this population thus far has fared poorly, with a median survival time of 6 to 12 months, which decreases to 3 months with CNS involvement. The addition of rituximab to chemotherapy has failed to improve overall survival in this patient population and is associated with increased infectious complications.

OUTCOME EVALUATION

Treatment response in lymphomas is measured using the response evaluation criteria in solid tumors (RECIST), a uniform criteria assessing tumor response developed by the National Cancer Institute. Lymphomas may have residual masses after completion of treatment, adding to the difficulty in establishing a definitive remission from treatment. Clinical trials with limited numbers of patients have been published suggesting the value of positron emission tomography (PET) scans to rule out whether residual tumor masses after treatment contain viable tumor. Integrated PET–computed tomography (CT) scanning is recommended as part of the initial workup and to evaluate for residual disease at the end of treatment.

Long-term follow-up monitors patients for continued disease remission or relapse with careful examination of the original areas of involvement and imaging studies including chest x-rays and CT scans to detect recurrence. Patients also require long-term monitoring for toxicities of their treatment.

Most patients treated for lymphoma with chemotherapy or radiation notice a regression of palpable lymphadenopathy within days. This is because of the high sensitivity of the rapidly proliferating malignant lymphocytes to chemotherapy and radiotherapy. This necessitates implementation of tumor lysis syndrome precautions with aggressive intravenous hydration and allopurinol. Rasburicase should be considered for patients with moderate to high tumor burdens. Most chemotherapy treatments for lymphoma have a significant risk of infectious complications. Combination regimens for both HL and NHL are associated with rates of severe leukopenia and/or neutropenia ranging from 20% to 100% of patients. Consideration must be given to supportive care with prophylactic antibiotics and CSFs. Most chemotherapy regimens discussed in this section are highly emetogenic. Antiemetic regimens are available to control chemotherapy-induced nausea and vomiting for most standard-dose regimens.

Advances in the treatment of lymphoma have increased the number of long-term survivors. Identification of long-term complications of lymphoma therapy is vital to patient follow-up and may influence treatment decisions in newly diagnosed patients. Outcomes associated with the treatment of HL make up the majority of data. However, advances in NHL treatment have provided more information regarding long-term toxicities. Two leading causes of death associated with lymphoma treatment are secondary malignancies and cardiovascular disease.
The use of combined modality of irradiation with doxorubicin-based therapy has been reported to increase the risk of cardiac dysfunction. Treatment-related pulmonary toxicity, hypothyroidism, and infertility have been associated with lymphoma therapy as well. Lymphoma survivors have an increased risk for developing myelodysplasia, acute myelogenous leukemia, and various solid tumors.41

A limitation of rituximab is severe, potentially fatal infusion-related reactions. Deaths have been reported resulting from the profound hypotension and circulatory collapse seen with the drug, particularly on the first dose. The package labeling recommends premedication with acetaminophen and diphenhydramine before each infusion. The initial infusion should be given slowly, at 50 mg/hour. The infusion rate may be increased as tolerated to a maximum of 400 mg/hour. In the absence of infusion reactions, subsequent doses may be started at a higher rate and titrated more aggressively. Reactivation of hepatitis B infections has occurred in patients treated with rituximab. Patients at high risk for hepatitis B should be screened and monitored carefully for reactivation of hepatitis. If hepatitis occurs, rituximab should be discontinued, and patients should be treated appropriately. Other associated toxicities of rituximab include fever, chills, headache, asthenia, nausea, vomiting, angioedema, bronchospasm, and skin reactions. KEY CONCEPT Rituximab is an effective treatment option for patients with various forms of NHL in combination with chemotherapy or as a single agent as long as patients are monitored appropriately. The radiolabeled CD-20 antibody causes more myelosuppression than rituximab alone and has a long-term risk of inducing secondary leukemias.42

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the rationale for using hematopoietic stem cell transplant (HSCT) to treat cancer.
2. Compare the different types of HSCTs, specifically (a) the types of donors (ie, autologous and allogeneic), (b) the source of hematopoietic cells (ie, umbilical cord, peripheral blood progenitor cells, and bone marrow), and (c) the type of preparative regimen (ie, myeloablative and nonmyeloablative).
3. List the nonhematologic toxicity to high-dose chemotherapy used in myeloablative preparative regimens, specifically busulfan-induced seizures, hemorrhagic cystitis, gastrointestinal toxicities, and sinusoidal obstruction syndrome.
4. Develop a plan for monitoring and managing engraftment of hematopoiesis.
5. Explain graft-versus-host disease (GVHD).
6. Recommend a prophylactic and treatment regimen for GVHD.
7. Choose an appropriate regimen to minimize the risk of infectious complications in HSCT patients.
8. Evaluate the long-term health care of HSCT survivors.

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) is a procedure used mainly to treat hematologic malignancies via high-dose chemotherapy and/or a graft-versus-tumor effect. HSCT may be either autologous; where a patient receives their own bone marrow or allogeneic; where the patient receives bone marrow from a donor. As an alternative to bone marrow, hematopoietic stem cells may be obtained from the peripheral blood progenitor cells (PBPCs) or umbilical cord blood. Bone marrow and PBPCs contain pluripotent stem cells and postthymic lymphocytes, which are responsible for long-term hematopoietic reconstitution, called engraftment and immune recovery.¹

The rationale of an autologous transplant is to administer myeloablative preparative regimen and eradicate the patient’s malignancy. Collecting the bone marrow or PBPCs prior to administering high dose chemotherapy essentially protects the collected PBPCs from the effects of chemotherapy and can restore hematopoiesis. Allogeneic use donor PBPCs to rescue the patient after myeloablative chemotherapy with an added advantage of the donor cells generating an immunologic response towards the recipient’s residual tumor, called the graft-versus-tumor effect. Unfortunately, graft-versus-host disease (GVHD) where the donor cells generate an immunologic response toward the recipient’s normal tissue also occurs. The type of HSCT performed depends on a number of factors, including the type and status of disease, availability of a compatible donor, patient age, performance status, and organ function. Examples of diseases treated with HSCT are listed in Table 98–1.

Epidemiology and Etiology

Worldwide, approximately 35,000 autologous HSCTs and 25,000 allogeneic HSCTs are performed per year, with approximately one-third of allogeneic HSCTs using reduced-intensity preparative regimens. In the late 1990s, the number of allogeneic HSCTs reached a plateau, most likely related to the introduction of effective oral therapies for the treatment of newly diagnosed chronic-phase chronic myelogenous leukemia (CML), a disease that was historically managed with allogeneic HSCT. Furthermore, the limited availability of suitable donors may have also contributed to the plateau effect.²

The use of allogeneic PBPCs is increasing; from years 2007 through 2011, almost 80% of allogeneic HSCTs performed worldwide used PBPCs as the source of hematopoietic cells rather than bone marrow in adult patients.³ Autologous PBPC use has increased and essentially has replaced bone marrow as a graft source in many transplant centers. From years 2007 through 2011, approximately 99% of autologous HSCTs in adults and 94% in children used PBPCs as the source of hematopoietic cells.³

Pathophysiology

Autologous HSCT, or infusion of a patient’s own hematopoietic cells, allows for the administration of higher doses of chemotherapy, radiation, or both to treat the malignancy or autoimmune disorder. In this setting, the hematopoietic cells “rescue” the recipient from otherwise dose-limiting hematopoietic toxicity. Autologous HSCT is used to treat intermediate-
high-grade non-Hodgkin lymphoma (NHL), multiple myeloma (MM), autoimmune diseases, and relapsed or refractory Hodgkin disease. Patients do not benefit from an immunologic graft-versus-tumor effect while undergoing an autologous transplant; instead, the administration of high-dose chemotherapy followed by an autologous stem cell transplant in chemotherapy-sensitive malignancies relies on the preparative regimen alone to eradicate the malignant disease. Autologous HSCT circumvents the need for histocompatible donors, is associated with a lower mortality rate, and is not restricted to younger patients.

**Histocompatibility**

Histocompatibility differences between the donor and the recipient necessitate immunosuppression after an allogeneic HSCT because considerable morbidity and mortality are associated with graft failure and GVHD. Rejection is least likely to occur with a syngeneic donor. In patients without a syngeneic donor, initial HLA typing is conducted on family members because the likelihood of complete histocompatibility between unrelated individuals is remote. Siblings are the most likely individuals to be histocompatible within a family. The chance for complete histocompatibility occurring in an individual with only one sibling is 25%. Approximately 40% of patients with more than one sibling will have an HLA-identical match. Having a matched-sibling donor is no longer a requirement for allogeneic HSCT because improved immunosuppressive regimens and the National Marrow Donor Program have allowed an increase in the use of unrelated or related matched or mismatched HSCTs. The use of alternative sources of allogeneic hematopoietic cells, such as related donors mismatched at one or more HLA loci or phenotypically (ie, serologically) matched unrelated donors, has been evaluated. Establishment of the National Marrow Donor Program has helped to increase the pool of potential donors for allogeneic HSCT. Through this program, an HLA-matched unrelated donor might be identified. Recipients of an unrelated graft are more likely to experience graft failure and acute GVHD relative to recipients of a matched-sibling donor. Determination of histocompatibility between potential donors and the patient is completed before allogeneic HSCT. Initially, HLA typing is performed using blood samples and compatibility for class I MHC antigens (ie, HLA-A, HLA-B, and HLA-C) is determined through serologic and DNA-based testing methods. In vitro reactivity between donor and recipient also can be assessed in mixed-lymphocyte culture, a test used to measure compatibility of the MHC class II antigens (ie, HLA-DR, HLA-DP, and HLA-DQ). Currently, most clinical and research laboratories are also performing molecular DNA typing using polymerase chain reaction (PCR) methodology to determine the HLA allele sequence.
The preparative regimen or GVHD prophylaxis may be altered based on the mismatch between the donor and the recipient. The risk of graft failure decreases with better matches such that those with a class I (ie, HLA-A, HLA-B, or HLA-C) antigen mismatch have the highest risk of rejection; those with just one class I allele mismatch have a minimal risk. Graft failure does not appear to be associated with mismatch at a single class II antigen or allele. GVHD and survival have been associated with disparity for classes I and II antigens and alleles.6

Stem Cell Sources

**KEY CONCEPT** Bone marrow, PBPCs, and umbilical cord blood can serve as the source of hematopoietic cells. The optimal cell source differs based on the donor and recipient characteristics.

Hematopoietic stem cells are obtained from bone marrow or peripheral blood. The technique for harvesting hematopoietic cells depends on the anatomic source (ie, bone marrow or peripheral blood). A surgical procedure is necessary for obtaining bone marrow. Multiple aspirations of marrow are obtained from the anterior and posterior iliac crests until a volume with a sufficient number of hematopoietic stem cells is collected (ie, 600–1200 mL of bone marrow). The bone marrow then is processed to remove fat or marrow emboli and usually is infused intravenously into the patient similar to a blood transfusion.

The shift to the use of PBPCs over bone marrow for HSCT is primarily because of the more rapid engraftment and decreased health care resource use. For an autologous transplant, the harvest occurs before administering the preparative regimen; therefore, autologous hematopoietic cells must be cryopreserved and stored for future use.

Allogeneic cells are usually harvested just prior to the HSCT and administered to the recipient without cryopreservation; however, they are sometimes collected and cryopreserved as well. The bone marrow may need additional processing if the donor and recipient are ABO incompatible, which occurs in up to 30% of HSCTs. Red blood cells (RBCs) may need to be removed before infusion into the recipient to prevent immune-mediated hemolytic anemia and thrombotic microangiopathic syndromes.

Transplantation with PBPCs essentially has replaced bone marrow transplantation (BMT). PBPCs are obtained by administering a mobilizing agent(s) followed by apheresis, which is an outpatient procedure similar to hemodialysis. Hematopoietic growth factors (HGFs) alone or in combination with myelosuppressive chemotherapy are used for mobilization of autologous PBPCs with similar results.5 HGFs are also used to mobilize donor PBPCs for allogeneic transplants, although chemotherapy is not used in this setting.

Transplant with umbilical cord blood offers an alternative stem cell source to patients requiring an allogeneic transplant who do not have an acceptable matched related or unrelated donor. When allogeneic hematopoietic cells are obtained from umbilical cord blood, the cord blood is obtained from a consenting donor in the delivery room after birth and delivery of the placenta. The cord blood is processed, a sample is sent for HLA typing, and the cord blood is frozen and stored for future use. Numerous umbilical cord blood registries exist, with the goal of providing alternative sources of allogeneic stem cells. One potential limitation to the use of umbilical cord blood transplants is the inability to use donor-lymphocyte infusions in the event of relapse. Engraftment is slower in umbilical cord blood transplants, with a potential lower risk of GVHD and similar survival rates relative to BMT.16 In children receiving an umbilical cord blood graft from an unrelated donor, cell dose (eg, nucleated cells) is related to engraftment, transplant-related morbidity, and survival.7 Although there were initial concerns regarding whether a umbilical cord blood transplant could provide enough nucleated cells to engraft adequately within an adult, there is growing experience to indicate that a umbilical cord blood transplant is feasible when at least 1 × 10^7 nucleated cells per kilogram of recipient body weight are administered.11 The prospective use of dual umbilical cord units and *ex vivo* expansion of umbilical cord units to obtain adequate engraftment are methods currently under exploration.

**TREATMENT Desired Outcome**

**KEY CONCEPT** Engraftment is defined as the point at which a patient can maintain a sustained ANC of greater than 500 cells/mm^3 (0.5 × 10^9/L) and a sustained platelet count of 20,000/mm^3 (20 × 10^7/L) or more lasting 3 or more consecutive days without transfusions and is the desired short term outcome in a transplant. The desired long-term outcome with HSCT is to cure the patient of his or her underlying disease while minimizing the short- and long-term morbidity associated with HSCT.

**Nonpharmacologic Therapy**

**Harvesting, Preparing, and Transplanting Autologous and Allogeneic Hematopoietic Cells**

**Autologous Transplants** The HGFs granulocyte-macrophage colony-stimulating factor (sargramostim, Leukine) and granulocyte colony-stimulating factor (filgrastim, Neupogen) are used as mobilizing agents. The use of pegylated granulocyte colony-stimulating factor (pegfilgrastim, Neulasta) for mobilization of PBPCs appears more convenient and is promising as a mobilization agent; however, further data are needed regarding graft composition, HSCT outcomes, and donor safety in allogeneic donations before widespread use of this agent can be recommended.

The combination of chemotherapy with an HGF enhances PBPC mobilization relative to HGF alone.1 In addition to treating the underlying malignancy, this approach lowers the risk of tumor cell contamination and the number of apheresis collections required, but there is a greater risk of neutropenia and thrombocytopenia. The HGF is initiated after completion of chemotherapy and is continued until apheresis is complete. Many centers monitor the number of cells that express the CD34 antigen (ie, CD34+ cells) to determine when to start apheresis. The CD34 antigen is expressed on almost all unipotent and multipotent colony-forming cells and on precursors of colony-forming cells but not on mature peripheral blood cells. Apheresis is continued daily until the target number of PBPCs per kilogram of the recipient’s weight is obtained. For adult recipients, the number of CD34+ cells correlates with time to engraftment. Lower yield of CD34+ cells is associated with administration of stem cell toxic drugs (eg, carmustine and melphalan) and intensive prior chemotherapy or radiotherapy, which should be avoided prior to transplant if possible.

If patients are unable to obtain an adequate yield of CD34+ cells per kilogram after mobilization attempts fail, then allogeneic transplant may be considered as an alternative. Additionally, plerixafor (Mobozil) is approved by the Food and Drug Administration (FDA) for use in combination with granulocyte colony-stimulating factor to mobilize PBPCs for collection...
and subsequent autologous transplantation in patients with NHL and MM. Plerixafor is an inhibitor of the CXCR4 chemokine receptor that results in more circulating PBPCs in the peripheral blood because of the inability of CXCR4 to assist in anchoring hematopoietic stem cells to the bone marrow matrix. Because administration of plerixafor with granulocyte colony-stimulating factor results in increased yield of CD34+ cells per kilogram compared to granulocyte colony-stimulating factor alone, this combination serves as an alternative mobilization strategy in patients deemed to be at risk for mobilization failure with conventional methods.

**Allogeneic Transplants** The allogeneic donor first undergoes mobilization therapy with an HGF to increase the number of hematopoietic cells circulating in the peripheral blood. The most commonly used regimen to mobilize allogeneic donors is a 4- to 5-day course of filgrastim, 10 mcg/kg/day, administered subcutaneously followed by apheresis on the fourth or fifth days when peripheral blood levels of CD34+ cells peak. An adequate number of hematopoietic cells usually are obtained with one to two apheresis collections, with the optimal number of CD34+ collected being a minimum of 4-8 x 10^6 cells/kg of recipient body weight. Higher numbers of CD34+ cells are associated with more rapid neutrophil and platelet engraftment; patients who receive less than 2 x 10^6/kg CD34+ cells are at risk for delayed engraftment.5 Hematopoietic stem cells obtained from the peripheral blood are processed like bone marrow–derived stem cells and may be infused immediately into the recipient or frozen for future use. Compared with bone marrow donation, allogeneic PBPC donation leads to quicker hematopoietic recovery. Neutrophil engraftment occurs 2 to 6 days earlier, and platelet engraftment occurs approximately 6 days earlier with PBPC grafts than bone marrow grafts.9 The donor may experience musculoskeletal pain, headache, and mild increases in hepatic enzyme or lactate dehydrogenase levels related to filgrastim administration. Hypocalcemia may also occur owing to citrate accumulation, which decreases ionized calcium concentrations during apheresis.

Allogeneic PBPC grafts contain approximately 10 times more T and B cells than bone marrow grafts. Historically, there has been significant concern that the greater T- and B-cell content of PBPCs could increase the risk of acute and/or chronic GVHD. In patients with a hematologic malignancy who have an HLA-matched sibling donor, a PBPC graft is optimal relative to bone marrow graft because the PBPC graft is associated with quicker neutrophil and platelet engraftment and potentially improved disease-free survival rates.10 Grafts from PBPCs are likely associated with a higher incidence of acute GVHD and an approximately 20% increase in the incidence of extensive-stage and overall chronic GVHD.10 Similar trends for engraftment and GVHD have been found with unrelated donors.11

**T-Cell Depletion** Immunocompetent T lymphocytes may be depleted from the donor bone marrow *ex vivo* before infusion (referred to as T-cell–depleted hematopoietic cells) into the recipient as a means of preventing GVHD. Depletion of T lymphocytes in donor hematopoietic cells is completed *ex vivo* using physical (eg, density-gradient fractionation) and/or immunologic (eg, antithymocyte globulin [ATG] antibodies) methods. Functional recovery of T cells in the recipient is delayed, and the risk of Epstein-Barr virus–associated lymphoproliferative disorders is higher with the use of T-cell–depleted bone marrow. The use of T-cell–depleted grafts reduces the incidence of GVHD, but graft failure and relapse are more common. The use of donor lymphocyte infusion in patients who relapse after receiving a T-cell–depleted HSCT is being investigated.

**Engraftment** After chemotherapy and radiation, pancytopenia lasts until the infused stem cells reestablish functional hematopoiesis. The median time to engraftment is a function of several factors, including the source of stem cells such as PBPCs, which can result in earlier engraftment than bone marrow. Myeloablative preparative regimens have significant regimen-related toxicity and morbidity and thus usually are limited to healthy, younger (ie, usually less than 50 years) patients. Alternatively, nonmyeloablative transplants are being performed with the hope of curing more patients with cancer by increasing the availability of HSCT with less regimen-related toxicity and by using the graft-versus-tumor effect.1

A delicate balance exists between host and donor effector cells in the bone marrow environment. Residual host-versus-graft effects may lead to graft failure, which is also known as graft rejection. Graft failure is defined as the lack of functional hematopoiesis after HSCT and can occur early (ie, lack of initial hematopoietic recovery) or late (ie, in association with recurrence of the disease or reappearance of host cells after initial donor cell engraftment). Engraftment usually is evident within the first 30 days in patients undergoing an HSCT; however, rejection can occur after initial engraftment. Therapeutic options for the treatment of graft rejection are limited; a second HSCT is the most definitive therapy, although the toxicities are formidable.12

**Graft-Versus-Tumor Effect**

A graft-versus-tumor effect caused by the donor lymphocytes occurs after transplant. This results in lower relapse rates in patients with GVHD relative to those who did not have GVHD; a higher rate of leukemia relapse after T-cell–depleted, autologous, or syngeneic HSCT; and the effectiveness of donor lymphocyte infusions in inducing remission in patients who relapsed after allogeneic HSCT. Rapid taper of immunosuppression in patients with residual disease may induce a graft-versus tumor effect. In donor lymphocyte infusion, lymphocytes are collected from the peripheral blood of the donor and administered to the recipient. Eradication of the recurrent malignancy is caused by either specific targeting of the tumor antigens or GVHD, which may affect cancer cells preferentially. Patients with hematologic

**Patient Encounter, Part 1**

A 55-year-old woman is diagnosed with acute myeloid leukemia with complex cytogenetics. The patient achieved complete remission with induction therapy and is now being evaluated for an allogeneic stem cell transplant with a peripheral blood stem cell graft from a full HLA-matched unrelated donor. She has no siblings. Her preparative regimen consists of cyclophosphamide and TBI and her GVHD prophylaxis consists of tacrolimus, methotrexate, and ATG.

**What nonhematologic toxicities are associated with the preparative regimen?**

**What are the advantages and disadvantages of obtaining and infusing hematopoietic stem cells from a peripheral blood stem cell source as opposed to a bone marrow source?**

**What are the implications for this patient of an unrelated stem cell donor?**

Preparative Regimens for HSCT

Examples of commonly used preparative regimens are included in Table 98–2.

Myeloablative Preparative Regimens In both autologous and allogeneic HSCT, infusion of stem cells circumvents dose-limiting myelosuppression, maximizing the potential value of the steep dose–response curve to alkylating agents and radiation, suppressing the host immune system, and creating space in the marrow compartment to facilitate engraftment. The preparative regimen is designed to eradicate immunologically active host tissues (lymphoid tissue and macrophages) and to prevent or minimize the development of host-versus-graft reactions. Most allogeneic preparative regimens for the treatment of hematologic malignancies contain cyclophosphamide, radiation, or both. The combination of cyclophosphamide and total-body irradiation (TBI) was one of the first preparative regimens developed and is still used widely today. This regimen is immunosuppressive and has inherent activity against hematologic malignancies (eg, leukemias and lymphomas). TBI has the added advantage of being devoid of active metabolites that might interfere with the activity of donor hematopoietic cells. In addition, TBI eradicates residual malignant cells at sanctuary sites such as the central nervous system. Modifications of the cyclophosphamide–TBI preparative regimen include replacing TBI with other agents (eg, busulfan) or adding other chemotherapeutic or monoclonal agents to the existing regimen in hopes of minimizing long-term toxicities. In the case of a mismatched allogeneic HSCT with a substantially increased chance of graft rejection, ATG also may be added to the preparative regimen to further immunosuppress the recipient.

The optimal myeloablative preparative regimen remains elusive. Busulfan–cyclophosphamide (BU-CY) and cyclophosphamide–TBI (CY-TBI) are prescribed in patients with AML and CML, which represent the more common indications for allogeneic HSCT. Intravenous busulfan with pharmacokinetic monitoring may improve outcomes when utilized with BU-CY compared to Cy-TBI in AML patients although preparative regimens should be tailored to the primary disease and to the degree of HLA compatibility.

Nonmyeloablative Preparative Regimens A nonmyeloablative preparative regimen is less toxic than a myeloablative regimen in the hope of being able to offer the benefits of an allogeneic HSCT to more patients. A nonmyeloablative HSCT is based on the concept of donor immune response having a graft-versus-tumor effect.

Because of the severe regimen-related toxicity of a myeloablative preparative regimen, the use of HSCT traditionally was limited to younger patients with minimal comorbidities. Most patients diagnosed with cancer are elderly; therefore, myeloablative HSCT could not be offered to a substantial portion of cancer patients. The concept of donor immune response having a graft-versus-tumor effect gave rise to the theory that a strongly immunosuppressive, but not myeloablative, preparative regimen (ie, a nonmyeloablative transplant may result in a state of chimerism in which the recipient and donor are coexisting). The toxicity and efficacy of nonmyeloablative transplants are being evaluated

in patients with malignant and nonmalignant conditions who are not eligible for a myeloablative HSCT.

A nonmyeloablative preparative regimen allows for development of mixed chimerism (defined as 5%–95% peripheral donor T cells) between the host and recipient to allow for a graft-versus-tumor effect as the primary form of therapy (Figure 98–1). Chimerism is assessed within peripheral blood T cells and granulocytes and bone marrow using conventional (eg, using sex chromosomes for opposite-sex donors) and molecular (eg, variable number of tandem repeats) methods for same-sex donors.

The nonmyeloablative preparative regimen does not completely eliminate host normal and malignant cells. Donor cells eradicate residual host hematopoiesis, and the graft-versus-tumor effects generally occur after the development of full donor T-cell chimerism. After engraftment, mixed chimerism should be present and is shown by the presence of both donor- and recipient-derived cells. Autologous recovery should occur promptly if the graft is rejected. The intensity of immunosuppression required for engraftment depends on the immunocompetence of the recipient and the histocompatibility and composition of the HSCT. More intensive conditioning regimens that are required for engraftment in the setting of unrelated-donor- or HLA-mismatched-related HSCT have been termed reduced-intensity myeloablative transplants. After chimerism develops, donor-lymphocyte infusion can be administered safely in patients without GVHD to eradicate malignant cells.

Nonmyeloablative preparative regimens typically consist of a purine analog (eg, fludarabine) in combination with an alkylating agent or low-dose TBI. Adverse effects in the early post-transplant period are decreased because of the lower intensity preparative regimen, thus making HSCT available to patients who in the past were not healthy or young enough to receive a myeloablative preparative regimen. The risk of GVHD remains with nonmyeloablative transplant; the GVHD prophylaxis regimens are reviewed in the GVHD section below. Presently, nonmyeloablative transplant is not indicated as first-line therapy for any malignant or nonmalignant conditions, although research is ongoing. Nonmyeloablative transplantation is being evaluated for cancers sensitive to a graft-versus-tumor effect (eg, CML and AML), in older patients, or for those with comorbidities who would not be able to tolerate a myeloablative HSCT.

**Toxicities and Management of Preparative Regimens** Myelosuppression is a frequent dose-limiting toxicity for antineoplastics when administered in the conventional doses used to treat cancer. However, because myelosuppression is circumvented with hematopoietic rescue in the case of patients receiving HSCT, the dose-limiting toxicities of these myeloablative preparative regimens are nonhematologic and vary with the preparative regimen used. Most patients undergoing HSCT experience toxicities commonly associated with chemotherapy (eg, alopecia, mucositis, nausea and vomiting, and infertility), albeit these toxicities are magnified in the HSCT population.

**Busulfan Seizures** Seizures have been reported in both adult and pediatric patients receiving high-dose busulfan for HSCT preparative regimens. Anticonvulsants are used to minimize the risk of seizures. Anticonvulsants are begun shortly before busulfan, with the loading dose completed at least 6 hours before the first busulfan dose. Oral loading and maintenance regimens generally are sufficient because target phenytoin concentrations of 10 to 20 mcg/mL (10–20 mg/L; 40–79 μmol/L) can be achieved by the peak time of seizure risk. If patients are experiencing

---

significant vomiting or have difficulty maintaining therapeutic phenytoin concentrations, intravenous (IV) phenytoin should be substituted. Benzodiazepines such as lorazepam or clonazepam also have been used for seizure prophylaxis during high-dose busulfan therapy before HSCT. Antiepileptic medications usually are discontinued 24 to 48 hours after administration of the last dose of busulfan. Seizures still can occur despite the use of prophylactic anticonvulsants and usually do not result in permanent neurologic deficits.

**Adaptive Dosing of Busulfan** The considerable interpatient variability in the clearance of both oral and IV busulfan along with the identified concentration–effect relationships, has led to the adaptive dosing of busulfan. Adjusting the oral busulfan dose to achieve a target concentration minimizes the toxicities of the BU-CY regimen, particularly hepatic sinusoidal obstruction syndrome (SOS; formerly referred to as veno-occlusive disease) while improving engraftment and relapse rates. Complete reviews of these relationships after oral busulfan administration are available elsewhere. An IV busulfan product, Busilux, was approved by the FDA in February 1999 in combination with cyclophosphamide as a preparative regimen before allogeneic HSCT for CML. In combination with either cyclophosphamide or fludarabine, the data available with busulfan suggests that therapeutic drug monitoring may be needed to optimize patient outcome with regards to efficacy and toxicity.

**Hemorrhagic Cystitis** High-dose cyclophosphamide causes moderate to severe hemorrhagic cystitis; acrolein, a metabolite of cyclophosphamide, is the putative bladder toxin. Preventive measures to lower the risk of hemorrhagic cystitis include vigorous hydration, continuous bladder irrigation, or concomitant use of the uroprotectant mesna. The American Society of Clinical Oncology (ASCO) Guidelines for the Use of Chemotherapy and Radiotherapy Protectants recommends the use of Mesna (2-mercaptopropane sulfonate) plus saline diuresis or forced saline diuresis to lower the incidence of urothelial toxicity with high-dose cyclophosphamide in the setting of HSCT.

**Chemotherapy-Induced Gastrointestinal Effects** Preparative regimens for myeloablative HSCT result in other end-organ toxicities, such as renal failure and idiopathic pneumonia syndrome. In addition, recipients of myeloablative preparative regimens are at risk for severe gastrointestinal (GI) toxicity, specifically chemotherapy-induced nausea and vomiting (CINV), diarrhea, and mucositis. CINV can be caused by administration of highly emetogenic chemotherapy over several days, TBI, and poor control of CINV before HSCT. Thus, patients who are undergoing a myeloablative HSCT should receive a prophylactic corticosteroid with a serotonin antagonist, with higher doses of serotonin antagonists potentially being needed in this patient population. In addition, these patients are at high risk for delayed CINV in the immediate posttransplant period, and these issues should be addressed accordingly as per published clinical practice guidelines.

Diarrhea is also an adverse effect experienced by a majority of patients undergoing HSCT. Chemotherapy-induced diarrhea occurs because of the effects of the preparative regimen, which results in inflammation and damage to the cells lining the GI tract. Diarrhea caused by the preparative regimen is usually apparent within the first week after the initiation of chemotherapy and/or radiation. Treatment strategies for chemotherapy-induced diarrhea include the administration of antidiarrheals after excluding infectious causes of diarrhea and the prevention of dehydration.

Virtually all patients receiving a myeloablative preparative regimen experience severe mucositis owing to its effects on rapidly dividing cells of the oral epithelium and subsequent inflammation of the oropharyngeal cavity. Routine oral care protocols are indicated to reduce the severity of mucositis, which may onset within the first week of HSCT and persist for up to approximately 2 weeks. Palifermin, a keratinocytic growth factor, may be considered for patients undergoing myeloablative HSCT with TBI-based preparative regimens. Patients may require parenteral opioid analgesics for pain relief owing to mucositis, and total parenteral nutrition may be necessary to prevent the development of nutritional deficiencies.

**Sinusoidal Obstruction Syndrome** Hepatic SOS is a life-threatening complication that may occur secondary to preparative regimens or radiation. The pathogenesis of SOS is not understood completely, but several mechanisms have been proposed. The key event appears to be endothelial damage caused by the preparative regimen. The primary site of the toxic injury is the sinusoidal endothelial cells; the endothelial damage initiates the coagulation cascade, induces thrombosis of the hepatic venules, and eventually leads to fibrous obliteration of the affected venules.

The clinical manifestations of SOS are hyperbilirubinemia, jaundice, fluid retention, weight gain, and right upper quadrant abdominal pain. To make a clinical diagnosis of SOS, these features must occur in the absence of other causes of posttransplant liver failure, including GVHD, viral hepatitis, fungal abscesses, or drug reactions. Most cases of SOS occur within 3 weeks of HSCT, and the clinical diagnosis can be confirmed histologically via liver biopsy.

Patients with mild SOS have an excellent prognosis, but those with more severe disease (ie, bilirubin greater than 20 mg/dL [342 μmol/L] or weight gain greater than 15%) have a high mortality rate. Pretransplant risk factors for SOS include a mismatched or unrelated graft, increased age, prior abdominal radiation or stem cell transplant, and increased transaminases before HSCT. Interpatient variability in the metabolism and clearance of the chemotherapy (ie, busulfan and cyclophosphamide) used within the preparative regimen also may be associated with a poor outcome, although the relationships vary within the various preparative regimens. The association of SOS with busulfan concentrations is discussed in the section on adaptive dosing of busulfan. Use of ursodiol, unfractionated heparin, or low-molecular-weight heparin has been associated with a lower incidence of SOS in a limited number of small, randomized studies and may be recommended for SOS prophylaxis.

The mainstay of treatment for established SOS is supportive care aimed at sodium restriction, increasing intravascular volume, decreasing extracellular fluid accumulation, and minimizing factors that contribute to or exacerbate hepatotoxicity and encephalopathy. Recombinant tissue plasminogen activator administered with or without heparin has been investigated for treatment of SOS, but the life-threatening risk of bleeding precludes any potential benefit. Defibrotide, an oligonucleotide with antithrombotic, anti-ischemic, and anti-inflammatory activity, is not FDA approved in the United States but has shown promising results in the treatment of SOS in clinical trials.

**Myelosuppression and Hematopoietic Growth Factor Use** HGFs may be administered to mobilize PBPCs before an HSCT, to hasten hematopoietic recovery during the period of aplasia after an autologous HSCT, and to stimulate hematopoietic recovery when the patient fails to engraft.
Autologous HSCT is associated with profound aplasia owing to the myeloablative preparative regimen. Aplasia typically lasts 7 to 14 days after an autologous PBPC transplant. During this period of aplasia, patients are at high risk for complications such as bleeding and infection. Filgrastim and sargramostim exert their effects by stimulating the proliferation of committed progenitor cells and accelerating recovery on hematopoiesis. Once engraftment occurs, HGFs may be discontinued. The anatomic source of hematopoietic cells predicts the degree of benefit, with the greatest benefit reached when bone marrow is the graft source. With autologous PBPC transplant, the effect of HGF on neutrophil recovery is variable. The use of HGF after allogeneic HSCT—whether from bone marrow or PBPC grafts—is controversial. The amount of data with sargramostim is limited in this setting; data with filgrastim have shown more rapid neutrophil but slower platelet engraftment in those receiving grafts from bone marrow or PBPCs. The effects of post-HSCT filgrastim use on acute and chronic GVHD have been conflicting, with either no effect or increases in both the incidence of acute and chronic GVHD and treatment-related mortality. Thus, there is little reason to treat allogeneic BMT with filgrastim as prophylaxis after HSCT.

**Clinical Presentation and Diagnosis of Sinusoidal Obstructive Syndrome**

**General**
- Sinusoidal obstructive syndrome (SOS) usually occurs within the first 3 weeks after HSCT.
- Busulfan, cyclophosphamide, pretransplant exposure to gemtuzumab, TBI-containing preparative regimens, and pretransplant abnormalities in liver function tests may increase the risk for SOS.

**Symptoms**
- Patients may complain of weight gain and abdominal pain.

**Signs**
- Fluid retention: Weight gain caused by ascites greater than 2% compared with pretransplant weight
- Hepatomegaly: May result in right upper quadrant pain
- Hepatic: Jaundice caused by hyperbilirubinemia defined as a bilirubin greater than 2 mg/dL (34.2 μmol/L)

**Laboratory Tests**
- Hepatic: Elevation of bilirubin, alkaline phosphatase, and γ-glutamyltransferase (GGT)
- Hematologic: Complete blood count with differential may reveal thrombocytopenia, elevated plasminogen activator-1 levels, decreased antithrombin III, protein C, and protein S

**Other Diagnostic Tests**
- Reversal of blood flow in portal and hepatic veins on Doppler ultrasonography
- Liver biopsy for pathologic review

**Graft Failure** A delicate balance between host and donor effector cells in the bone marrow is necessary to ensure adequate engraftment because residual host-versus-graft effects may lead to graft rejection. The incidence of graft rejection is higher in patients with aplastic anemia and those undergoing HSCT with histoincompatible marrow or T-cell–depleted marrow. Graft rejection is uncommon in leukemia patients receiving myeloablative preparative regimens with a histocompatible allogeneic donor.

Therapeutic options for the treatment of graft rejection or graft failure are limited. A second HSCT is the most definitive therapy, although the associated complications and toxicities may preclude its use. Graft rejection is best managed with immunosuppressants such as ATG. Primary graft failure occasionally can be treated successfully using HGFs, although patients who received purged autografts are less likely to respond.

**Graft-Versus-Host Disease**

**KEY CONCEPT** GVHD is caused by the activation of donor lymphocytes, leading to immune damage to the skin, gut, and liver in the recipient. Immune-mediated destruction of tissues, a hallmark of GVHD, disrupts the integrity of protective mucosal barriers and thus provides an environment that favors the establishment of opportunistic infections. **KEY CONCEPT** An immunosuppressive regimen is administered to prevent GVHD in recipients of an allogeneic graft; this regimen is based on the type of preparative regimen and the source of the graft. The combination of GVHD and...
infectious complications are leading causes of mortality for allogeneic HSCT patients. GVHD is divided into two forms (ie, acute and chronic) based on clinical manifestations. Traditionally, the boundary between acute and chronic GVHD was set at 100 days after HSCT; however, more recent definitions hinge upon different clinical symptoms rather than the time of onset.27,28

**Acute GVHD** The degree of histocompatibility between donor and recipient is the most important factor associated with the development of acute GVHD. The pathophysiology for acute GVHD is a multistep phenomenon, including the development of an inflammatory milieu that results from host tissue damage induced by the preparative regimen; both recipient and donor antigen-presenting cells and inflammatory cytokines triggering activation of donor-derived T cells; and the activated donor T cells mediate cytotoxicity through a variety of mechanisms, which leads to tissue damage characteristic of acute GVHD.28

Despite prophylaxis, 20% to 80% of patients will develop acute GVHD.29 Other factors that increase the risk of acute GVHD include increasing recipient or donor age (older than 20 years), female donor to a male recipient, and mismatches in minor histocompatibility antigens in HLA-matched transplants.28 T-cell depletion or receipt of an umbilical cord blood graft appears to lower the risk of acute GVHD.1

**Clinical Presentation and Staging of Acute GVHD** Acute GVHD targets the skin, liver, and GI tract; it must be distinguished accurately from other causes of skin, liver, or GI toxicity in HSCT patients. Other causes of toxicities affecting the skin, liver, or GI tract may include a drug reaction or an infectious process. A staging system based on clinical criteria is used to grade acute GVHD (Figure 98–2). The severity of organ involvement is scored on an ordinal scale from 0 (no symptoms) to IV (severe symptoms), and then an overall grade is established based on the number and extent of involved organs.

**Immunosuppressive Prophylaxis of Acute GVHD** GVHD is a leading cause of morbidity and mortality after allogeneic HSCT and thus, efforts have focused on preventing acute GVHD. The donor graft and preparative regimen influence the prophylactic regimen for acute GVHD, with two approaches having been taken by clinicians over time. One approach involves T-cell depletion, which was discussed more fully in the section on T-cell depletion earlier. The more common method is to use two-drug immunosuppressive therapy that typically consists of a calcineurin inhibitor (ie, cyclosporine or tacrolimus) with methotrexate after myeloablative HSCT. Prophylaxis of acute GVHD for nonmyeloablative preparative regimens is varied, but a calcineurin inhibitor with either methotrexate or mycophenolate mofetil is used.16

The calcineurin inhibitors (ie, cyclosporine and tacrolimus) should be initiated before donor cell infusion (eg, day –1) when used for GVHD prophylaxis. This schedule is recommended because of the known mechanism of action of calcineurin inhibitors, which entails blocking the proliferation of cytotoxic T cells by inhibiting production of T helper cell–derived interleukin-2 (IL-2). Administering calcineurin inhibitors before the donor cell infusion allows inhibition of IL-2 secretion to occur before a rejection response has been initiated. Studies comparing cyclosporine and tacrolimus in combination with methotrexate have shown that tacrolimus administration is associated with a lower incidence of grade II to IV acute GVHD and a similar incidence of chronic GVHD but variable effects on overall survival.10,31

**Adaptive Dosing of the Calcineurin Inhibitors** Most HSCT centers have their own standardized approach to dose adjust the calcineurin inhibitors cyclosporine and tacrolimus to target concentration ranges. Cyclosporine and tacrolimus trough concentrations are associated with acute GVHD and nephrotoxicity. Cyclosporine trough concentrations usually are maintained between 150 and 400 ng/mL (125 and 333 nmol/L) in patients undergoing allogeneic HSCT. Tacrolimus trough concentrations are targeted to a range of 10 to 20 ng/mL (10–20 mcg/L; 12.4–24.8 nmol/L).32 Dosage adjustments to either calcineurin inhibitor also should be made for elevated serum creatinine regardless of their serum concentrations. Nephrotoxicity can occur despite low or normal concentrations of the calcineurin

---

**FIGURE 98–2.** Staging System for graft-versus-host disease.
Clinical Presentation and Diagnosis of Acute Graft-versus-Host Disease

General
- Patients may present with any or all of the following: skin rash, GI complaints, jaundice.
- Signs and symptoms present after engraftment when donor lymphoid elements begin to proliferate.

Symptoms
- Patients may complain of nausea, vomiting, bloody diarrhea, or itching from skin rash.

Signs
- Skin: Maculopapular skin rash on the face, trunk, extremities, palms, soles, and ears which may progress to generalized total-body erythroderma, bullous formation, and skin desquamation.
- GI: Ileus, malnutrition, dehydration and electrolyte abnormalities due to nausea, vomiting, and diarrhea.
- Hepatic: Jaundice due to hyperbilirubinemia.

Laboratory Tests
- Hepatic: Elevation of bilirubin, alkaline phosphatase, and hepatic transaminases.
- GI: Send stool for bacterial, viral, and parasitic cultures to rule out infectious causes.

Other Diagnostic Tests
- Biopsy of affected site for pathologic review

Inhibitor cyclosporine and may be a consequence of other drug- or disease-related factors known to influence the development of nephrotoxicity (eg, genetic risk factors, concurrent use of other nephrotoxic agents, and sepsis). Careful monitoring for drug interactions via CYP 3A4 and P-glycoprotein is also warranted. The calcineurin inhibitor doses are adjusted based on serum drug levels and the calculated creatinine clearance. Common adverse effects to these agents include neurotoxicity, hypertension, hyperkalemia, hypomagnesemia, and/or nephrotoxicity (which may lead to an impaired clearance of methotrexate).

Tapering schedules for the calcineurin inhibitors after myeloablative HSCT vary widely. In patients without GVHD, the calcineurin inhibitor doses usually are stable to day +50 and then are tapered slowly with the intent of discontinuing all immunosuppressive agents by 6 months after HSCT. By this time, immunologic tolerance has developed, and patients no longer require immunosuppressive therapy. There is a paucity of information regarding the optimal duration of GVHD prophylaxis after nonmyeloablative HSCT, with data suggesting that a 2-month duration of cyclosporine with a 4-month taper lowers the rate of severe acute GVHD.30

Treatment of Acute GVHD The most effective way to treat GVHD is to prevent its development. Corticosteroids, usually in combination with a calcineurin inhibitor, are the first-line therapy for treatment of established acute GVHD. Corticosteroids indirectly halt the progression of immune-mediated destruction of host tissues by blocking macrophage-derived IL-1 secretion. IL-1 is a primary stimulus for T helper cell-induced secretion of IL-2, which, in turn, is responsible for stimulating proliferation of cytotoxic T lymphocytes. The recommended dosage of methylprednisolone in this setting is 2 mg/kg/day; there is no advantage to higher corticosteroid doses (ie, 10 mg/kg/day).28 A partial or complete response is seen in approximately 50% of patients treated with corticosteroids. Once a clinical improvement occurs, there is no consensus on the optimal method for tapering the corticosteroids. Patients with steroid-refractory acute GVHD have a poor prognosis, and a number of medications are being studied for salvage therapy.

Chronic GVHD Occurring in 20% to 70% of HSCT recipients surviving longer than 100 days, chronic GVHD is the most frequent and serious late complication of allogeneic HSCT.29 Chronic GVHD is the major cause of nonrelapse mortality and morbidity. The clinical course of chronic GVHD is multifaceted, involving almost any organ in the body, and its symptoms resemble autoimmune and immunologic disorders (eg, scleroderma). Chronic GVHD symptoms usually present within 3 years of allogeneic HSCT and often are preceded by acute GVHD.27 Traditionally, the boundary between acute and chronic GVHD was set at 100 days after HSCT; however, more recent definitions hinge on different clinical symptoms rather than the time of onset.24 A consensus document regarding the diagnosis and scoring of chronic GVHD has been published that proposes a clinical scoring system to describe chronic GVHD as opposed to historical descriptions of chronic GVH, which described the phenomenon as being “limited” versus “extensive” in nature.29 The diagnosis of chronic GVHD requires distinction from acute GVHD; the presence of at least one diagnostic clinical sign of chronic GVHD or presence of at least one distinctive manifestation confirmed by pertinent biopsy or other relevant tests; and exclusion of other possible diagnoses.

Prevention and Treatment of Chronic GVHD Chronic GVHD is not a continuation of acute GVHD, and separate approaches are needed for its prevention and management. Prevention of chronic GVHD through prolonged use of immunosuppressive medications has been unsuccessful.24 Thus, its prevention is focused on minimization of factors associated with higher rates of chronic GVHD. Several recipient, donor, and transplant factors are relevant. Recipient risk factors that are not modifiable include older age, certain diagnoses (eg, chronic myeloid leukemia), and lack of an HLA-matched donor. Modifiable factors that may lower the risk of chronic GVHD include selection of a younger donor, avoidance of a multiparous female donor, use of umbilical cord blood or bone marrow grafts rather than PBPCs, and limitation of CD34+ and T-cell dose infused.24 Development of acute GVHD is a major predictor for chronic GVHD, with 70% to 80% of those with grade II to IV acute GVHD developing chronic GVHD.24 Relative to no treatment, survival in those with chronic GVHD is improved by extended corticosteroid therapy; however, multiple long-term adverse effects are associated with corticosteroid use. The prednisone dosage is 1 mg/kg/day administered orally in divided doses for 30 days and then slowly converted to an alternate-day therapy. One to two months may pass before an improvement in clinical symptoms is noted, and therapy usually is continued for 9 to 12 months. Therapy can be tapered slowly after resolution of signs and symptoms of chronic GVHD. If a flare of chronic GVHD occurs during the tapering schedule or after therapy is discontinued, immunosuppressive therapy
is restarted. Other potential approaches for patients who are refractory to initial therapy include etanercept (Enbrel), infliximab (Remicade), mycophenolate mofetil (Cellcept), rituximab (Rituxan), extended use of calcineurin inhibitors, or extracorporeal photochemotherapy. When immunosuppressive therapy is administered for long periods, the patient must be monitored closely for chronic toxicity. Cushingoid effects, asptic necrosis of the joints, and diabetes can develop with long-term corticosteroid use. Other severe complications include a high incidence of infection with encapsulated organisms and atypical pathogens such as Pneumocystis jiroveci, cytomegalovirus (CMV), and varicella zoster virus (VZV).

**Infectious Complications**

Recipients of HSCT are at higher risk of bacterial, viral, and fungal infections and usually receive a prophylactic or preemptive regimen to minimize the morbidity and mortality associated with infectious complications. After myeloablative and nonmyeloablative HSCT, opportunistic infections are a major source of morbidity and mortality. There are three periods of infectious risks, preengraftment (from 15 days prior and to 45 days after HSCT), postengraftment (engraftment to day 100 days post engraftment), and late 100 days after engraftment. From days 0 to 30 after HSCT, particularly for patients undergoing myeloablative HSCT, the primary pathogens are aerobic bacteria, Candida spp., and herpes simplex virus (HSV). Respiratory viruses such as respiratory syncytial virus (RSV), influenza, adenovirus, and parainfluenza virus are recognized increasingly as pathogens causing pneumonia, particularly during community outbreaks of infection with these organisms. Because of the need to administer chemotherapy, blood products, antibiotics, and other adjunctive medications, the placement of a semipermanent double- or triple-lumen central venous catheter is necessary before HSCT. However, the indwelling IV central catheters put HSCT recipients at increased risk for Staphylococcus infections.

The second period of infectious risk occurs after engraftment to post transplant day 100. Bacterial infections are still of concern, but pathogens such as CMV, adenovirus, and Aspergillus spp. are common. A common manifestation of infection is interstitial pneumonitis (IP), which can be caused by CMV, adenovirus, Aspergillus, and P. jiroveci. Suppression of the immune system from acute GVHD and corticosteroids contributes to the risk of such infections during this period. Therefore, patients undergoing nonmyeloablative transplant who are receiving corticosteroids to treat GVHD can be expected to have a similar risk for infection as those undergoing myeloablative HSCT. Invasive fungal infections over the first year after HSCT occur at a similar rate in nonmyeloablative transplant compared with historical control participants receiving a myeloablative preparative regimen.

During the late period (100 days after engraftment), the predominant organisms are the encapsulated bacteria (eg, Strep- tococcus pneumoniae, Haemophilus influenzae, and Neisseria meningitidis), fungi, and VZV. The encapsulated organisms commonly cause sinopulmonary infections. The risk of infection during this late period is increased in patients with chronic GVHD as a result of prolonged immunosuppression.

**Prevention and Treatment of Bacterial and Fungal Infections**

Between the time of administration of the preparative regimen and successful engraftment, allogeneic myeloablative HSCT patients undergo a period of pancytopenia that can last from 2 to 6 weeks. The risk of infection is also reduced by aggressive use of antibacterial, antifungal, and antiviral therapy both prophylactically and for the treatment of documented infection. The antibacterial prophylactic regimens vary substantially among HSCT centers. Some HSCT centers use a prophylactic fluorquinolone (eg, levofloxacin) on admission for HSCT and then switch to a broad-spectrum IV antibiotic (eg, cefepime) when the patient experiences his or her first neutropenic fever. Although fluorquinolones reduce the incidence of gram-negative bacteremia, they have not been shown to affect mortality; the possibility of developing clostridium difficile-associated diarrhea exists with fluorquinolone use and infectious causes should be ruled out if diarrhea occurs. Concerns with fluorquinolone use in the prophylactic setting during HSCT include the emergence of resistant organisms and an increased risk for streptococcal infection. Broad-spectrum IV antibiotics should be initiated immediately at the time of the first neutropenic fever under the treatment guidelines endorsed by the Infectious Disease Society of America for management of fever of unknown origin in the neutropenic host.

**Prevention of HSV and VZV**

Patients who are HSV antibody seropositive before HSCT are at high risk for reactivation of their HSV infection. Acyclovir is highly effective in preventing HSV reactivation, and thus, prophylactic acyclovir is used commonly in HSV-seropositive patients who are undergoing an allogeneic or autologous HSCT. In the setting of HSV prophylaxis, dosing regimens for prophylactic acyclovir vary widely and most centers discontinue acyclovir at the time of hematopoietic recovery. Valacyclovir (Valtrex), a prodrug of acyclovir with improved bioavailability, may allow for adequate serum concentrations to prevent HSV in patients undergoing HSCT as well.

In those with a history of VZV infection, VZV disease occurs in 30% of allogeneic HSCT recipients. The appropriate duration of VZV prophylaxis is controversial. Although VZV infections are reduced by prophylactic acyclovir administered from 1 to 2 months until 1 year after HSCT, the risk of VZV persists in those on continued immunosuppression.

**Prevention and Preemptive Therapy of CMV Disease**

After allogeneic HSCT, CMV disease is common and has high morbidity and mortality rates. Allogeneic patients are at greater risk than autologous recipients primarily because the latter more efficiently reconstitute their immune system after transplantation. However, autologous HSCT recipients who are CMV seropositive before HSCT are at risk for CMV infection, and prophylaxis should be considered in a select minority of patients. Infection caused by CMV is usually asymptomatic and develops when CMV replication occurs. Replication occurs primarily in body fluids such as the blood (viremia), bronchoalveolar fluid, or urine (viruria). CMV disease is symptomatic and occurs when the virus invades an organ or tissue. Pneumonia and gastritis are the most common types of CMV disease after allogeneic HSCT. The presence of a CMV infection substantially increases the risk for developing invasive CMV disease. Strategies to prevent CMV infection have resulted in dramatic reductions in the incidence of CMV disease.

Primary CMV can be prevented with CMV seromatching, which includes transplanting PBPCs or bone marrow from CMV-seronegative donors and infusing CMV-negative blood products to CMV-negative recipients. Antivirals are important in those who are CMV seropositive or have a CMV-seropositive graft, with two available approaches to minimize the morbidity associated with CMV. The first is universal prophylaxis, in which
ganciclovir is begun at the time of engraftment and is continued until approximately 100 days after engraftment. The second approach is called preemptive therapy, for which ganciclovir is selectively administered based on detection of CMV reactivation.

Preemptive therapy is the most commonly used strategy for preventing CMV disease after allogeneic HSCT because ganciclovir is used only in patients at highest risk for developing CMV disease. This approach minimizes administration of ganciclovir, thus lowering the risk of ganciclovir-induced neutropenia with its subsequent increased risk of invasive bacterial and fungal infections. Preemptive strategies typically use an induction course of ganciclovir for 7 to 14 days followed by a maintenance course until 2 or 3 weeks after the last positive antigenemia result or until 100 days after HSCT. Oral valganciclovir (Valcyte) is an orally bioavailable prodrug of ganciclovir that is converted to ganciclovir in vivo after intestinal absorption and has been used for preemptive therapy. Foscarnet may be given as an alternative to ganciclovir to prevent CMV disease, although its use is complicated by nephrotoxicity and electrolyte wasting.

Fungal Infections

Prevention of Fungal Infections. The widespread use of fluconazole prophylaxis since the early 1990s has led to a significant decline in the morbidity and mortality associated with invasive candidiasis in HSCT recipients. However, invasive aspergillosis (IA); zygomycetes; and fluconazole-resistant Candida spp., such as Candida krusei and Candida glabrata, have increased markedly in incidence. Itraconazole, another azole antifungal agent, has better in vitro activity against fluconazole-resistant fungi (eg, Aspergillus and some Candida spp.) and is more effective than fluconazole for long-term prophylaxis of invasive fungal infections after allogeneic HSCT; however, itraconazole is used less often because of frequent GI side effects and concern for potential drug interactions. Posaconazole (Noxafil) is a triazole antifungal that has been approved by the FDA for prophylaxis against IA in HSCT patients with GVHD and is now the recommended prophylactic agent for this subset of HSCT patients on immunosuppression. Posaconazole oral suspension should be given with food for adequate absorption. The posaconazole tablet can be administered without regard to food. Micafungin (Mycamine), an agent of the newer class of antifungals known as the echinocandins, has been FDA approved for prophylaxis of Candida infections in patients undergoing HSCT.

Risk Factors for Invasive Mold Infections. Invasive mold infections (eg, Aspergillus spp., Fusarium spp., Zygomyces, and Scedosporium spp.) are an increasing cause of morbidity and death after allogeneic and autologous HSCT. It has been estimated that up to one-third of febrile neutropenic patients who do not respond to antibiotic therapy after 1 week are harboring a fungal infection. In HSCT recipients, risk factors for invasive fungal infections include previous history of IA; recipient factors, including older age, CMV seropositivity, and type of stem cell transplant; treatment factors (eg, a fludarabine-based preparative regimen); transplant complications (eg, prolonged neutropenia, graft failure, and higher grade GVHD); and host factors (eg, diabetes, iron overload). Infections with Aspergillus spp. remain the most common mold infections diagnosed in the HSCT population and optimal treatment must be promptly initiated if indicated.

Treatment of Invasive Aspergillosis. Early diagnosis and initiation of appropriate therapy may reduce the high mortality rate of IA. Outcomes also depend on recovery of the recipient’s immune system and reduction of immunosuppression. Diagnosis is difficult with the use of computed tomography scans and cultures. Research is ongoing to evaluate the benefit of using nonculture-based methods, such as galactomannan and (1,3)-β-D-glucan antigen detection, which are components of the fungal cell wall that can be detected by commercially available assays.

Practice guidelines are available for the treatment of invasive Aspergillus infections in immunocompromised patients. Available mold-active agents include triazole antifungals (itraconazole, voriconazole, and posaconazole), echinocandins (caspofungin, micafungin, and anidulafungin), and amphotericin B formulations.

Historically, conventional amphotericin B (c-AmB) was considered the “gold standard” antifungal therapy for any IA infection; however lipid analogs of amphotericin have shown equivalent efficacy and a reduction in side effects, albeit at a higher acquisition cost. With significant toxicity limiting the overall utility of conventional amphotericin B, voriconazole (Vfend) was compared with c-AmB for treatment of IA. For initial therapy of IA, voriconazole had higher response and survival rates than c-AmB and is now considered the primary option for patients with IA.

In patients who have failed initial therapy (ie, salvage), lipid formulations of amphotericin products, itraconazole, posaconazole or an agent from the echinocandin class may be used.

The optimal duration of appropriate antifungal therapy for treating IA is individualized to the reconstitution of the patient’s immune system and his or her response to antifungal treatment. Most clinicians continue aggressive antifungal therapy until the infection has stabilized radiographically and may continue with less aggressive “maintenance” therapy (eg, oral voriconazole) until immunosuppression is lessened or completed. In general, it is common to require several months of antifungal therapy to treat IA.

Pneumocystis jiroveci. After allogeneic HSCT, prophylaxis for P. jiroveci (formerly P. carinii) pneumonia (PCP) is used because Pneumocystis is a serious infection with a high mortality rate if left untreated. Most centers use sulfamethoxazole/trimethoprim for 6 to 12 months after HSCT, aerosolized or IV pentamidine and oral dapsone are alternatives for patients who are allergic to sulfa drugs or who do not tolerate cotrimoxazole. Because PCP most often occurs after engraftment, cotrimoxazole usually is begun after neutrophil recovery because of its myelosuppressive effects. Patients receiving prophylactic cotrimoxazole should be monitored closely for rash and unexplained neutropenia or thrombocytopenia. Cotrimoxazole usually is avoided on days of methotrexate administration because the sulfonamides can displace methotrexate from plasma binding sites and decrease renal methotrexate clearance, resulting in higher methotrexate concentrations. Autologous HSCT patients do not receive posttransplant immunosuppression, and thus, their risk of developing PCP is lower. PCP prophylaxis is used often after autologous HSCT in patients with a hematologic malignancy.

Issues of Survivorship After HSCT

The number of long-term HSCT survivors is increasing as 5-year disease-free survival rates improve. Because nonmyeloablative preparative regimens were developed over the past decade, the late effects reported in HSCT survivors describe those resulting from myeloablative preparative regimens. HSCT recipients—with either an autologous or an allogeneic graft—have a higher mortality rate than the general population. Long-term survivors of HSCT should be monitored closely, particularly for infections and secondary malignant neoplasms. Survivors of HSCT are at higher risk for secondary malignant neoplasms.
including the kidneys, liver, and lungs, may be caused by the preparative regimen, infectious complications, and/or post-transplant immunosuppression. Many HSCT recipients experience endocrine dysfunction, such as hypothyroidism from TBI, adrenal insufficiency from long-term corticosteroids to treat GVHD, and infertility from radiation and/or high doses of alkylating agents in myeloablative preparative regimens. Osteopenia has been found in more than half of HSCT recipients, most likely from gonadal dysfunction and/or corticosteroid administration.

Close monitoring of HSCT recipients for infections is necessary because recovery of immune function is slow, sometimes requiring more than 2 years, even in the absence of immunosuppressants. Fevers should be assessed and treated rapidly to minimize the likelihood of a fatal infection. HSCT recipients—both autologous and allogeneic—lose protective antibodies to vaccine-preventable diseases; international guidelines have been published regarding recommendations for reimmunization of HSCT recipients.

Survivors of HSCT should be monitored routinely for signs of relapse and, if an allogeneic graft was used, chronic GVHD. They should be advised regarding revaccination and obtaining prompt medical care for fevers or signs of infection. Routine evaluations of organ function (ie, renal, hepatic, thyroid, and ovarian) and osteopenia should occur and the appropriate management strategies initiated as necessary.

**OUTCOME EVALUATION**

Monitor for symptoms and signs of the disease that is being treated by HSCT to assess the effectiveness of the HSCT. For example, the monitoring plan for a patient with CML would be to monitor disease response by PCR of the BCR-ABL transcript. The actual clinical outcome monitored, along with the frequency of monitoring, is based on the underlying disease. Monitor for nonhematologic toxicity of the preparative regimen during its administration. Monitor these symptoms at least daily, with more frequent monitoring if the patient is experiencing these nonhematologic effects. The goal is to prevent or minimize these adverse effects. Specifically:

- **Busulfan:** Seizures, busulfan concentrations if being used with the BU-CY preparative regimen, number of vomiting episodes, and nausea by patient self-report, total bilirubin, and sudden weight changes (SOS)
- **Cyclophosphamide:** Electrocardiography during IV administration, RBCs in urine, frequency of urination, pain on urination, urinary output, number of vomiting episodes, and nausea by patient self-report, total bilirubin, and SOS
- **Etoposide:** Blood pressure, respiratory rate, serum pH, serum bicarbonate with arterial blood gases, and evaluation of anion gap if necessary

**Patient Encounter, Part 3**

The patient is admitted for allogeneic HSCT with a reduced-intensity preparative regimen consisting of fludarabine and busulfan. Her hospital course was complicated for neutropenic fever and gastrointestinal toxicities. Neutrophil engraftment occurred on day +12 after HSCT, and the patient was discharged from the hospital on day +14 with minimal complaints. She presents to the transplant clinic on day +22 complaining of a skin rash on her palms and trunk. She does not report diarrhea, nausea, vomiting, or any other symptoms.

**What is the differential diagnosis for the patient’s current condition?**

**How should this patient be monitored for progression of GVHD?**
• **Total-body irradiation:** Number of vomiting episodes, nausea by patient self-report, SOS, total bilirubin, and skin assessment for the presence of irritation or blister formation

Until the patient has achieved engraftment, monitor the patient for engraftment with at least daily complete blood counts with differentials; these tests may be needed more often if the patient is critically ill or had a prior low hemoglobin. Patients will require transfusion support with blood products and platelets until engraftment occurs if hemoglobin and/or platelets drop below unsafe levels.

Until engraftment has occurred, monitor the patient’s temperature every 4 to 8 hours for signs of infection. Also guide monitoring signs of focal point of infection based on clinical symptoms. For example, if the patient develops shortness of breath, then imaging of the lungs should occur to assess pulmonary infection. Monitor for the toxicity of prophylaxis and/or treatment of bacterial, fungal, or viral infections.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the impact of various supportive care interventions on the prognosis of patients with cancer.
2. Discuss the scientific basis for providing various supportive care interventions in the oncology patient population.
3. Identify patient-related and disease-related risk factors in defining a population for whom supportive care interventions would be of benefit.
4. Recognize typical presenting signs and symptoms of common complications and emergencies that require supportive care interventions.
5. Outline appropriate prevention and management strategies for various supportive care interventions.
6. Prepare a monitoring plan to evaluate the efficacy and toxicity of pharmacotherapy interventions for supportive care problems.

INTRODUCTION

Patients with cancer are at risk for serious adverse events that result from their treatment, the cancer, or both. The management of these complications is generally referred to as supportive care (or symptom management). Examples of treatment-related complications include chemotherapy-induced nausea and vomiting (CINV), myelosuppression, febrile neutropenia (FN), hemorrhagic cystitis, mucositis, and tumor lysis syndrome (TLS). Tumor or cancer-related complications include superior vena cava (SVC) obstruction, spinal cord compression, hypercalcemia, and brain metastases. In some cases, these events can be life threatening. SVC obstruction, spinal cord compression, TLS, and hypercalcemia have traditionally been defined as oncologic emergencies. Treatment- and disease-related complications in the oncology population require rapid assessment and supportive care interventions. The onset of oncologic emergencies may herald the onset of an undiagnosed malignancy or progression or relapse of a preexisting malignancy. Optimal management of patients with various oncologic emergencies and complications requiring supportive care interventions can significantly decrease morbidity and mortality in patients with cancer. This chapter provides an overview of these issues. First, an overview of the management of common side effects of treatment is given. Later, a summary of common oncologic emergencies is presented.

CHEMOTHERAPY-INDUCED TOXICITIES: NAUSEA/VOMITING

Nausea and vomiting are among the most commonly feared toxicities by patients undergoing chemotherapy.\(^1\)** KEY CONCEPT** The optimal method of managing CINV is to provide adequate pharmacologic prophylaxis given a patient’s risk level for emesis. Insufficient control during the first cycle of chemotherapy leads to more difficulty in controlling emesis for subsequent cycles.\(^2\)

EPIDEMIOLOGY AND ETIOLOGY

Although it is widely known that chemotherapy causes nausea and vomiting, the rate of emesis varies depending on individual patient risk factors and drug therapy regimen. Therefore, cancer treatments are stratified into varying risk levels: high, moderate, low, and minimal. Agents with a “high” emetic risk cause emesis in more than 90% of cases if not given any prophylaxis. The rates of emesis for “moderate,” “low,” and “minimal” are 30% to 90%, 10% to 30%, and less than 10%, respectively. Table 99–1 lists the individual agents and their risk category.\(^3\)

PATHOPHYSIOLOGY

The pathophysiology of nausea and vomiting is described in Chapter 20. Specific to CINV, the key receptors include serotonin (5-HT\(_3\)) receptors (located in the chemoreceptor trigger zone, emetic center of the medulla, and gastrointestinal [GI] tract) and neurokinin-1 (NK1) receptors (located in the emetic center of the medulla). Serotonin plays an important role in the genesis of acute vomiting, occurring within the first 24 hours of chemotherapy, because some cancer drug therapies can stimulate a release of serotonin from enterochromaffin cells in the GI tract. Serotonin then activates the emetic response by binding to 5HT\(_3\) receptors in the emetic center. This short-lived release of serotonin likely explains why serotonin antagonists are more beneficial for preventing acute versus delayed vomiting.\(^4\) Other sites that are targeted by antiemetics include dopamine, muscarinic (acetylcholine), histamine, and cannabinoid receptors.

CLINICAL PRESENTATION AND DIAGNOSIS

CINV, although frequently discussed as one syndrome, includes two distinct clinical entities, including both nausea and vomiting. Nauseous patients may present with general GI upset and reflux and may report a sensation or desire to vomit without being able to do so. In all cases, it is important that other etiologies of nausea and vomiting are ruled out before diagnosing chemotherapy as the cause. Other causes of nausea and vomiting may include bowel obstruction, opioid intolerance, electrolyte imbalances, brain metastases, and vestibular dysfunction.

TREATMENT

Desired Outcomes

The desired outcome is to completely prevent or minimize the severity of nausea, vomiting, and the use of breakthrough antiemetic medications. In clinical trials, a common end point is “complete response,” defined as having no emesis and no breakthrough medication use within a defined period of time. If patients experience nausea or emesis, the goal is to quickly relieve the episode and prevent future nausea or vomiting, whether in the next few days or for the next cycle of chemotherapy.

General Approach to Treatment

Treatment-related factors and patient-related factors can help define a patient population at risk for developing CINV. Treatment-related factors include those chemotherapy agents with high levels of emetogenicity (see Table 99–1 for a complete listing). CINV is typically a cyclical occurrence. Although this section focuses on CINV, it can be helpful for practitioners to remember that patients undergoing concomitant radiation therapy and chemotherapy are at risk for more severe nausea and vomiting. Radiation (particularly total-body irradiation as part of a conditioning regimen for stem cell transplant) can cause a more cumulative (versus cyclical) nausea/vomiting phenomenon.

Specific patient-related factors such as female gender, age less than 50, history of motion sickness, pregnancy-induced nausea or vomiting, and poor emetic control in previous chemotherapy cycles increase the risk of emesis. Interestingly, patients...
with a history of alcohol abuse have a reported decreased risk of emesis. It is important to design an antiemetic regimen with consideration of these patient-specific risk factors. A well-designed regimen includes a prophylactic regimen and a breakthrough antiemetic drug "as needed." Although many drugs are recommended as "breakthrough" drugs, choose a drug with a different mechanism of action compared with the drugs used for prophylaxis.

**Nonpharmacologic Therapy**

Nonpharmacologic therapy for nausea and vomiting can be useful adjuncts to drug therapy, particularly in the setting of anticipatory nausea and vomiting. Behavior therapies such as relaxation, guided imagery, and music therapy as well as acupuncture or acupressure as useful in this setting. Other general measures that can be taken include ensuring adequate sleep before treatment, eating smaller meals, and avoiding greasy foods and foods with strong odors.

**Pharmacologic Therapy**

Nonprescription medications such as antacids, histamine-2 receptor blockers, and proton pump inhibitors can be helpful in reducing gastroesophageal reflux associated with some cancer treatments that may trigger or exacerbate CINV. Nonprescription antihistamines marketed for nausea associated with motion sickness are not usually helpful in managing CINV. Four drug classes are highly effective in preventing CINV: corticosteroids (dexamethasone), serotonin receptor antagonists, NK1 receptor antagonists (aprepitant or fosaprepitant), and the thienobenzodiazepine, olanzapine. Drugs with differing mechanisms of action are combined, depending on the emetic risk level of the chemotherapy regimen. (Table 99–2).

Intravenous (IV) antiemetics are usually administered 30 minutes before chemotherapy, and oral antiemetics are administered 60 minutes before chemotherapy. Dexamethasone is the preferred agent to prevent CINV in the delayed setting (days 2–4 after chemotherapy administration) for moderately and highly emetogenic chemotherapy and is given at dose of 4 mg orally twice daily (or 8 mg once daily) for 3 to 4 days. In some cases, the serotonin antagonists may also be continued orally for 3 to 4 days after chemotherapy or be used in place of dexamethasone. When oral aprepitant is used prechemotherapy, the aprepitant is continued as 80 mg orally once daily on days 2 and 3 of the chemotherapy cycle. No oral aprepitant is necessary when fosaprepitant is given on day 1.

Concerns of QT prolongation have resulted in the IV formulation of dolasetron to be removed from the market and dosing of ondansetron has been reduced to 16 mg IV as the 32 mg IV was reported to extend the QT interval.

The other classes of antiemetics are usually prescribed “as needed” for breakthrough nausea or vomiting. The dopamine antagonists prochlorperazine and metoclopramide are usually recommended because they antagonize a different receptor than the drugs already given for prophylaxis. Other medications, including serotonin receptor antagonists, cannabinoids, dexamethasone, scopolamine, or olanzapine, may be used as alternatives to dopamine antagonists for breakthrough nausea and vomiting. Breakthrough medications should have different mechanisms of action than the medications a patient is taking to prevent nausea and vomiting. For those in any risk group who experience anticipatory nausea and vomiting, the addition of lorazepam for prophylaxis and breakthrough is recommended for its antiemetic and antianxiety properties. Table 99–3 lists the doses of the antiemetic agents for prophylaxis and breakthrough use.

---

|                                                               | Dexamethasone: Day 1  
| Moderate (30%–90%)                                            | 5-HT, serotonin receptor antagonist: days 1–3  
|                                                               | Dexamethasone: day 1  
|                                                               | Or  
|                                                               | 5-HT, serotonin receptor antagonist: day 1  
|                                                               | Dexamethasone: days 1–3  
|                                                               | Dexamethasone: day 1  
| Low (10%–30%)                                                 | 5-HT, serotonin receptor antagonist: Day 1  
|                                                               | Dexamethasone: day 1  
|                                                               | Or  
|                                                               | As needed  
| Minimal (< 10%)                                               | As needed  

A prophylactic antiemetic regimen for high emetic risk levels of IV chemotherapy should be with a triple-drug combination using dexamethasone, aprepitant, and 5-HT₃ antagonist to prevent both acute and delayed emesis. Dexamethasone should be continued until day 4, and aprepitant is also administered on days 2 and 3 if the oral formulation is used. When fosaprepitant 150 mg IV is administered on day 1, no oral aprepitant is needed on days 2 and 3 of therapy. Alternatively, olanzapine in combination with palonosetron and dexamethasone can be used. A phase 3 trial of 241 patients comparing aprepitant, palonosetron, and dexamethasone to olanzapine with a palonosetron and dexamethasone for patients treated with highly emetogenic chemotherapy had similar rates of CINV control (87%–97% prevention of acute CINV, 73%–77% prevention of delayed CINV), though nausea was better controlled by the olanzapine-based regimen (69% overall vs 38% overall). For moderately emetogenic regimens, acute emesis is still of major concern, but the incidence of delayed emesis is less.

### Patient Care Process: CINV

#### Patient Assessment:
- Evaluate patient’s chemotherapy regimen and assess emetic potential.
- Using a visual analogue or numerical rating scale (0–10), have the patient rate the severity of nausea (assess nausea first; then move on to emesis).
- Daily, ask about the number of emesis episodes in the last 24 hours.
- Assess scheduled and breakthrough medication adherence.
- Assess patient for risk factors for CINV such as history of motion sickness, pregnancy-induced nausea/vomiting, anxiety, lack of sleep, etc.
- Evaluate patient’s outpatient medications and determine if there are drug interactions, precautions, or other contraindications to intended antiemetic therapy.
- On subsequent cycles, evaluate continued effectiveness of initial antiemetic regimen and assess the need for breakthrough antiemetics.

#### Therapy Evaluation:
- Evaluate patient for complete response to therapy, especially after the first cycles—no vomiting and no nausea.
- Monitor patient diary of recording of breakthrough antiemetic use.

#### Care Plan Development:
- Counsel the patient on how to take the antiemetic regimen, side effects, drug interactions. Emphasize the need to take the regimen regardless of whether the patient feels nauseous or not—the goal is prevention.
- Explain which drugs are taken as prophylaxis to prevent nausea and vomiting and which are taken as needed to treat it.
- Counsel patient on nonpharmacological management of CINV—adequate sleep, small meals, stress management, etc.
- Have the patient journal when a dose is taken in relation to the chemotherapy. Encourage journaling the severity and frequency of nausea, vomiting, diet, and antiemetic adherence.

#### Follow-Up Evaluation:
- Ensure no episodes of nausea or vomiting at each chemotherapy visit.

Therefore, dexamethasone plus a 5-HT\textsubscript{3} antagonist should be given on day 1. On days 2 to 4, choose to continue either the dexamethasone or the 5-HT\textsubscript{3} antagonist to prevent delayed emesis. One exception is when palonosetron is given as the 5-HT\textsubscript{3} antagonist on day 1. Because its half-life is long, no redosing is necessary on subsequent days. Aprepitant and fosaprepitant 115 mg IV are also approved by the Food and Drug Administration (FDA) for the prevention of CINV in the moderate setting. While an NK1 receptor antagonist is not routinely used for moderately emetogenic chemotherapy, if patients have clinical risk factors or if they experienced uncontrolled emesis with previous chemotherapy cycles, the same regimen for “high” risk levels may be used.

For low emetic risk IV chemotherapy regimens, single antiemetic prophylaxis with either dexamethasone or a dopamine antagonist is recommended. For minimal emetic risk groups, guidelines do not recommend routine prophylaxis with antiemetics; instead, patients should be provided with a drug to take as needed for nausea and vomiting. Table 99–2 summarizes regimens for antiemetic prophylaxis for the different risk levels of IV chemotherapy.

Many oral anticancer agents are now available and are typically administered daily. For highly and moderately emetogenic oral anticancer therapy, an oral 5HT\textsubscript{3}-antagonist is administered before each dose with or without lorazepam and/or an H\textsubscript{2}-blocker or proton pump inhibitor. Low-minimal risk oral anticancer agents are given in conjunction with “as needed” antiemetics similar to the approach for IV chemotherapy.

OUTCOME EVALUATION

It is often difficult to evaluate nausea and vomiting when chemotherapy is given as an outpatient. After drug administration, patients return home and may or may not report inadequate control of emesis. Subsequent chemotherapy cycles may also be poorly controlled, especially if patients do not state their experience with the previous cycle. To ameliorate this problem, patients’ experiences with CINV should be assessed, particularly after the first and second cycles of chemotherapy. Patients should be asked about their previous emesis control with subsequent cycles of chemotherapy, and a prophylactic regimen may need to be adjusted. Patients should also be encouraged to self-report poor control of emesis while at home. Side effects of the antiemetic regimen should also be assessed and reported.

MUCOSITIS

Mucositis is the degradation of mucosal lining in the oral cavity and GI tract caused by damage from radiation or chemotherapy. Mucositis is a common supportive care issue that deserves attention and is associated with many negative health consequences, including pain, inadequate nutritional intake, and risk for infection. Patients with mucositis often require parenteral analgesics, nutrition supplementation, and antiinfectives to treat concomitant bacterial, fungal, or viral infections. Furthermore, mucositis is associated with economic consequences, primarily increased lengths of hospital stay. An understanding of the current guidelines for prevention and treatment of mucositis can help improve patient outcomes.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of chemotherapy or radiation-induced mucositis depends mostly on the type of chemotherapy, the type and area of radiation, and the specific cancer. Studies have reported an incidence of about 85% in head and neck cancer patients receiving chemoradiation. The World Health Organization estimates that approximately 75% of patients who are treated with high-dose chemotherapy for stem cell transplantation developed oral mucositis. Specific chemotherapy agents associated with moderate-severe mucositis include taxanes, anthracyclines, platinum analogues, methotrexate, and the fluoropyrimidines.

PATHOPHYSIOLOGY

The classical concept of mucositis pathophysiology asserts that direct cytotoxicity from chemotherapy or radiation to basal epithelial cells results in ulcerative lesions caused by a lack of regeneration. These lesions are further complicated by trauma or microorganism growth. However, the most recent theory of mucositis pathophysiology is more detailed and involves a multistage, dynamic process that builds upon the historical model. According to this theory, there are five stages of mucositis: initiation, primary damage response, signal amplification, ulceration, and healing. It is important to note that these stages do not occur sequentially. Rather, they are dynamic and may overlap. Prevention of mucositis or treatment in early stages results in the best outcomes for patients.

CLINICAL PRESENTATION AND DIAGNOSIS

Patients with mucositis may present along a continuum of mild, painless, erythematous ulcers to those that are painful and/or bleeding that may interfere with eating and swallowing or that may require treatment with hydration, antibiotics, or even parenteral nutrition in its most severe forms.

TREATMENT

Nonpharmacologic Treatment

The goal of nonpharmacologic measures to prevent mucositis is to reduce the bacterial load. The fundamental approach to lessen the severity of mucositis begins with basic, good oral hygiene (brushing with a soft-bristled toothbrush at least twice daily, flossing, bland rinses, and saliva substitutes). Cryotherapy with ice chips is also helpful for almost all patients at risk for mucositis. Low-level laser therapy (in centers that have the resources to offer it) is also helpful to prevent mucositis in the hematopoietic cell transplant (HCT) setting.

Pharmacologic Treatment

In the setting of radiation therapy, amifostine, a free radical scavenger, at doses equal to or greater than 340 mg/m\textsuperscript{2} intraretal before each dose of radiation therapy for rectal cancer may be considered to prevent gastrointestinal mucositis. Gelclair, Caphasol, and Biotene are gels that provide a protective barrier between damaged oral mucosa and the environment, lessening pain and irritation and are also sometimes used as part of the overall treatment of patients with mucositis. Antimicrobial lozenges, sucralfate and chlorhexidine rinses, and “magic-mouthwash” compounded rinses are not generally recommended by clinical practice guidelines for mucositis prevention even though they are sometimes used in practice. Ranitidine or omeprazole orally are recommended to prevent pain associated with mucositis and reflux following offending chemotherapy.

Unfortunately, little evidence is available to recommend specific treatments for mucositis. Pain assessment and appropriate management are important. Pain management may be achieved with oral morphine, topical anesthetic products, and compounded rinses that incorporate lidocaine. In more severe cases in which infection of the oral mucosa is suspected, appropriate antibiotic therapy is necessary to prevent systemic infection.
Clinical Presentation and Diagnosis of Mucositis

- Painful, erythematous ulcers develop on the lips, cheeks, soft palate, floor of mouth, and throughout the entire gastrointestinal (GI) tract.
- Assess mucositis using validated scales, either oral mucositis assessment scale (OMAS) or University of Nebraska oral assessment score (MUCPEAK).
- Symptoms appear within 5 to 7 days after chemotherapy and resolve in 2 to 3 weeks.
- Pain may affect ability to swallow and eat.
- The patient may have concomitant localized or systemic infection.
- Diarrhea is a symptom of mucositis in the lower GI tract.

Palifermin is FDA approved for the prevention and treatment of mucositis in patients receiving high-dose chemotherapy as part of stem cell transplant or induction regimens for leukemia. Palifermin is administered as an IV bolus injection at a dosage of 60 mcg/kg/day for 3 consecutive days before and 3 consecutive days after myelotoxic therapy for a total of six doses. Administering palifermin within 24 hours of chemotherapy can result in an increased sensitivity of rapidly dividing epithelial cells to the cytotoxic agent. For this reason, palifermin should not be administered for 24 hours before, 24 hours after, or during the infusion of myelotoxic chemotherapy to avoid increasing the severity and the duration of oral mucositis.

OUTCOME EVALUATION

The goal of therapy is to prevent or decrease the severity and duration of mucositis. Outcomes measured in clinical trials often assess the incidence, duration, and severity of mucositis with a given intervention intended to prevent or treat mucositis. Agents that are intended to palliate the symptoms of mucositis are usually assessed by measures in pain scales and the ability to eat or drink.

HEMATOLOGIC COMPLICATIONS: FEBRILE NEUTROPENIA (FN)

INTRODUCTION

FN is a common adverse effect after administration of cytotoxic chemotherapy. The mortality rate in neutropenic patients caused by infectious complications currently remains between 5% and 10%; therefore, FN is considered a true oncologic emergency. Patients frequently require hospitalization for prompt administration of broad-spectrum antibiotics that are critical to avoid morbidity and mortality.

EPIDEMIOLOGY AND ETIOLOGY

The microorganisms responsible for infections in neutropenic patients have changed significantly in the last 50 years. From the 1960s through the mid-1980s, gram-negative organisms were the most common bacteria isolated. This pattern shifted to the gram-positive organisms in the late 1980s, which remain the most common isolates. Recent data indicate that gram-positive organisms account for 62% to 76% of all bloodstream infections. 

Palifermin is a common adverse effect after administration of cytotoxic chemotherapy to avoid increasing the severity and mortality. FN, febrile neutropenia.

Patient Encounter 2: FN

A 63-year-old woman receiving treatment for metastatic breast cancer presents today, 8 days after chemotherapy, for follow-up and laboratory check. Relevant laboratory study results include WBC count, 0.7 × 10^9/mL (0.7 × 10^3/L); Hgb 9.0 g/dL (90 g/L; 5.59 mmol/L); HCT 26.6% (0.266); PLT, 6 × 10^9/mL (6 × 10^3/L); serum chemistries within normal limits except; SCr, 1.3 mg/dL (115 μmol/L); and estimated GFR 54 mL/min/1.73m². Vitals: T 98.2°F (36.8°C); P 71 beats/min; RR 18 breaths/min; BP 116/64 mm Hg. The patient has no known drug allergies.

What risk factors for FN does this patient have?
How would you approach this patient?
Fungal infections caused by Candida spp. (especially Candida albicans) have emerged as significant pathogens, especially in patients with hematologic malignancies and those undergoing bone marrow transplantation (BMT). In addition, Aspergillus spp. are important pathogens in patients with prolonged and severe neutropenia.

**PATHOPHYSIOLOGY**

The neutrophils are the primary defense mechanism against bacterial and fungal infection. Most infections in neutropenic patients are a result of organisms contained in endogenous flora, both on the skin and within the GI tract. These organisms are provided access to the bloodstream through breakdowns in host defense barriers (mucositis, use of central venous catheters).

Neutropenia is defined as an absolute neutrophil count (ANC) less than 500/μL (0.50 × 10⁹/L) cells or an ANC less than 1000/μL (1.00 × 10⁹/L) cells with a predicted decrease to less than 500/μL (0.50 × 10⁹/L) cells over the next 48 hours. The ANC is calculated by multiplying the total WBC by the percentage of neutrophils (segmented neutrophils plus "bands"). Fever is defined as a single oral temperature greater than or equal to 38.3°C (101°F) or a temperature greater than or equal to 38.0°C (100.4°F) for at least 1 hour. The combination of these two factors defines FN. The risk of infection during the period of neutropenia depends primarily on two factors:

- The duration of the neutropenia (time period of ANC less than 500/μL [0.50 × 10⁹/L] cells)
- The severity of the neutropenia (lowest ANC level reached [nadir])

A multitude of other risk factors for FN have been identified. Many of these are also risk factors for poor outcome in patients who experience FN. Cancer drug therapy regimens are also categorized as being high risk (greater than 20% incidence of FN reported in clinical trials) or intermediate risk (10%–20% risk of FN reported in clinical trials). Similar to the approach to the prevention of CINV, it is important to consider both the regimen and patient-specific risk factors when determining whether a patient should receive prophylactic therapy for FN.

FN, febrile neutropenia; LDH, lactate dehydrogenase.

It is clear that patients with FN represent a heterogenous group. Some patients are at lower risk and could potentially be treated as outpatients, thereby avoiding the risk and cost of hospitalization.

- The Multinational Association for Supportive Care in Cancer (MASCC) has validated a risk assessment tool that assigns a risk score to patients presenting with FN. Patients with a risk-index score greater than or equal to 21 are identified as low risk and are candidates for outpatient therapy (discussed under section Treatment).

*Note: A risk-index score of 21 or higher indicates that the patient is likely to be at low risk for complications and morbidity.

*Choose one symptom assessment.

*Does not apply to patients 16 years of age or younger.

COPD, chronic obstructive pulmonary disease; FN, febrile neutropenia; MASCC, Multinational Association for Supportive Care in Cancer.

PREVENTION

- Three primary modalities for preventing infection in patients who are expected to become neutropenic have been utilized, the first of which is the least expensive and simplest:
  - Vigilant hand hygiene
  - Prophylactic antibiotics
  - Colony-stimulating factors (CSFs)

  The advantages and disadvantages of these strategies are discussed individually in the following sections.

**Hand Hygiene**

As previously discussed, most infections in neutropenic patients are a result of endogenous flora; however, prevention of further acquisition of environmental pathogens is also important. Patients who are or will become neutropenic should practice careful handwashing and avoid contact with people who neglect hand hygiene. In addition, ingestion of certain fresh fruits and vegetables as well as unprocessed dairy products should be avoided during the neutropenic period. Practitioners should also engage in vigilant hand hygiene after each patient encounter to limit the spread of infections between patients.
**Clinical Presentation and Diagnosis of FN**¹⁷,¹⁸

**General**
- Only 50% of patients with FN have a clinically documented infection.
- Only 25% of patients with FN have a microbiologically documented infection.

**Signs and Symptoms**
- Fever is typically the only sign of infection, although septic patients may have chills.
- Infected catheter sites may be erythematous and tender to the touch.

**Laboratory Tests**
- CBC with differential
- Two blood cultures from each access site (peripheral and central), urinalysis, urine culture, chest x-ray, sputum cultures

**Other Diagnostic Tests**
- Detailed physical examination of the oral mucosa, sinuses, skin, catheter access sites, perineal area (no rectal examination because of the risk of bacteremia)

**Prophylactic Antibiotics**

Routine antibacterial prophylaxis is controversial and has been attempted primarily with sulfamethoxazole–trimethoprim (SMZ-TMP) and quinolones. SMZ-TMP offers improved prophylaxis against gram-positive organisms compared with quinolones; quinolones are more effective prophylaxis against gram-negative infections. The 2010 Infectious Diseases Society of America (IDSA) guidelines recommend fluoroquinolone prophylaxis in patients who are at high risk for "prolonged and profound" neutropenia. The IDSA does not recommend routine antibiotic prophylaxis for low-risk patients because of the lack of a clear benefit on mortality rates and concerns regarding increasing antibiotic resistance. One exception is that SMZ-TMP is recommended for prophylaxis of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonitis (PCP) in all at-risk patients (ie, hematopoietic cell transplant recipients, AIDS), regardless of the presence of neutropenia.

Two meta-analyses add fuel to the controversy of routine antibiotic prophylaxis. Decrees in infection-related mortality and gram-negative bacteremia were demonstrated with the use of quinolones; however, overall adverse events were higher, and most of the studies were conducted in patients with hematologic malignancies (an inherently high-risk group). Although two additional randomized trials in patients with both solid tumors and hematologic malignancies demonstrated lower rates of FN, infection, and hospitalization with oral prophylactic levofloxacin compared with placebo, both the NCCN and IDSA only recommend prophylactic levofloxacin for patients with expected duration of neutropenia (defined as an ANC less than 1000/μL [1.00 × 10⁹/L]) for more than 7 days because of the:
- Unknown long-term consequences on the development of resistant organisms
- Emergence of *Clostridium difficile* and methicillin-resistant *Staphylococcus aureus* (MRSA) from fluoroquinolone overuse

- Ability to treat lower-risk patients on an outpatient basis, reducing the need for prophylactic antibiotics.¹⁹

Therefore, the use of prophylactic quinolones in patients who are at high risk for infection (ie, hematologic malignancies) is reasonable; however, use should not be routine for low-risk patients. If prophylactic quinolone use is adopted, changes in local patterns of resistance should be closely monitored.

**Colonial-Stimulating Factors**

The CSFs stimulate the maturation and differentiation of neutrophil precursors. Four agents are currently approved for use in the United States (Table 99–7). The prophylactic use of these agents decreases days of hospitalization and use of empiric antibiotics by shortening the duration of severe neutropenia (defined as ANC less than 500/μL [0.50 × 10⁹/L]). There is little to no effect on the depth of neutrophil nadir. A recent meta-analysis found that the use of prophylactic granulocyte CSF (either filgrastim or pegfilgrastim) results in a 46% risk reduction of FN and a 48% risk reduction in infectious mortality, although absolute differences are small (3.3% vs 1.7%).²² It is critical to note that patients who receive these agents may still experience FN despite the risk reduction. The primary limitation of the use of these agents is cost. CSFs are recommended beginning with the first cycle (primary prophylaxis) of chemotherapy when the risk of FN is greater than or equal to 20%, regardless if the goal of therapy is curative or palliative. This is the point where the use of CSFs is cost effective when balanced against the cost of hospitalization and antimicrobials. Secondary prophylaxis refers to the subsequent prophylactic use of a CSF after a patient has had an episode of FN. This strategy should be used especially when the chemotherapy is being given in patients with the intention of cure (ie, Hodgkin lymphoma, early breast cancer). In this circumstance, administration of full doses of chemotherapy on time without delays has been shown to improve patient outcomes.

Although generally well tolerated, CSFs may cause bone pain in around 25% of patients. This may be managed with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs), although attention to the platelet count is warranted with the use of NSAIDs. Sargramostim in particular may result in low-grade fever and myalgias, perhaps as a result of its wider pattern of effector cell stimulation.²⁰

**TREATMENT**

**Desired Outcomes**

Because rapid death may occur with certain infections in neutropenic patients, prompt and emergent treatment is indicated. The primary goal is to prevent morbidity and mortality during the neutropenic period. This is accomplished by effectively treating subclinical or established infections.

**General Approach to Treatment**

A risk assessment should be performed at presentation of FN to identify low-risk patients for potential outpatient treatment (see Table 99–6). Patients who do not meet low-risk criteria should be hospitalized for parenteral administration of broad-spectrum antibacterials. The IDSA has published evidence-based guidelines for the management of FN (Figure 99–1). The choice of initial antimicrobial agent(s) depends on the following factors:

- Presence of a central venous catheter
- Drug allergies
- Concurrent renal dysfunction or use of nephrotoxic agents

- Institutional and/or community susceptibility patterns
- Cost

**MY CONCEPT** The administration of empiric therapy should begin immediately after cultures are taken. Therapy should not be withheld until after culture results are obtained.

As illustrated in Figure 99–1, specific criteria exist for the addition of vancomycin for coverage of resistant gram-positive organisms or agents for coverage of fungal infections. Additional agents are necessary in the setting of continued fever or declining clinical status in neutropenic patients. In general, all empiric therapy is continued until recovery of the ANC to levels above 500 cells/µL (0.500 × 10⁹/L) in patients with negative culture results. If a specific etiology is identified, appropriate therapy should be continued until 7 days after neutropenia resolves. Specific regimens with recommended dosages are summarized in Table 99–8.

**Nonpharmacologic Therapy**

Prevention of infection is key. Handwashing is critical in the prevention of disease transmission. It is also important to ensure that patients receive annual influenza vaccines and have had a pneumonia and meningococcal vaccine, and neutropenic patients should avoid individuals with active respiratory infections. Indwelling catheters are often sources of infection; however, the IDSA acknowledges that catheters do not always need to be removed. Catheters should be removed in the following circumstances: established tunnel infection (subcutaneous tunnel or periport infection, septic emboli, hypotension associated with catheter use, or a nonpatent catheter), recurrent infection, or no response to antibiotics within 2 or 3 days. Wound debridement should also be performed upon catheter removal. In the setting of peripheral blood stem cell or bone marrow transplant, the Centers for Disease Control and Prevention recommends the use of high-efficiency particulate air (HEPA) filtration systems in patient rooms, and the NCCN suggests that HEPA filters are reasonable to be considered for other patients who experience prolonged neutropenia. HEPA filters are likely to be most useful in preventing mold infections. Although several small studies have attempted to evaluate the effectiveness of isolation of neutropenic patients as a mechanism for infection prevention, no clear data are available to support this practice.

**Pharmacologic Therapy**

There are two primary choices for the initial management of high-risk FN: monotherapy and dual therapy (see Figure 99–1) when vancomycin is not needed. Both regimens have been shown to be equivalent in randomized studies and meta-analyses. Monotherapy avoids the nephrotoxicity of the aminoglycosides and is potentially less expensive but lacks significant gram-positive coverage and may increase selection of resistant organisms. Dual therapy provides synergistic activity, decreased resistance, and dual coverage of Pseudomonas aeruginosa but requires therapeutic monitoring for aminoglycosides. The choice between monotherapy and dual therapy is usually provider and institution preference, although dual therapy may be preferred in an acutely symptomatic patient (eg, hypotensive).

Vancomycin adds broad-spectrum gram-positive coverage; however, the increasing emergence of vancomycin-resistant organisms (ie, Enterococcus spp.) prompts conservative use of this medication. Vancomycin should only be included as part of the initial therapy if the following are present:

- Severe mucositis
- Soft tissue infection
Fever and neutropenia

Comprehensive evaluation physical examination and cultures

Low risk

- Oral
- Ciprofloxacin
- and
- Amoxicillin–clavulanate
  (adults only)

No etiology identified

- Low risk
- Change to:
  - Ciprofloxacin
  - and
  - Amoxicillin–clavulanate
    (adults)
  or
  - Cefixime (child)
- Discharge

High risk

- IV
- Vancomycin not needed

- Low risk
- Oral
- Ciprofloxacin
- and
- Amoxicillin–clavulanate
  (adults only)

- Initial low risk
- Clinically well
- Stop when afebrile for 5–7 days

- Initial high risk
- • ANC < 100 cells/mm³
- • Mucositis
- • Unstable signs
- Stop when ANC < 500 cells/mm³
- Continue antibiotics

- Stop 4–5 days after ANC > 500 cells/mm³
- Reassess
- Reassess
- Stop if no disease and condition is stable

High risk

- IV
- Vancomycin needed

- Low risk
- Oral
- Ciprofloxacin
- and
- Amoxicillin–clavulanate
  (adults only)

- Initial low risk
- Clinically well
- Stop when afebrile for 5–7 days

- Initial high risk
- • ANC < 100 cells/mm³
- • Mucositis
- • Unstable signs
- Stop when ANC < 500 cells/mm³
- Continue antibiotics

- Stop 4–5 days after ANC > 500 cells/mm³
- Reassess
- Reassess
- Stop if no disease and condition is stable

Monotherapy

- • Cefepime,
- • Ceftazidime,
- or
- • Carbapenem

Two drugs

- Aminoglycoside
- and
- Antipseudomonal penicillin,
- • Cefepime,
- • Ceftazidime,
- or
- • Carbapenem

Vancomycin and:

- • Cefepime,
- • Ceftazidime,
- or
- • Carbapenem

with or without aminoglycoside

Reassess after 3–5 days

Afebrile within first 3–5 days of treatment

Etiology identified

- No etiology identified

- Low risk
- Change to:
  - Ciprofloxacin
  - and
  - Amoxicillin–clavulanate
    (adults)
  or
  - Cefixime (child)
- Discharge

- High risk
- Continue same antibiotics

- Adjust to most appropriate treatment while maintaining broad-spectrum coverage during neutropenia

Persistent fever during first 3–5 days of treatment: no etiology

Reassess patient on days 3–5

- Continue initial antibiotics

- If no change in patient's condition, consider stopping vancomycin

- If progressive disease
- • If criteria for vancomycin are met
- Antifungal drug, with or without antibiotic change

- If febrile through days 5–7 and resolution of neutropenia is not imminent

- Stop if no disease and condition is stable

ANC ≥ 500 cells/mm³

- for 2 consecutive days

- Stop antibiotics 48 hours after afebrile and ANC ≥ equal to 500 cells/mm³

ANC < 500 cells/mm³

- by day 7

- Initial low risk
- Clinically well
- Stop when afebrile for 5–7 days

- Initial high risk
- • ANC < 100 cells/mm³
- • Mucositis
- • Unstable signs
- Stop when ANC < 500 cells/mm³
- Continue antibiotics

- Stop 4–5 days after ANC > 500 cells/mm³
- Reassess
- Reassess
- Stop if no disease and condition is stable

ANC ≥ 500 cells/mm³

- Stop 4–5 days after ANC > 500 cells/mm³
- Reassess
- Reassess
- Stop if no disease and condition is stable

ANC < 500 cells/mm³

- Continue for 2 weeks

*Dosaging for adult patients; adjust doses for renal dysfunction.

- Quinolone or TMP-SMX prophylaxis
- Hypotension or septic shock
- Colonization with resistant gram-positive organisms (ie, MRSA)
- Evidence of central venous catheter infection
- Vancomycin may be added to the empiric regimen after 3 to 5 days in persistently febrile patients or if cultures reveal gram-positive organisms. Vancomycin should be changed if the gram-positive organism is susceptible to other antibiotics or discontinued in patients with persistent fever after 3 days with negative culture results. Linezolid, quinupristin–dalfopristin, tigecycline, and daptomycin may be used in cases of vancomycin-resistant organisms or if vancomycin is not an option because of drug allergy or intolerance. Empiric antifungal agents are typically added in persistently febrile patients after 5 to 7 days, especially if continued neutropenia is expected. Amphotericin B has historically been the drug of choice because of its broad-spectrum activity against both yeast (Candida spp.) and mold (Aspergillus spp.) infections. Because frequent toxicity (nephrotoxicity, infusion reactions) limits the use of amphotericin B, less toxic alternatives have been studied. Lipid formulations of amphotericin provide decreased toxicity, and liposomal amphotericin B (AmBisome) has been shown to be equivalent to conventional amphotericin B as empiric therapy but is significantly more expensive;
Caspofungin is equivalent with less toxicity compared with liposomal amphotericin B in a randomized trial and is FDA approved for this indication.\textsuperscript{14,15} Voriconazole is equivalent to liposomal amphotericin in mortality, but response was improved in those receiving liposomal amphotericin. Voriconazole does not have an indication, but it is sometimes used. Itraconazole has also been used in some institutions, but its use is complicated by poor bioavailability of oral preparations and numerous drug interactions. Posaconazole is a newer azole that is sometimes used prophylactically in neutropenic patients with acute myeloid leukemia or myelodysplastic syndrome and for patients with graft-versus-host disease while receiving intensive immunosuppressive therapy. It is not FDA approved as primary or salvage therapy for the treatment of invasive fungal infections but is approved by the European Union for invasive aspergillosis and other fungal infections that are refractory to standard antifungal agents.

As stated earlier, low-risk patients fulfilling the MASCC criteria (see Table 99–6) may be treated empirically as an outpatient with a regimen combining amoxicillin–clavulanic acid and ciprofloxacin. Ciprofloxacin and clindamycin are reasonable alternatives for penicillin-allergic patients.

The CSF should not routinely be used for treatment of FN in conjunction with antimicrobial therapy.\textsuperscript{14,15} However, the use of CSFs in certain high-risk patients with hypotension, documented funga infection, pneumonia, or sepsis is reasonable. A meta-analysis demonstrated that hospitalization and neutrophil recovery are shortened and infection-related mortality is marginally improved with CSF prophylaxis in high-risk patients.\textsuperscript{24} As with prophylactic use of these agents, cost considerations limit their use to high-risk patients.

**OUTCOME EVALUATION**

The success of the treatment of FN depends on the adequate recovery of the ANC and either optimal antimicrobial coverage of identified organisms or empiric coverage of unidentified organisms. Monitor the complete blood count (CBC) with differential and $T_{\text{max}}$ (maximum temperature during previous 24 hours) daily. Assess renal and hepatic function at least twice weekly, especially in patients receiving nephrotoxic agents. Vital signs should be taken every 4 hours. Follow-up on blood and urine culture results daily because many cultures do not become positive for several days. Assess the patient daily for pain that may indicate an infectious source. Conduct daily physical examination of common sites of infection. Repeat cultures and chest x-ray in persistently febrile patients and culture developing organism or empiric coverage of unidentified organisms.

SECTION 16  | ONCOLOGIC DISORDERS

**Patient Care Process: FN**

**Patient Assessment:**
- Review patient history for cytotoxic chemotherapy.
- Evaluate risk of FN with cytotoxic chemotherapy using NCCN practice guideline for myeloid growth factors.
- Obtain a complete patient history:
  a. What chemotherapy did the patient receive and when? Is the ANC on the way down (before nadir) or on the way up (after nadir)? Was the patient receiving prophylactic antibiotics, filgrastim, sargramostim, or pegfilgrastim?
  b. Did the patient have previous episodes of FN? What were the previous culture results to determine colonization status?
- Evaluate patient-specific risk factors.
- Evaluate other sources of infection, such as catheters and surgery sites.
- Assess patient for temperature, onset of fever, duration of fever.
- Ensure patient has not taken NSAIDs, acetaminophen, or other therapies which may give a false impression of a lower temperature/lack of fever.
- Assess patient for severe signs/symptoms of systemic infection such as chills, headache, disorientation, etc.
- Determine patient allergies, especially to antibiotics, antifungals, and antivirals.

**Therapy Evaluation:**
- Select empiric antibiotic therapy if patient meets criteria for prophylactic treatment. Do not wait for culture results. Verify patient allergies.
- Change antimicrobials once culture results are obtained, if applicable. Verify antimicrobial effectiveness against institutional nomogram.

**Care Plan Development:**
- Discuss with interprofessional team advantages/disadvantages of treating patient as an outpatient, if applicable.
- Counsel patients receiving cytotoxic chemotherapy or alemtuzumab to promptly report fever. Provide patients with a diet to use during the neutropenic period. Counsel patients to avoid close contact with sick friends and relatives and remind patients and caregivers of the importance of handwashing.

**Follow-Up Evaluation:**
- Assess the patient daily for any new signs or symptoms of infection. Evaluate the patient for adverse drug reactions, drug allergies, and interactions. Have all antibiotics been dose adjusted for renal or hepatic dysfunction?
- For patients receiving oral antibiotics either prophylactically or as treatment of FN: Counsel patients that initial or persistent fever should be promptly reported and that compliance with the regimen is critical. Patients should also have easy access to medical care and adequate caregiver support. Provide information on drug interactions and adverse effects.
INTRODUCTION
Superior vena cava syndrome (SVCS) is a relatively rare complication that, although nonmalignant, may occur in patients with cancer. SVCS is rarely immediately life threatening except in patients with airway compromise and/or laryngeal or cerebral edema. However, rapid recognition of typical presenting symptoms facilitates referral for tissue diagnosis (if unknown) and treatment.

Epidemiology and Etiology
SVCS occurs in around 15,000 patients per year, 90% of which are caused by malignancy. Specific cancers most commonly associated with SVCS are listed in Table 99–9. Lung cancer is the most frequent cause, of which small cell lung cancer (SCLC) is the most frequent subtype associated with SVCS. This is thought to be because of its predilection for the central and perihilar areas of the lung. Interestingly, right-sided lung cancers are four times more likely than left-sided lesions to cause SVCS. Mediastinal masses from lymphomas are the second most common cause.

The most common nonmalignant etiology of SVCS is catheter-related thrombosis, primarily caused by the increasing use of central access devices. Other causes include benign teratoma, tuberculosis, silicosis, and sarcoidosis.

Pathophysiology
The SVC is the primary drainage vein for blood return from the head, neck, and upper extremities. It is a relatively thin-walled vein that is particularly vulnerable to obstruction from adjacent tumor invasion or thrombosis. The obstruction leads to elevated venous pressure, although collateral veins partially compensate. This is one reason for the relatively slow onset of the classic symptoms of SVCS. In fact, 75% of patients have signs and symptoms for more than 1 week before seeking medical attention.

Clinical Presentation and Diagnosis of SVCS

General
- Presentation depends on the degree of SVCS obstruction
- Almost complete obstruction is necessary to demonstrate classic symptoms

Signs and Symptoms
- Most common: swelling of face, neck, and upper extremity edema; dyspnea; cough; dilated upper extremity veins; orthopnea
- Less common: hoarseness, dysphagia, dizziness, headache, lethargy, chest pain
- Patients with elevated ICP may have mental status changes
- Patients with airway obstruction may have shortness of breath

Diagnostic Tests
- Tissue biopsy to determine underlying malignancy (if unknown), chest x-ray, CT scan, bronchoscopy, mediastinoscopy

CLINICAL PRESENTATION AND DIAGNOSIS

TREATMENT

Desired Outcomes

- The primary goal of treatment of SVCS is to relieve the obstruction of the SVC by treating the underlying malignancy.
- In the case of SVCS caused by thrombosis, the goal is to eliminate the thrombus and prevent further clot formation. Resolution of the obstruction will rapidly relieve symptoms and restore normal SVC function. The final goal of therapy is to avoid potentially fatal complications of SVCS such as cerebral edema from rapid increases in intracranial pressure (ICP) and intracranial thrombosis or bleeding.

General Approach to Treatment
Because the majority of SVCS is not immediately life threatening, a tissue diagnosis (if malignancy is unknown) to specifically identify the cancer origin is critical because treatment approaches vary considerably according to tumor histology. Thus, therapy can typically be withheld until a definitive tissue diagnosis is established. While biopsy results are pending, supportive measures such as head elevation, diuretics, corticosteroids, and supplemental oxygen may be used.

Nonpharmacologic Therapy
Radiation therapy is the treatment of choice for chemotherapy-resistant tumors such as NSCLC or in chemotherapy-refractory patients with SVCS. Between 70% and 90% of patients experience relief of symptoms. Radiation therapy may also be combined with chemotherapy for chemotherapy-sensitive tumors such as SCLC and lymphoma. In the rare emergency situations of airway obstruction or elevated ICP, empiric radiotherapy before tissue diagnosis should be used. In most patients, symptoms resolve within 1 to 3 weeks.
Cytotoxic chemotherapy is the treatment of choice for chemotherapy-sensitive tumors such as SCLC and lymphoma. As indicated earlier, chemotherapy may also be combined with radiotherapy, especially in patients with lymphoma who have bulky mediastinal lymphadenopathy.

Corticosteroids play a key role in the management of SVCS, particularly in cases of lymphoma, because these tumors inherently respond to corticosteroid therapy. They are also helpful in the setting of respiratory compromise. Corticosteroids benefit patients who are receiving radiation therapy by reduction of local radiation-induced inflammation and patients with increased ICP. Dexamethasone 4 mg IV or by mouth every 6 hours is a frequently used regimen. The dosage should be tapered upon completion of radiation therapy or resolution of symptoms.

The role of diuretics in the management of SVCS is controversial. Although patients may derive symptomatic relief from edema, complications such as dehydration and reduced venous blood flow may exacerbate the condition. If diuretics are used, furosemide is most frequently used with diligent monitoring of the patient’s fluid status and blood pressure.

In the case of thrombosis-related SVCS, anticoagulation is controversial because there is a lack of survival benefit. However, thrombolitics (ie, alteplase) and anticoagulation with heparin and warfarin may be beneficial in patients with thrombosis caused by indwelling catheters if used within 7 days of onset of symptoms, although catheter removal may be required.

**OUTCOME EVALUATION**

The major measure of outcome of treatment of SVCS is the relief of symptoms, regardless of the therapy used.

**NEUROLOGIC COMPLICATIONS: SPINAL CORD COMPRESSION**

**INTRODUCTION**

Although not typically life threatening, spinal cord compression is a true oncologic emergency because delays in treatment by mere hours may lead to permanent neurologic dysfunction. Practitioners must quickly recognize the signs and symptoms of this condition to facilitate rapid management strategies.

**EPIDEMIOLOGY AND ETIOLOGY**

Around 20,000 cancer patients experience spinal cord compression in the United States every year, most of which involves the thoracic spine (~70%). Cancers that inherently metastasize to the bone (ie, breast, prostate, and lung) are the most frequent underlying malignancies associated with this complication. Most spinal cord compression occurs in patients with a known malignancy; however, 8% to 34% of cases occur as the initial presentation of cancer, especially in patients with non-Hodgkin lymphoma, multiple myeloma, and lung cancer. Recently, predictive models have been developed to predict survival from SCC from myeloma and NSCLC.

**PATHOPHYSIOLOGY**

The spinal cord emerges from the brain stem at the base of the skull and terminates at the second lumbar vertebra. The thoracic spine is most vulnerable to cord compression because of natural kyphosis and because the width of the thoracic spinal canal is the smallest among the vertebrae. Most spinal cord compression is caused by adjacent vertebral metastases that compress the spinal cord or from pathologic compression fracture of the vertebra. This results in significant edema and inflammation in the affected area.

Patients with spinal cord compression are in acute, severe back and/or neck pain and may present to the emergency department
Clinical Presentation and Diagnosis of Spinal Cord Compression

**General**
- Once neurologic deficits appear, progression to irreversible paralysis may occur within hours to days
- Around 10% to 38% of patients present with multiple sites of spinal involvement

**Signs and Symptoms**
- Back pain is present in more than 90% of patients
- Initially localized and increases in intensity over several weeks
- Aggravated by movement, supine positioning, coughing, sneezing, neck flexion, straight leg raise, Valsalva maneuver, palpation of spine
- Sensory deficit
- Cervical spine compression: quadriplegia
- Thoracic spine compression: paraplegia
- Upper lumbar spine compression: bowel and bladder dysfunction (constipation and urinary retention) and abnormal extensor plantar reflexes
- Weakness

**Diagnostic Tests**
- MRI with gadolinium enhancement is the gold standard
- X-rays may be helpful to identify bone abnormalities

for evaluation. Diagnosis is made based on symptoms and imaging studies that show fractured vertebrae.

**TREATMENT**

**Desired Outcomes**

KEY CONCEPT: Because patients with spinal metastases are generally incurable, the primary goal of treatment of spinal cord compression is palliation. The most important prognostic factor for patients presenting with spinal cord compression is the degree of underlying neurologic dysfunction. Only around 10% of patients who present with paralysis are able to ambulate after treatment. Therefore, the goals of treatment are recovery of normal neurologic function, local tumor control, pain control, and stabilization of the spine. Therapeutic options depend primarily on the following factors:
- Underlying malignancy
- Prior therapies
- Stability of the spine at presentation
- Overall patient prognosis

**Nonpharmacologic Therapy**
Radiation therapy is generally considered to be the treatment of choice for most patients. Exceptions to this include patients with prior radiation to the treatment site and patients with inherently radio-resistant tumors (ie, melanoma, renal cell carcinoma). The radiation field should include two vertebral bodies above and below the involved area.

Surgery for spinal cord compression typically involves either laminectomy for posterior lesions or decompression with fixation. Surgery is the treatment of choice for the following patients: (a) patients with unstable spine requiring stabilization, (b) immediately impending sphincter dysfunction requiring rapid spinal decompression, (c) patients who do not respond to or have received their maximum dose of radiotherapy, and (d) direct compression of the spinal cord caused by spinal bony fragments. Recent evidence suggests that surgery followed by radiation therapy may be superior to radiotherapy alone in terms of increased ambulation time after treatment, maintenance of continence, and rates of nonambulatory patients becoming ambulatory. Surgery is also useful for establishing a tissue diagnosis in cases of unknown malignancy. Overall, the risks and benefits of surgery must be weighed against the expected prognosis of the patient in light of the significant rehabilitation required after surgery.

**Pharmacologic Therapy**

Corticosteroids play a vital role in the management of spinal cord compression. Dexamethasone is most frequently used to reduce edema, inhibit inflammation, and delay the onset of...
neurologic complications. Dexamethasone has been shown to improve ambulation in combination with radiation compared with radiation alone. Signiﬁcant controversy exists regarding the optimal dosing of dexamethasone. Oral loading doses of 10 to 100 mg followed by 4 to 24 mg orally four times daily have been used. Higher doses may be used in cases of rapidly progressing symptoms, but adverse effects, including GI bleeding and psychosis, are more severe. Steroids should be continued during radiation therapy and then tapered appropriately.

Pain management is also of critical importance in patients with spinal cord compression. Although dexamethasone will provide some beneﬁt, opioid analgesics should also be used and titrated rapidly to achieve adequate pain control.

OUTCOME EVALUATION
Patients who receive deﬁnitive treatment with radiation and/or surgery generally derive beneﬁt within days.

COMPLICATIONS OF BRAIN METASTASES

INTRODUCTION
Brain metastases are among the most feared complications of cancer and generally carry a poor prognosis. One serious consequence of brain metastases is elevated ICP, which can rapidly lead to fatal intracranial herniation and death. Rapid identiﬁcation of the signs and symptoms of brain metastases is critical to improve long-term outcome and avoid mortality. The signs and symptoms of brain metastasis can be confused with common psychological distress or other neurologic problems (eg, headaches) that may go unrecognized. It is important that patients who are suspected to have brain metastasis are quickly referred for appropriate management.

EPIDEMIOLOGY AND ETIOLOGY
Brain metastasis is the most common neurologic complication seen in patients with cancer. Approximately 170,000 patients develop brain metastases in the United States each year. Many malignancies are frequently associated with brain metastases (Table 99–10). Although melanoma is the tumor type most likely to metastasize to the brain, brain metastases caused by lung and breast cancer are seen more often because they are among the most common cancers. In addition, brain metastases may be diagnosed at the same time as the primary malignancy in around 20% of cases. Around 80% of brain metastases occur in the cerebral hemispheres, 15% in the cerebellum, and 5% in the brain stem.

PATHOPHYSIOLOGY
A delicate balance of normal pressure is maintained in the brain and spinal cord by brain, blood, and cerebrospinal ﬂuid. Because the brain is contained within a conﬁned space (skull), any foreign mass contained within that space causes adverse sequelae. This results in either destruction or displacement of normal brain tissue with associated edema. Most brain metastases occur through hematogenous spread of the primary tumor and around 80% of patients have multiple sites of metastases within the brain.

TREATMENT

Desired Outcomes
Therapeutic modalities used for the management of brain metastases may be divided into symptomatic management and deﬁnitive management. The goals of treatment of brain metastases are to manage symptoms by reducing cerebral edema, treat the underlying malignancy both locally and systemically, and improve survival.

General Approach to Treatment
Patients with brain metastases have a poor prognosis. Untreated patients generally have a median survival of 1 month. The choice of treatment depends primarily on the status of the patient’s underlying malignancy and the number and sites of brain metastases. The primary deﬁnitive treatments for brain metastases are surgery and radiation therapy. Pharmacologic modalities are primarily used to control symptoms, although cytotoxic chemotherapy plays a limited role in the management.

Nonpharmacologic Therapy
Radiation therapy is the treatment of choice for most patients with brain metastases. Most patients receive whole-brain radiation because the majority of brain metastases are multifocal. Another method known as stereotactic radiosurgery provides intense focal radiation, typically using a linear accelerator or gamma knife, in patients who cannot tolerate surgery or have lesions that are surgically inaccessible (ie, brain stem). Because brain metastases can occur in up to 50% of patients with small cell lung cancer, prophylactic cranial irradiation is recommended in patients with good performance status who at least partially respond to chemotherapy to both prevent the development of brain metastases and to prolong survival.35 Although other cancers can metastasize to the brain, the benefits of routine prophylactic cranial irradiation have only been demonstrated in studies conducted in patients with small cell lung cancer.36 In fact, a recent meta-analysis reported that prophylactic cranial irradiation may reduce overall survival when used in NSCLC patients even though it reduced brain metastases in these patients.37

Pharmacologic Therapy
Corticosteroids are a mainstay in the management of brain metastases. They reduce edema that typically surrounds sites of metastases thereby reducing ICP. A loading dose of dexamethasone 10 mg IV followed by 4 mg by mouth or IV every 6 hours is typically used. Symptom relief may occur shortly after the loading dose, although the maximum benefit may not be seen for several days (after definitive therapy).31

Mannitol is an agent that may be used in patients with impending cerebral herniation. Mannitol is an osmotic diuretic that shifts brain osmolarity from the brain to the blood. Doses of 100 g (1–2 g/kg) as an IV bolus should be used. Repeated doses are typically not recommended because mannitol may diffuse into brain tissue, leading to rebound increased ICP.31

Around 20% patients with brain metastases may present with seizures and require anticonvulsant therapy. Phenytoin is the most frequently used agent with a loading dose of 15 mg/kg followed by 300 mg by mouth daily (titrated to therapeutic levels between 10 and 20 mcg/mL [40 and 79 µmol/L]). Diazepam 5 mg IV may be used for rapid control of persistent seizures. Prophylactic anticonvulsants have frequently been used; however, a systematic review did not support their use.32 Thus, because adverse effects and drug interactions are common, the routine use of prophylactic anticonvulsants is not recommended.

OUTCOME EVALUATION
The success of therapy is based on the ability to decrease symptoms, treat the underlying sites of disease within the brain, and prolong survival.

UROLOGIC COMPLICATIONS: HEMORRHAGIC CYSTITIS

INTRODUCTION
Hemorrhagic cystitis is defined as acute or insidious bleeding from the lining of the bladder. Although therapy with certain medications is the most common cause, it is also the most preventable. Once it occurs, hemorrhagic cystitis causes significant morbidity and mortality rates between 2% and 4%. This section focuses on preventive strategies for chemotherapeutic causes of hemorrhagic cystitis.

EPIDEMIOLOGY AND ETIOLOGY
Numerous etiologies have been linked to hemorrhagic cystitis (Table 99–11).34 Of these, the oxazaphosphorine alkylating agents (cyclophosphamide and ifosfamide) are most
frequently implicated. Hemorrhagic cystitis is the dose-limiting toxicity of ifosfamide and predisposes patients with bladder cancer. Incidence rates vary considerably but generally range between 18% and 40% with ifosfamide and 0.5% to 40% with high-dose (300 mg/m² or more) cyclophosphamide in the absence of prophylactic measures. Chronic, low-dose oral cyclophosphamide as typically used in autoimmune disorders and chronic lymphocytic leukemia is infrequently associated with hemorrhagic cystitis.

Around 20% patients receiving pelvic irradiation may experience hemorrhagic cystitis, especially with concurrent cyclophosphamide. Viral infections commonly associated with this condition most frequently occur in bone marrow transplant recipients who may also receive cyclophosphamide.

**PATHOPHYSIOLOGY**

Cyclophosphamide- or ifosfamide-induced damage to the bladder wall is primarily caused by their shared metabolite known as acrolein. Acrolein causes sloughing and inflammation of the bladder lining, leading to bleeding and hemorrhage. This is most common when urine output is low because higher concentrations of acrolein come into contact with the bladder urothelium for longer periods of time.

**PREVENTION**

The use of effective prevention strategies can decrease the incidence of hemorrhagic cystitis to fewer than 5% in patients receiving cyclophosphamide or ifosfamide. Three methods are used to reduce the risk: administration of Mesna (2-mercaptoethane sulfonate), hyperhydration, and bladder irrigation with catheterization. Mesna is the primary method used with ifosfamide; all three strategies are used with cyclophosphamide.

Mesna is a thiol compound that is rapidly oxidized in the bloodstream after administration to dimesna, which is inactive. However, after being filtered through the kidneys, dimesna is reduced back to Mesna, which binds to acrolein, leading to its inactivation and excretion. ASCO has published evidence-based guidelines for the dosing and administration of Mesna (Table 99–11). The dose of oral Mesna must be double the IV dose because of its oral bioavailability between 40% and 50%. Because the half-life of Mesna (~1.2 hours) is much shorter than that of ifosfamide or cyclophosphamide, prolonged administration of Mesna beyond the end of the chemotherapy infusion is critical (Figure 99–2). Patients should receive at least 2 L of IV fluids beginning 12 to 24 hours before and ending 24 to 48 hours after the last dose of chemotherapy.

Hyperhydration with normal saline at 3 L/m²/day with IV furosemide to maintain urine output greater than 100 mL/hour has also been used with cyclophosphamide. Continuous bladder irrigation by catheterization uses normal saline at 250 to 1000 mL/hour to flush acrolein from the bladder. Mesna is equivalent to both strategies in patients receiving high-dose cyclophosphamide and avoids the discomfort and infection risk with catheterization and the intensity of hyperhydration. Thus, Mesna is the preventive method of choice.

**TREATMENT**

**Desired Outcomes**

If hemorrhagic cystitis occurs, the goals of treatment are to decrease exposure to the offending etiology, establish and maintain urine outflow, avoid obstruction and renal compromise, and maintain blood and plasma volume. Restoration of normal bladder function is the ultimate goal following acute treatment.

**General Approach to Treatment**

The treatment of hemorrhagic cystitis first involves discontinuation of the offending agent. Agents such as anticoagulants and inhibitors of platelet function should also be discontinued. IV fluids should be aggressively administered to irrigate the bladder. Blood and platelet transfusions may be necessary to maintain normal hematologic values. Pain should be managed with opioid analgesics. Local intravesicular therapies may be necessary if hematuria does not resolve (Figure 99–3).

**FIGURE 99–2.** Examples of Mesna (2-mercaptoethane sulfonate) administration with ifosfamide. (IV, intravenous; po, oral.)
Nonpharmacologic Therapy

A large-diameter, multihole urethral catheter should be inserted to facilitate saline lavage and evacuation of blood clots. Surgical removal of blood clots under anesthesia may be required if saline lavage is ineffective. Active bleeding from isolated areas may be cauterized with an electrode or laser. In severe cases that are unresponsive to local or systemic pharmacologic intervention, urinary diversion with percutaneous nephrostomy or surgical removal of the bladder may be required.

Pharmacologic Therapy

A number of local or systemic agents are used in the treatment of hemorrhagic cystitis. Local (direct instillation into the bladder), one-time administration of hemostatic agents such as alum, prostaglandins, silver nitrate, and formalin may be used; however, general anesthesia is required, especially with formalin, because of pain. Systemic agents, including estrogens, vasopressin, and aminocaproic acid, may be used in patients who are refractory to local therapy, although they introduce the risk of systemic side effects. These agents should be continued until bleeding stops.

Antispasmodic agents such as oxybutynin 5 mg by mouth two to three times daily may be used for bladder spasms. In patients with refractory pain, opioid analgesics should be titrated to adequate pain control.

OUTCOME EVALUATION

The goal of treatment is resolution of bladder symptoms and appropriate pain management.

Monitor the patient for resolution of hematuria after each successive therapeutic intervention. The frequency of monitoring is based on the severity of hemorrhaging. Monitor urinary output and serum chemistries (including sodium, potassium, chloride, blood urea nitrogen, and serum creatinine) daily for renal dysfunction. Check the CBC at least daily to monitor hemoglobin and platelet count.
**Assess onset and severity of symptoms of hemorrhagic cystitis such as hematuria, anuria, oliguria.**

**Assess the patient receiving ifosfamide or cyclophosphamide at least daily for the development of hematuria.**

**Therapy Evaluation:**
- Ensure administration of adequate hydration and proper doses of Mesna.

**Care Plan Development:**
- Initiate Mesna if indicated and assure adequate hydration.
- Counsel patient receiving oral Mesna on the importance of compliance, when to take doses, and to immediately report any episodes of vomiting for IV readministration.
- Evaluate the patient for drug interactions, allergies, and adverse effects with chemotherapy, Mesna, or systemic therapies for management.

**Follow-Up Evaluation:**
- Assess the quantity of urinary bleeding and promptly refer to a urologist for local or surgical management.
- Patients receiving systemic treatment should be monitored every 4 hours for resolution of hematuria. Promptly refer to urologist for refractory hematuria.

**METABOLIC COMPLICATIONS:**

**HYPERCALCEMIA OF MALIGNANCY**

**INTRODUCTION**

Hypercalcemia is the most common metabolic abnormality experienced by patients with cancer. A small percentage of as yet undiagnosed patients present with hypercalcemia. Once hypercalcemia occurs, it is associated with a very poor prognosis because of the frequent association with advanced or metastatic disease.

**EPIDEMIOLOGY AND ETIOLOGY**

Hypercalcemia occurs in 10% to 30% of patients with cancer during the course of their disease. The most common tumor types associated with hypercalcemia are breast cancer; squamous cell carcinomas of the head, neck, and lung; and renal cancer. Hematologic malignancies such as multiple myeloma and, rarely, lymphomas are other underlying malignancies associated with hypercalcemia.

**PATHOPHYSIOLOGY**

Around 99% of calcium is contained in the bones; the other 1% resides in the extracellular fluid. Of this extracellular calcium, approximately 40% is bound to albumin, and the remainder is in the ionized, physiologically active form. Normal calcium levels are maintained by three primary factors: parathyroid hormone (PTH), 1,25-dihydroxyvitamin D, and calcitonin. PTH increases renal tubular calcium resorption and promotes bone resorption. The active form of vitamin D, 1,25-dihydroxyvitamin D, regulates absorption of calcium from the GI tract. Calcitonin serves as an inhibitory factor by suppressing osteoclast activity and stimulating calcium deposition into the bones.

The delicate balance maintained by these factors is altered in patients with cancer by two principal mechanisms: tumor production of humoral factors that alter calcium metabolism (humoral hypercalcemia) and by local osteolytic activity from bone metastases. Humoral hypercalcemia causes around 80% of all hypercalcemia cases and is primarily mediated by systemic secretion of PTH-related protein (PTHrP). This protein mimics the action of endogenous PTH on bones. Local osteolytic activity causes 20% to 30% of hypercalcemia cases, although local osteolytic activity may also have a humoral component. Local production of various factors directly stimulates osteoclastic bone resorption, which releases growth factors and cytokines (ie, transforming growth factor-β) that are necessary for tumor growth. Thus, these metastatic tumors perpetuate their own growth through this mechanism. Calcium is also released by the osteolytic activity, resulting in hypercalcemia. A third and less common mechanism is production of 1,25-dihydroxyvitamin D by tumor cells (usually lymphoma), which increases GI absorption of calcium and enhances osteoclastic bone resorption.

**TREATMENT**

**Desired Outcomes**

*The primary goal of treatment for hypercalcemia is to control the underlying malignancy. Therapies directed at lowering the calcium level are temporary measures that are useful until anticancer therapy begins to work. The goals of calcium-lowering therapy are to (a) lower the corrected calcium to normal levels, (b) regain fluid and electrolyte balance, (c) relieve symptoms, and (d) prevent life-threatening complications. Patients who are refractory to available therapies may have calcium-lowering therapy withheld (usually resulting in coma and death), which may be a humane approach.*

**General Approach to Treatment**

Therapeutic options for the treatment of hypercalcemia should be directed toward the level of corrected serum calcium and the presence of symptoms (Figure 99–4). Hypercalcemia may be classified as mild (corrected calcium equal to 10.5–11.9 mg/dL [2.63–2.98 mmol/L]), moderate (12–13.9 mg/dL [3.00–3.49 mmol/L]), and severe (greater than 14 mg/dL [3.50 mmol/L] or more). Adequate treatment of mild or asymptomatic hypercalcemia may be achieved on an outpatient basis with nonpharmacologic measures. Moderate to severe or symptomatic hypercalcemia almost always requires pharmacologic intervention.

**Nonpharmacologic Therapy**

Calciuric therapy in the form of hydration is a key component in the treatment of hypercalcemia, regardless of severity or presence of symptoms. Mild or asymptomatic patients may be encouraged to increase their oral fluid intake (3–4 L/day). Patients with moderate to severe or symptomatic hypercalcemia should receive normal saline at 200 to 500 mL/hour according to their dehydration and cardiovascular status. Patients should...
**Clinical Presentation and Diagnosis of Hypercalcemia**

**General**
- Presence of symptoms depends not only on the calcium level but the rapidity of onset
- Normal calcium level is 8.5 to 10.5 mg/dL (2.13–2.63 mmol/L) (varies by laboratory)
- Serum calcium level must be corrected for albumin level using the following formula:
  \[
  \text{Corrected calcium (mg/dL)} = \text{Serum calcium} + 0.8 (4 - \text{Serum albumin})
  \]
  or
  \[
  \text{Corrected calcium (mmol/L)} = \text{Serum calcium} + 0.02 (40 - \text{serum albumin})
  \]
- Five primary organ systems may be affected:
  - GI: anorexia, nausea, vomiting, constipation
  - Musculoskeletal: weakness, bone pain, fatigue, ataxia

**Laboratory Tests**
- Elevated corrected serum calcium level (≥ 10.5 mg/dL [2.63 mmol/L]), serum albumin, low to normal serum phosphate
- Patient may have elevated blood urea nitrogen and serum creatinine
- Elevated alkaline phosphatase may indicate bone destruction
- ECG may indicate prolonged PR interval, shortened QT interval, widened T wave

**Other Diagnostic Tests**
- Rule out other causes of hypercalcemia, including primary hyperparathyroidism, hyperthyroidism, vitamin D intoxication, chronic renal failure

**FIGURE 99–4.** Treatment algorithm for the hypercalcemia of malignancy.
be encouraged to ambulate as much as possible because immobility enhances bone resorption. Although calcium should be discontinued from parenteral feeding solutions, oral calcium supplementation minimally contributes to hypercalcemia unless it is mediated by vitamin D. In these cases, oral calcium should be discontinued. Finally, agents that may contribute to hypercalcemia (thiazide diuretics, vitamin D, lithium) or decrease renal function (NSAIDs) should be discontinued. Dialysis may be used in refractory cases or patients who cannot tolerate aggressive saline hydration.6

Pharmacologic Therapy

Multiple pharmacologic interventions are available for the treatment of hypercalcemia (Table 99–13). Furosemide 20 to 40 mg/day may be added to hydration after rehydration has been achieved to avoid fluid overload and enhance renal excretion of calcium. Although effective in relieving symptoms, hydration and diuretics are temporary measures that are useful until the onset of antiresorptive therapy; thus, hydration and antiresorptive therapy should be initiated simultaneously.36

- The antiresorptive therapy of choice for hypercalcemia of malignancy is a bisphosphonate. Because of poor oral bioavailability, only IV agents should be used. Pamidronate and zoledronic acid are most commonly used and are potent inhibitors of osteoclast activity.35 The bisphosphonates should be administered at diagnosis of hypercalcemia because of their delayed onset of action.

Calcitonin is the drug of choice in cases of emergent hypercalcemia (patients with life-threatening electrocardiographic [ECG] changes, arrhythmias, or central nervous system [CNS] effects) because of its rapid onset of action. Calcitonin inhibits osteoclast activity and decreases renal tubular calcium resorption. Corticosteroids are useful in patients with steroid-responsive malignancies, such as lymphomas or multiple myeloma, and may delay tachyphylaxis to calcitonin. Gallium nitrate is another treatment option, although the 5-day

### Table 99–13

| Treatment Options for Hypercalcemia of Malignancy |
|---|---|---|---|---|---|
| **Agent** | **Dosage** | **Onset** | **Duration** | **Reduction in Serum Calcium Concentration** | **Comments** |
| Calciuric therapy | IV normal saline | 200–500 mL/hour | 24–48 hours | 2–3 days | 0.5–2 mg/dL (0.13–0.50 mmol/L) | Avoid fluid overload, monitor electrolytes |
| Furosemide | 20–40 mg IV | 4 hours | 2–3 days | | Monitor for hypokalemia, dehydration |
| Antiresorptive therapy | Pamidronate | 60–90 mg IV over 2–24 hoursa | 24–72 hours | 3–4 weeks | > 1 mg/dL (0.25 mmol/L) | Nadir not seen until after 4–7 days; may cause fever, renal dysfunction; pamidronate less expensive |
| Zoledronic acid | 4 mg IV over 15 minutes | 24–48 hours | 4+ weeks | > 1 mg/dL (0.25 mmol/L) | Monitor for hyperglycemia, insomnia, immunosuppression |
| Prednisone (or equivalent) | 50–100 mg/day | 5–7 days | 3–4 days | 0.5–3 mg/dL (0.13–0.75 mmol/L) | |
| Calcitonin | 4–8 IU/kg SC or IM every 6–12 hours | 2–4 hours | 1–3 days | 2–3 mg/dL (0.50–0.75 mmol/L) | Salmon-derived formulation preferred; 1-unit test dose recommended; can be given in renal failure; may cause flushing, nausea |
| Gallium nitrate | 100–200 mg/m² | 24–48 hours | | | Do not administer if creatinine > 2.5 mg/dL (221 μmol/L); may cause renal failure |
| CIV daily for 5 days | | | | | |
| Denosumab | 120 mg SQ days 1, 8, and 15 the first month, then day 1 only | 48–96 hours | 4+ weeks | > 1 mg/dL (0.25 mmol/L) | Not renally cleared, may be used in patients with renal dysfunction, but reduce dose as increased risk of hypocalcemia in renally impaired |

CIV, continuous intravenous infusion; IM, intramuscular; IV, intravenous; SC, subcutaneous.
a60 mg of pamidronate may be used in smaller patients or in patients with mild hypercalcemia or renal dysfunction. May use longer infusion time in patients with renal dysfunction.

frequently affected because they frequently have aggressive malignancies. TLS is typically induced by cancer treatment modalities, including chemotherapy, hormonal therapy, radiation, biologic therapy, or corticosteroids, although some patients may present spontaneously before treatment.

PATHOPHYSIOLOGY

Patients with TLS experience a wide range of metabolic abnormalities. The massive cell lysis that occurs leads to the release of intracellular electrolytes, resulting in hyperkalemia and hyperphosphatemia. High concentrations of phosphate bind to calcium, leading to hypocalcemia and calcium phosphate precipitation in the renal tubule. Purine nucleic acids are also released, which are subsequently metabolized to uric acid through multiple enzyme-mediated steps (Figure 99–5). Uric acid is poorly soluble at urinary acidic pH, leading to crystallization in the renal tubule. The precipitation of uric acid and calcium phosphate leads to metabolic acidosis, facilitating further uric acid crystallization. Acute renal failure may be the end result.

TREATMENT

Desired Outcomes

The primary goals of management of TLS are (a) prevention of renal failure and (b) prevention of electrolyte imbalances. Thus, the best treatment for TLS is prophylaxis to enable delivery of cytotoxic therapy for the underlying malignancy. For patients who present with or develop TLS despite prophylaxis, treatment goals include (a) decreasing uric acid levels, (b) correcting electrolyte imbalances, and (c) preventing compromised renal function. These goals should be achieved in a cost-effective manner.

General Approach to Treatment

Prevention of TLS is generally achieved by increasing the urine output and preventing accumulation of uric acid. Prophylactic strategies should begin immediately upon presentation, preferably 48 hours prior to cytotoxic therapy. Treatment modalities primarily increase uric acid solubility, maintain electrolyte balance, and support renal output.

Nonpharmacologic Therapy

- Vigorous IV hydration with dextrose 5% in water with half normal saline at 3 L/m²/day to maintain a urine output greater than or equal to 100 mL/m²/hour is necessary unless the patient presents with acute renal dysfunction. Alkalinization of the urine to a pH greater than or equal to 7.0 with 50 to 100 mEq/L (50–100 mmol/L) of sodium bicarbonate has been used to promote uric acid solubility for excretion. This measure is controversial because xanthine and hypoxanthine are less soluble at alkaline pH, potentially leading to crystallization, especially during and after allopurinol therapy (see Figure 99–5).

Medications that increase serum potassium (angiotensin-converting enzyme inhibitors, spironolactone) or block tubular resorption of uric acid (probenecid, thiazides) should be discontinued. Nephrotoxic agents such as amphotericin B or aminoglycosides should also be avoided. Hemodialysis may be required in patients who develop anuria or uncontrolled hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, or volume overload.

Pharmacologic Therapy

Pharmacologic prevention strategies for TLS are aimed at low- and high-risk patients (Figure 99–6). Allopurinol is an xanthine oxidase inhibitor that is used for prevention only because it has no effect on preexisting elevated uric acid. Rasburicase is a recombinant form of urate oxidase that is useful for both prevention and treatment, but is expensive (Table 99–15). Although the approved dose is 0.2 mg/kg/day for 5 days, recent studies using abbreviated courses (1–3 days) and/or lower doses (0.05–0.1 mg/kg/day) may be equally efficacious with significantly reduced cost. Because uric acid levels generally fall within 4 hours of the first dose, one dose may be administered with frequent, serial monitoring of the uric acid level for repeat dosing if necessary (see Figure 99–6). Of note, rasburicase continues to break down uric acid in blood samples drawn from patients. This can be avoided by immediately placing the sample in an ice bath for processing to avoid falsely lowered uric acid levels.
Low Risk

- Normal uric acid level (< 10 mg/dL)
- Solid tumor, Hodgkin disease, chronic myeloid leukemia
- WBC ≤ 50,000/mm³
- LDH ≤ two times normal
- Mild cytotoxic therapy intensity
- No tumor infiltration in kidneys

Oral allopurinol (IV if unable to tolerate or take oral meds)

Normal uric acid level

Prophylaxis

Rasburicase dose prior to cytotoxic therapy

High Risk

- Elevated uric acid level (≥ 10 mg/dL)
- Burkitt lymphoma, ALL, or AML
- WBC > 50,000/mm³
- LDH > two times normal
- Aggressive chemotherapy
- Kidney tumor infiltration

Elevated uric acid level

Continue through cytotoxic therapy

Uric acid levels increase

Administer daily until normalized

Monitor uric acid every 6 hours

Do not continue

Clinical Presentation and Diagnosis of TLS

General
- Patients present primarily with laboratory abnormalities.
- Normal uric acid is equal to 2 to 8 mg/dL (119–476 μmol/L).
- Most often occurs within 12 to 72 hours of initiation of cytotoxic therapy.

Signs and Symptoms
- Most patients are asymptomatic.
- Patients may develop edema, fluid overload, and oliguria, which may progress to anuria with acute renal failure.
- Some patients with hyperuricemia may have nausea, vomiting, and lethargy.
- Hyperkalemia: lethargy, muscle weakness, paresthesia, ECG changes, bradycardia.
- Hypocalcemia: muscle cramps, tetany, irritability, paresthesias, arrhythmias.

Laboratory Tests (Adults)
- Serum uric acid level greater than 8 mg/dL (476 μmol/L).
- Serum potassium greater than 6 mEq/L (6 mmol/L).
- Serum phosphorus greater than 4.5 mg/dL (1.45 mmol/L).
- Serum calcium less than 7 mg/dL (1.75 mmol/L).
- Elevated blood urea nitrogen and creatinine once renal dysfunction develops.
- A change of greater than 25% from baseline in the above laboratory values.

Patient Care Process: TLS

Patient Assessment:
- Assess patient’s medical history for risk factors of TLS, including cancer and chemotherapy history.
- Assess patient for signs/symptoms of TLS, including uremia, visual disturbances, muscle cramping, etc.
- Order laboratory tests: Uric acid, potassium, phosphate, calcium, electrolytes, renal function tests.

Therapy Evaluation:
- Monitor daily at-risk patients who present with normal laboratory values daily for serum uric acid, electrolytes, renal function tests.
- Monitor for signs of fluid overload during aggressive hydration.

Care Plan Development:
- Initiate allopurinol.

Follow-Up Evaluation:
- Continue hydration and prophylaxis until 2 to 3 days after cytotoxic therapy.
- In patients undergoing urinary alkalinization with sodium bicarbonate, assess the urine pH every 6 hours and maintain above 7.

OUTCOME EVALUATION

The most successful outcome in TLS is prevention. If the condition is not able to be prevented, the goal of therapy is to avoid renal failure and quickly return electrolytes to normal.

Abbreviations Introduced in This Chapter

ANC Absolute neutrophil count
AWP Average wholesale price
BMT Bone marrow transplantation
BUN Blood urea nitrogen
CI V Continuous intravenous infusion
CSF Colony-stimulating factor
G6PD Glucose-6-phosphate dehydrogenase
ICP Intracranial pressure
IV Intravenous
LDH Lactate dehydrogenase
NSAID Nonsteroidal anti-inflammatory drug
NSCLC Non–small cell lung cancer
PCP Pneumocystis jiroveci pneumonia (formerly Pneumocystis carinii)
PTHR P Parathyroid hormone–related protein
SCLC Small cell lung cancer
SVCS Superior vena cava syndrome

Electrolyte disturbances that develop in patients with TLS should be aggressively managed to avoid renal failure and cardiac sequelae. One exception pertains to the use of IV calcium for hypocalcemia. Adding calcium may cause further calcium phosphate precipitation in the presence of hyperphosphatemia and should be used cautiously.

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List appropriate indications for parenteral nutrition (PN) in adult patients.
2. Describe the components of PN and their role in nutrition support therapy.
3. List key elements of nutrition assessment and factors considered in assessing an adult patient’s nutritional status and nutritional requirements.
4. Explain the pharmaceutical and compounding issues with PN admixtures.
5. Develop a plan to design, initiate, and adjust a PN formulation for an adult patient based on patient-specific factors.
6. Describe the etiology and risk factors for PN macronutrient-associated complications in adult patients receiving PN.
7. Describe the etiology and risk factors for refeeding syndrome.
8. Design a plan to assess the efficacy and monitor for safety, as well as fluid, electrolyte, vitamin, and trace element abnormalities in adult patients receiving PN.

INTRODUCTION

Malnutrition in hospitalized patients is associated with significant complications (eg, increased infection risk, poor wound healing, prolonged hospital stays, increased mortality), especially in surgical and critically ill patients. Maintaining adequate nutritional status, especially during periods of illness and metabolic stress, is an essential part of patient care. Nutrition support therapy refers to the administration of nutrients via the oral, enteral, or parenteral route for therapeutic purposes. Parenteral nutrition (PN), also called total parenteral nutrition (TPN), is the intravenous (IV) administration of fluids, macronutrients, electrolytes, vitamins, and trace elements for the purpose of weight maintenance or gain, to preserve or replete lean body mass and visceral proteins, and to support anabolism and nitrogen balance when the oral or enteral route is not feasible or adequate. PN is a potentially lifesaving therapy in patients with intestinal failure but can be associated with significant complications.

Desired Outcomes and Goals

The goals of nutrition support therapy include:

- Correction or avoidance of fluid and electrolyte abnormalities
- Correction or avoidance of vitamin and trace element abnormalities
- Improving clinical outcomes

Indications for PN

PN can be a lifesaving therapy in patients with intestinal failure, but the oral or enteral route is preferred when providing nutrition support therapy. Compared with PN, enteral nutrition is associated with a lower risk of hyperglycemia and fewer infectious complications (eg, pneumonia, intra-abdominal abscess, catheter-related infections). However, if used appropriately PN can be safe and effective and can improve nutrient delivery. Indications for PN are listed in Table 100–1.

PN should be reserved for patients with altered intestinal function or absorption or when the gastrointestinal (GI) tract cannot be used. The anticipated duration of adequate PN therapy should be at least 5 to 7 days because shorter durations are unlikely to have a beneficial effect on a patient’s clinical and nutritional outcomes but may increase infection risk.

PN COMPONENTS

PN should provide a balanced nutrition formula, including macronutrients, micronutrients, fluids, and electrolytes. Macronutrients, including amino acids, dextrose, and IV fat emulsions (IVFE), are important sources of structural and energy-yielding substrates. In a balanced PN formulation for adult patients, total daily calories are typically provided as 10% to 20% from amino acids, 20% to 30% from dextrose, and 40% to 50% from fat.
Indications for Parenteral Nutrition in Adults

- Bowel obstruction
- Functional (e.g., ileus, colonic pseudo-obstruction)
- Diffuse peritonitis
- Adult patients with < 50 cm of small bowel if the colon is intact
- Adult patients with < 100 cm of small bowel distal to the ligament of Treitz without a colon
- Major small bowel resection (e.g., short-bowel syndrome)
- Severe intractable vomiting
- Physical or mechanical (e.g., tumor compressing intestinal lumen)
- Preoperative nutrition support in patients with moderate to severe malnutrition who cannot tolerate EN and in whom surgery can be delayed safely for at least 7 days
- In critically ill patients without malnutrition who cannot receive oral or EN in the first 7 days of ICU admission, PN should only be initiated after the first 7 days of admission and if oral or EN is still not feasible

Patient Encounter, Part 1

PG is a 59-year-old man with a history of hypertension and colon cancer, status post colon resection and colostomy, followed by chemotherapy, and subsequent colon reanastomosis. He was admitted approximately 2 weeks ago with signs and symptoms consistent with a bowel obstruction. He was taken to the OR for an exploratory laparotomy and found with multiple adhesions causing small bowel obstructions in two locations. He underwent a small bowel resection (jejunum) and extensive lysis of adhesions, and he was discharged 8 days ago. PG is readmitted with foul-smelling drainage from his surgical incision for 2 days along with nausea, decreased appetite, and decreased oral intake for the past 2 to 3 days. Since his diagnosis of colon cancer he has had weight loss, poor oral intake, and malnutrition. Most recently with his bowel obstructions and current symptoms, he reports an unintentional weight loss of about 10 lb (4.5 kg) over the past 4 to 5 weeks.

PMH: Hypertension × 10 years
Colon cancer diagnosed 2 years ago, status post colectomy, chemotherapy, and reanastomosis
Malnutrition since diagnosis of colon cancer

Past Surgical History
Colon resection with colostomy, colostomy takedown with reanastomosis 2 years ago
Exploratory laparotomy with small bowel resection and lysis of adhesions due to small bowel obstruction (greater than 100 cm of small intestine remaining, ileocecal valve intact, part of the colon remaining)
FH: Mother and father: hypertension; grandmother: chronic constipation
SH: 30 pack–year smoking history, quit 2 years ago; patient reports only occasional alcohol; no recreational drugs

Is PN therapy indicated in this patient? Why or why not?
patients with acute kidney injury contain higher proportions of essential amino acids. Formulations for patients with hepatic encephalopathy contain higher amounts of branched-chain and lower amounts of aromatic amino acids. However, these specialized formulations have not been clearly shown to improve patient outcomes and therefore are not routinely used in clinical practice. Crystalline amino acid solutions have an acidic pH (pH ≈ 5–7) and may contain inherent electrolytes (eg, sodium, potassium, acetate, phosphate).

**Dextrose**

**KEY CONCEPT** Dextrose (D-glucose) is the major energy source, and it is vital for cellular metabolism, body protein preservation, and cellular growth. The central nervous system, red blood cells, and the renal medulla depend primarily on dextrose as a source of energy.

Typically a 70% (70 g/100 mL) parenteral dextrose (hydrous dextrose) stock solution is used in PN compounding (a 50% stock solution is also available). Hydrous dextrose provides 3.4 kcal/g (14.2 kJ/g). A dextrose infusion rate of 2 mg/kg/min in adult patients is typically sufficient to suppress gluconeogenesis and spare body proteins from being used for energy. Dextrose infusion rate in hospitalized adult patients generally should not exceed 4 to 5 mg/kg/min.² Use adjusted body weight (AdjBW) rather than actual weight in obese patients when calculating the dextrose infusion rate.

**Intravenous Fat Emulsions**

**KEY CONCEPT** Intravenous fat emulsions (IVFE) are provided to prevent or treat essential fatty acid deficiency (EFAD) and as an energy source. IVFE particles consist of a triglyceride core surrounded by a layer of egg phospholipids (emulsifiers). These particles carry a negative charge on their surface that creates repulsive electrostatic forces between droplets and maintains the stability of the emulsion. Glycerol is added to adjust the tonicity, and water is the solvent. The negative charges on the surface of lipid particles can be disrupted by cations, especially divalent cations such as calcium, magnesium, and iron² and extreme pH changes, particularly acidic pH. Cremaing, coalescence, and oiling out are signs of a destabilized IVFE. If there is any apparent disruption to IVFE, it should not be infused into a patient.

IVFEs differ in their concentration (10%, 20%, and 30%), caloric density by volume, natural source of fats/triglycerides, and ratio of phospholipids to triglycerides (PL:TG ratio). Table 100–2 shows a comparison of standard commercially available IVFEs in the United States. Most standard IVFEs marketed in the United States contain long-chain triglycerides derived from soybean oil. Because of the addition of phospholipid emulsifiers and glycerol, the caloric density of IVFEs by weight is approximately 10 kcal/g (42 kJ/g; dietary fat is ~9 kcal/g [38 kJ/g]). Compared with the 10% IVFE, 20% and 30% IVFEs have a lower PL:TG ratio and lower phospholipid content, and this translates to better plasma clearance compared to the 10% IVFE.⁸ The 30% IVFE is only approved by the Food and Drug Administration (FDA) for infusion in a total nutrient admixture (TNA) and should not be infused directly into patients nor via Y-site injection.

IVFE particles are hydrolyzed in the bloodstream by lipoprotein lipase to release free fatty acids and glycerol. Fatty acids are taken up into adipose tissue for storage (triglycerides), oxidized to energy in various tissues (eg, skeletal muscles), or recycled in the liver to make lipoproteins.

The essential fatty acids that cannot be produced endogenously in humans are linoleic acid (C18:2 n-6) and α-linolenic acid (C18:3 n-3) (long-chain triglycerides). Arachidonic acid (C20:4 n-6) is also essential but can be synthesized in vivo from linoleic acid. Adult patients should receive a minimum of 2% to 4% of total daily calories as linoleic acid and 0.25% to 0.5% of total daily calories as α-linolenic acid to prevent essential fatty acid deficiency.⁴ This can be achieved by providing a minimum of ~500 mL of 20% (100 g) IVFE per week (in a single dose, or divided doses [eg, 250 mL twice a week]) for most adult patients. The typical daily dose of IVFE in adults is about 0.5 to 1 g/kg/day (or ~15%–30% of total daily calories). The maximum dose is 2.5 g/kg/day or 60% of total daily calories, although doses this high are rarely used in practice and should be avoided to prevent complications.

Biochemical evidence of essential fatty acid deficiency (eg, decreased serum linoleic acid, α-linolenic acid, and arachidonic acid concentrations; elevated mead acid concentrations; elevated

PL, phospholipid; TG, triglyceride.

¹¹kcal/mL is equivalent to 4.19 kJ/mL.
triene-to-tetraene ratio) can develop in well-nourished adult patients within about 2 to 4 weeks of receiving PN without IVFE, and clinical manifestations (eg, dry skin, skin desquamation, hair loss, hepatomegaly, anemia, thrombocytopenia, poor wound healing) may appear after an additional 1 to 2 weeks, although skin changes may take longer to develop.\textsuperscript{9}

Complications and safety concerns related to the administration of IVFE include severe hypertriglyceridermia, infection, anaphylactic reactions, and infusion-related reactions. Patients with a history of hypertriglyceridermia, acute kidney injury, chronic kidney disease, hepatic dysfunction, severe metabolic stress, or pancreatitis (particularly if caused by hypertriglyceridermia) may have reduced lipid clearance and be at risk of developing hypertriglyceridermia. IVFE should be withheld in adult patients with serum triglyceride concentrations exceeding 400 mg/dL (4.52 mmol/L).

IVFEs support the growth of bacterial and fungal pathogens, but bacterial growth is slower in TNA than in IVFE alone\textsuperscript{10,11} due to the acidic pH of amino acid solutions and higher osmolarity of PN formulations. Because of this, the Centers for Disease Control and Prevention (CDC) recommends that TNA infusions be completed within 24 hours of initiation. Recent guidelines suggest that IVFE infusion should be completed within 12 to 24 hours if administered from the original manufacturer container, but completed within 12 hours if repackaged/transfered to another container and infused separately from a 2-in-1 PN admixture (although repackaging/transfer to another container was not recommended).\textsuperscript{12} There is still debate about the optimal approach when infusing IVFE separately from a 2-in-1 PN admixture.

PN infusion lines must contain an appropriate filter (a 0.22-μm filter or a 1.2-μm filter). A 0.22-μm filter cannot be used on the TNA or IVFE infusion line because the average size of IVFE particles is approximately 0.4- to 0.5-μm (which cannot pass through the smaller filter intact and will clog the filter).

Patients with an allergy to eggs or specific legumes (eg, soy beans, broad beans, lentils) may develop cross-allergic reactions to IVFE. Rarely, infusion-related adverse effects may occur with rapid infusion, including fever, chills, headache, palpitations, dyspnea, chest tightness, and nausea. Extending the IVFE infusion time (eg, over 12–24 hours) can minimize infusion-related adverse events and improves IVFE clearance. Infusion rate of IVFE should not exceed 0.12 g/kg/hour.\textsuperscript{6}

Recently the FDA approved Clinolipid for use in adult patients. Clinolipid is a mixture of refined olive and soybean oils in a 4:1 ratio. This combination reduces the amount of omega-6 fatty acids in the IVFE. This may have a positive impact on immune function and inflammation, but this is theoretical and this product has not been demonstrated to improve patient outcomes. The exact role of this IVFE product in patient care is not yet known.

**Fluid**

**Key Concept** Parenteral nutrition should not be used to treat acute fluid abnormalities. PN should be adjusted to provide maintenance fluid requirements and to minimize worsening of underlying fluid disturbances, taking into account other fluids the patient is receiving. Daily maintenance fluid requirements for adults can be estimated with the following equation:

\[
\text{Total daily fluid requirements} = 1,500 \text{ mL} + (20 \text{ mL/kg} \times [\text{Wt (kg)} - 20])^\dagger
\]

\dagger For elderly patients (eg, greater than 60 years old), use 15 mL/kg for every kilogram above 20 kg.

For patients with significant fluid deficits, it is safer and more cost effective to correct fluid abnormalities using standard IV fluids (eg, 0.9% sodium chloride in water, dextrose 5% and sodium chloride 0.45% in water, lactated Ringer solution). Minimizing PN fluid volume may be indicated in patients with fluid overload, patients with oliguric or anuric acute kidney injury, or those with congestive heart failure or symptomatic pleural effusion. It is reasonable to provide total daily fluid requirements (maintenance requirements and replacement for GI or other abnormal losses) in the PN admixture in patients who require long-term PN. However, diluting a PN admixture can affect its physical and chemical properties (eg, IVFE stability, calcium–phosphate solubility/compatibility); therefore, stability and compatibility data must be confirmed before diluting a PN admixture.

**Micronutrients**

**Key Concept** Electrolytes, vitamins, and trace elements are essential for numerous biochemical and metabolic functions and should be added to PN daily unless otherwise not indicated.

**Electrolytes**

Electrolytes are essential for many metabolically important and homeostatic functions, including enzymatic and biochemical reactions, maintenance of cell membrane structure and function, neurotransmission, hormone function, muscle contraction, cardiovascular function, bone composition, and fluid homeostasis. The causes of electrolyte abnormalities in patients receiving PN may be multifactorial, including altered absorption and distribution; excessive or inadequate intake; altered hormonal, neurologic, and homeostatic mechanisms; altered excretion and losses via the GI tract (eg, gastric, diarrhea, ostomy, enterocutaneous fistula) and kidneys; changes in fluid status and fluid shifts; and medication therapies. PN should not be used to treat acute electrolyte abnormalities but should be adjusted to meet maintenance requirements and to minimize worsening of underlying electrolyte disturbances.

Electrolytes that are included routinely in PN admixtures include sodium, potassium, phosphorus (as phosphate), calcium, magnesium, chloride, and acetate. Always assess the patient’s kidney function when determining electrolyte doses in PN admixtures. Typical daily electrolyte maintenance requirements for adults with normal kidney function are listed in Table 100–3.\textsuperscript{6,13} For additional details regarding management of fluid, electrolyte and acid–base disorders refer to Chapters 27 and 28.

**Calcium-Phosphate Solubility**

The FDA published a safety alert in response to two deaths from microvascular pulmonary emboli associated with calcium–phosphate precipitation in PN.\textsuperscript{14} Because calcium and phosphate can bind and precipitate in solution, caution must be exercised when mixing these two electrolytes in PN admixtures. Several factors can affect calcium–phosphate solubility, including:

- **Amino acid concentration.** Primary factor that affects pH of the PN admixture. The pH of amino acid stock solutions may vary between commercial products. In general, the higher the final amino acid concentration, the lower the pH of the final admixture. Phosphates can also bind with amino acids, leaving fewer phosphates available to bind with calcium.

- **pH.** Largely affected by the amino acid brand and concentration, to a lesser extent by the dextrose concentration; the lower the solution pH, the less chance for calcium–phosphate precipitation. Monobasic phosphates...
predominate at low pH, leaving fewer free dibasic phosphates for precipitation with divalent calcium; monobasic calcium phosphate is more soluble than dibasic calcium phosphate.

- **Calcium salt.** Calcium gluconate is the preferred calcium salt in PN because it has a lower dissociation constant in solution with less free calcium available at a given time to bind phosphate.

- **Time.** The longer calcium and phosphate are in solution, the more calcium and phosphate will dissociate over time and increase the risk for calcium–phosphate precipitation.

- **Temperature.** As temperature increases, more calcium and phosphate dissociate and increase the risk of calcium–phosphate precipitation.

- **Order of mixing.** Calcium and phosphate should not be added simultaneously or consecutively when compounding PN admixtures (eg, add phosphate first, then add other PN components, and then add calcium near the end of compounding). The volume in the PN admixture at the time calcium is added (not necessarily the final volume) must be used to determine the maximum calcium that can be added.

When compounding PN admixtures, use calcium–phosphate solubility curves (based on the specific brand and final concentration of amino acids and dextrose) to determine safe and appropriate calcium and phosphate concentration limits.

**► Acetate**

Acetate is converted to bicarbonate at a 1:1 molar ratio, and this conversion appears to occur mostly outside the liver. Bicarbonate should never be added to or coinfused with PN admixtures. This can lead to the release of carbon dioxide and result in the formation of insoluble calcium or magnesium carbonate salts.

**► Vitamins**

- Water-soluble and fat-soluble vitamins in the parenteral multivitamin products are essential cofactors for numerous biochemical reactions and metabolic processes. Parenteral multivitamins are added daily to the PN admixture. Water-soluble vitamins, with the exception of vitamin $B_{12}$, are generally readily excreted and not stored in the body in significant amounts. Deficiencies of water-soluble vitamins can occur rapidly in the absence of adequate vitamin supplementation in PN. Severe refractory lactic acidosis and deaths were reported in patients who received PN without added thiamine. Thiamine is an essential cofactor in carbohydrate metabolism (via the tricarboxylic acid cycle). Deficiency of thiamine pyrophosphate prevents the formation of acetyl-CoA from pyruvate, which is instead converted to lactate via anaerobic metabolism, resulting in lactic acidosis. Parenteral multivitamin products contain 150 mcg of vitamin K in accordance with FDA recommendations. A parenteral adult multivitamin formulation is available without vitamin K, but standard compounding of PN formulations should include a product that contains vitamin K unless otherwise indicated. Patients with chronic kidney disease are at risk for vitamin A accumulation and potential toxicity. Serum vitamin A concentrations should be measured in patients with chronic kidney disease when vitamin A accumulation is a concern. Not all vitamins are available individually in injectable form, so restricting vitamin A may compromise provision of other vitamins.

**► Trace Elements**

- Trace elements are essential cofactors for numerous biochemical processes. Trace elements added routinely to PN include zinc, selenium, copper, manganese, and chromium (Table 100–4). Various individual and multi-ingredient parenteral trace element formulations can be added to PN admixtures. Trace element supplementation in PN should be individualized, especially for long-term PN-dependent patients, rather than using a fixed dose of multitrace element products. Zinc is important for wound healing, and patients with high-output enterocutaneous fistulas, diarrhea, burns, and large open wounds may require additional zinc supplementation. Patients may lose as much as 12 to 17 mg zinc/L of GI output (eg, diarrhea, enterocutaneous fistulas)

Requirements may vary based on patients' kidney function, liver function, gastrointestinal losses, nutritional status, specific metabolic and endocrine functions, serum levels, and medication therapy. Contamination of some PN ingredients with trace elements (e.g., chromium, manganese) can contribute significantly to the total amount the patient receives. Monitor serum trace element levels in patients receiving long-term PN therapy.

**Histamine-2 Receptor Antagonists**

Intravenous histamine-2 receptor antagonists such as ranitidine, famotidine, and cimetidine are compatible with PN admixtures and can be added when indicated.

**Heparin**

Heparin (0.5–1 unit/mL of final PN volume) has been added to PN admixtures for three reasons:

- Maintain catheter patency (although this effect is debated)
- Reduce thrombophlebitis (with PPN infusion)
- Enhance lipid particle clearance as a cofactor for the lipoprotein lipase enzyme (temporary effect, and data are limited)

The benefits and necessity of adding heparin to PN are unclear, and this practice is becoming less common in adult patients. There are also concerns about the stability and compatibility of IVFE with heparin. Heparin should be omitted in patients with active bleeding, thrombocytopenia, heparin-induced thrombocytopenia (HIT), or heparin allergy.

**Human Albumin**

Human albumin is a colloid used as a plasma volume expander and not a source of nutrition. Albumin should not be added to the PN admixture and should be administered separately from PN.

**Parenteral Iron**

Chronic PN-dependent patients are at risk for iron-deficiency due to underlying clinical conditions and the lack of regular iron supplementation in PN. Parenteral iron dextran should be used with caution due to its infusion-related adverse effects. Iron dextran is compatible with 2-in-1 PN formulations, but is not commonly added to PN admixtures due to incompatibility with IVFE; Other parenteral iron formulations (e.g., iron sucrose, ferric gluconate) should NOT be added to PN admixtures due to a lack of compatibility data.

**NUTRITION ASSESSMENT AND NUTRIENT REQUIREMENTS**

A nutrition assessment is used to determine a patient’s nutritional status, identify patients with malnutrition, identify risk factors for nutrition-related problems, identify or rule out specific nutrient deficiencies, and determine nutrient requirements. A complete description of nutrition assessment is beyond the scope of this chapter, and a nutrition assessment should be completed by a health care professional with appropriate training and expertise (e.g., dietitian, nutrition-certified pharmacist). Briefly, key components of a nutrition assessment include...
• Patient history
• Physical assessment, including height, weight, ideal body weight (IBW), body mass index (BMI = weight [kg]/height [m²]), and recent weight changes (intentional or unintentional)
• BMI is a vague indicator of total body fat mass in adults and is not an indicator of body nutrient stores. BMI categories do not account for frame size, muscle mass, bone, and water weight. Classifications of BMI:
  • Underweight, less than 18.5 kg/m²
  • Normal, 18.5 to 24.9 kg/m²
  • Overweight, 25 to 29.9 kg/m²
  • Obese, more than or equal to 30 kg/m²
• Degree of malnutrition can be classified by assessing the percentage of unintentional weight loss or percentage of usual weight. For example:
  • Severe malnutrition: greater than 5% weight loss within 1 month or greater than 10% weight loss over 6 months;
  • Moderate malnutrition: 5% to 10% weight loss over 6 months;
  • Mild malnutrition/well-nourished: less than 5% weight loss over less than or equal to 6 months
• Anthropometrics and physical examination of the musculoskeletal system (eg, biceps, triceps, quadriceps, temporalis, deltoid, and interosseous muscles) for loss of muscle mass or decreased grip strength, and examination of the skin and mucous membranes for abnormalities (eg, dry or flaky skin, bruising, edema, ascites, poorly healing wounds) and loss of subcutaneous fat
• Changes in eating habits, GI function, and associated GI symptoms
• Presence and severity of underlying and concurrent disease(s)
• Serum visceral protein concentrations (eg, albumin, prealbumin). Hypoalbuminemia at baseline or before hospitalization may indicate malnutrition, and severe hypoalbuminemia may be associated with poor outcomes. Serum albumin and prealbumin are negative acute phase proteins and therefore are not sensitive or specific indicators of nutritional status and protein stores in patients under metabolic stress or with evidence of inflammatory response (eg, postsurgery, organ failure, severe burns, trauma, sepsis). Measuring serum C-reactive protein (CRP) may help assess inflammatory response (eg, CRP greater than 2.5 mg/dL [25 mg/L]). Synthesis and distribution of albumin and prealbumin may be altered, and serum concentrations are affected by non-nutritional factors, including hydration status, kidney function, and liver function. Because prealbumin has a shorter half-life (~2 days) than albumin (~20 days), serum prealbumin concentrations may be measured usually once weekly to help evaluate the net anabolism in response to nutrition support therapy in the absence of acute stress/inflammation
• Serum concentrations of vitamins, trace elements, and iron studies as indicated

After performing a nutrition assessment, estimate the patient’s daily energy and protein requirements (Table 100–5). Indirect calorimetry involves measuring the volumes of oxygen consumption (VO₂) and carbon dioxide production (VCO₂) to determine the resting metabolic rate (RMR) or resting energy expenditure (REE) and respiratory quotient (RQ = VCO₂/VO₂).

The REE or RMR is the amount of calories required during 24 hours by the body in a nonactive state and is approximately 10% higher than the basal energy expenditure (BEE, metabolic activity required to maintain life) as it adjusts for the thermic effect of food and awake state. Critically ill patients may have variable energy expenditure (EE), and indirect calorimetry is a valuable tool in assessing EE in these patients. Indirect calorimetry requires specific equipment and trained personnel and therefore is not feasible in all settings.

More than 200 equations and derivations have been developed to predict EE for adults. The Harris-Benedict equations, Penn State equations (for nonobese critically ill patients receiving mechanical ventilation), and Mifflin-St. Jeor equations (for nonobese and obese noncritically ill patients) are some of the most widely used, and they take into account several variables (depending on the equation) including a patient’s sex, weight, height, age, and mechanical ventilation data to determine the BEE. A “stress” or “injury” factor is sometimes applied to estimate the daily total EE (TEE), although there is debate about the appropriateness and validity of this approach. Daily energy requirements are about 100% to 130% of the RMR with adequate protein intake. Alternatively, EE can be estimated based on EE per body weight (ie, kilocalories per kilogram or in kilojoules per kilogram). However, dry weight or hospital admission weight should be used, and this estimation may not be appropriate in obese or elderly patients. There is debate over the best method to estimate energy requirements for obese patients. Indirect calorimetry would be the preferred method but may not always be available. Several equations have been developed to estimate EE in obese patients. Although there is no consensus on the weight used to estimate EE in obese patients, it is reasonable to use an AdjBW in obese patients to avoid overfeeding. AdjBW can be calculated with 25% to 50% of the difference between the actual weight and IBW added to the IBW. Using a 25% difference in calculating the AdjBW further avoids overfeeding when estimating energy requirements:

\[
\text{AdjBW} = \text{IBW} + (0.25 \times [\text{Actual weight} – \text{IBW}])
\]

Hypocaloric feeding is another approach for nutrient dosing in obese critically ill patients (discussed as follows).

Amino acid requirements are based on the patient’s nutritional status, clinical condition(s), kidney function, and liver function. Amino acids are needed in adequate amounts to facilitate anabolism, restore lean body mass, or promote wound healing while avoiding adverse effects from excessive amino acid loading (eg, azotemia). No evidence-based data are available confirming the optimal body weight (actual, ideal, or adjusted) to use for dosing amino acids in adult patients. It is suggested to dose amino acids based on actual body weight for normal body sized or malnourished adult patients (ie, when actual weight is at or below IBW) and based on IBW or AdjBW for obese patients.

Hypocaloric nutrition support is an approach to dosing nutrition therapy for obese patients (BMI greater than or equal to 30 kg/m² or actual weight greater than 130% of IBW). Hypocaloric feeding involves providing high doses of protein (greater than or equal to 2–2.5 g/kg IBW/day) to support anabolism with lower amounts of total calories (average ~11–14 kcal/kg actual weight/day [~46–59 kJ/kg actual weight/day] or ~22–25 kcal/kg IBW/day [~92–105 kJ/kg IBW/day]) with primary goals to promote net protein anabolism and avoid hyperglycemia or exacerbation of metabolic stress in critically ill patients.219 Other benefits could include avoiding fat weight gain
or promoting fat weight loss. Most data with hypocaloric feeding are in critically ill adult patients, but this approach has been used in other patients. Hypocaloric feeding should not be used in patients with kidney or liver dysfunction. Also, the optimal safe duration of hypocaloric feeding is unknown.

Permissive underfeeding refers to providing a lower calorie nutrition support regimen to critically ill adult patients for a short period of time during the initial phase of high metabolic stress. The aims of permissive underfeeding are to avoid the burden of caloric intake on worsening metabolic stress and the negative effects of carbohydrate loading and associated hyperglycemia, increased carbon dioxide production, and fat accumulation. Typically, a permissive underfeeding PN regimen provides about 60% to 80% of daily energy requirements. Because the optimal amounts of calories for critically ill patients is not well defined, strong clinical evidence to support the use of permissive underfeeding is also lacking. Furthermore, severe underfeeding should be avoided because it can result in energy deficit to the patient with the consequences of increased infectious complications with negative outcomes.

### PARENTERAL NUTRITION SAFETY

Serious and sometimes fatal adverse events have occurred with inappropriate use of PN. Shortages of key PN components have also presented challenges to meet nutritional needs of patients requiring PN therapy. The American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) has published several key PN safety documents, including comprehensive safe practice guidelines, PN safety recommendations, and revised guidelines that address PN ordering, order review, compounding, labeling, and dispensing. A.S.P.E.N. has also provided guidance for managing shortages of PN components. These are essential resources for pharmacists and other health care professionals for the safe and efficacious use of PN therapy, and they represent the standards of practice as related to PN prescribing, compounding, stability, compatibility, labeling, administration, and quality assurance. There are several key points and recommendations.
in these documents to improve the safety of the PN use process, including:

- Adopting published guidelines and literature.
- Developing standardized processes for PN prescribing, order verification, compounding, labeling, dispensing, administering, and monitoring.
- Developing PN-specific policies and procedures.
- Develop education and competency assessments at least annually for all health care professionals involved in the PN use process.
- Optimizing computerized prescriber order entry (CPOE) and clinical decision support for PN orders.
- Build, test, and heed clinical decision support warnings in CPOE systems and in automated compounding devices.
- Avoiding use of handwritten PN orders and eliminate transcription of PN orders.
- Matching templates between ordering/CPOE, compounding software/automated compounding devices, and PN labels.
- PN use process and development policies, procedures, education, and competencies should include health care professionals with expertise in nutrition support, preferably from multiple disciplines.

Although application of these guidelines is voluntary, health care professionals who are involved in prescribing, compounding, dispensing, administering, and monitoring PN therapy should review and apply them to their practice.

**PREPARING THE PN PRESCRIPTION: ADMINISTRATION, COMPOUNDING, AND PHARMACEUTICAL ISSUES**

After performing a nutrition assessment and estimating nutritional requirements, determine the optimal route to provide nutrition support therapy (eg, oral, enteral, or parenteral). If PN is indicated, venous access for PN infusion must be obtained. Finally, formulate a PN prescription and administer PN according to safety guidelines.

**Route of PN Administration: Peripheral versus Central Vein Infusion**

- **PN can be administered via a smaller peripheral vein or via a larger central vein (Figure 100–1).** Peripheral PN (PPN) is generally reserved for short-term administration (up to 7 days) when central venous access is not available. PN formulations are hyperosmolar, and PN infusion via a peripheral vein can cause thrombophlebitis. Factors that increase the risk of phlebitis include high solution osmolarity, extreme pH, rapid infusion rate, vein properties, catheter properties (eg, diameter, material), and infusion time via the same vein. The osmolarity of PPN admixtures should be limited to less than or equal to 900 mOsm/L to minimize the risk of phlebitis. The approximate osmolarity of a PN admixture can be calculated from the osmolarity of the individual components:
  - Amino acids ~10 mOsm/g (or 100 mOsm/L% final concentration in PN)
  - Dextrose ~5 mOsm/g (or 50 mOsm/L% final concentration in PN)
  - Sodium (chloride, acetate, and phosphate) = 2 mOsm/mEq (or 2 mOsm/mmol)
  - Potassium (chloride, acetate, and phosphate) = 2 mOsm/mEq (or 2 mOsm/mmol)
  - Calcium gluconate = 1.4 mOsm/mEq (2.8 mOsm/mmol)
  - Magnesium sulfate = 1 mOsm/mEq (2 mOsm/mmol)

- PPN admixtures should be coinfused with IVFE when using 2-in-1 PN because the iso-osmolarity and near-neutral pH of IVFE may decrease the risk of phlebitis (see Table 100–2). Infectious and mechanical complications may be lower with PPN compared with central venous PN administration. However, because of the risk of phlebitis, severe soft tissue damage if extravasation occurs, and osmolarity limit, PPN admixtures have

![Selected vascular anatomy](image)

low macronutrient concentrations and therefore usually require large fluid volumes to meet a patient’s nutritional requirements. Given these limitations, every effort should be made to obtain central venous access and initiate central PN in patients who have an appropriate indication (see Table 100–1).

Central PN refers to the administration of PN via a large central vein, and the catheter tip must be positioned in the superior vena cava (Figure 100–2). Central PN allows the infusion of a highly concentrated, hyperosmolar nutrient admixture. The typical osmolarity of a central PN admixture is about 1500 to 2000 mOsm/L. Central veins have much higher blood flow and the PN admixture is diluted rapidly on infusion, so phlebitis is usually not a concern. Patients who require PN therapy for longer periods of time (greater than 7 days) should receive central PN. Central PN requires placement of a central venous catheter and an x-ray to confirm placement of the catheter tip. A commonly used central catheter for PN infusion is a peripherally inserted central venous catheter (PICC), which is inserted into a peripheral vein but the catheter tip is placed in the superior vena cava (Figure 100–3). Central venous catheter placement may be associated with complications, including pneumothorax, arterial injury, air embolus, venous thrombosis, infection, chylothorax, and brachial plexus injury.1,2

Types of PN Formulations: 3-in-1 versus 2-in-1

**KEY CONCEPT** PN admixtures can be prepared by mixing all components into one bag, or IVFE may be infused separately (via a Y-site infusion or through a separate IV catheter or lumen). When all components are mixed together, it is referred to as a 3-in-1 admixture or TNA.23 When dextrose, amino acids, and all other PN components are mixed together without IVFE, this is referred to as a 2-in-1 PN admixture. There are various advantages and disadvantages to using either TNA or 2-in-1 PN admixtures (Table 100–6). With a 2-in-1 PN admixture, IVFE can be infused separately on a daily or intermittent basis. When IVFE is mixed in the PN, the TNA becomes an emulsion with respect to physical and chemical characteristics. The final concentration of IVFE in a 3-in-1 admixture should be greater than or equal to 2% (20 g/L) to prevent compromising the stability of the emulsion.23 Electrolyte, dextrose, and amino acid concentrations may also be more limited in a 3-in-1 admixture.

Safety is a primary concern with PN therapy. The FDA has provided recommendations for safe infusion of PN admixtures containing calcium and phosphate:
- A 0.22-μm air-eliminating in-line filter should be used for infusion of non–IVFE-containing PN.
- A 1.2-μm in-line filter should be used for the infusion of a TNA because it can remove large and unstable fat droplets and particulate matter.24

Another safety concern is the coinfusion of IV medications with PN admixtures. For safety reasons, medications should not be admixed or coinfused with PN unless necessary, and it should only be done if reasonable and safe (based on toxicity profile, pharmacokinetic and pharmacodynamic considerations).21 Always consult compatibility data before adding a medication to or coinfusing with a PN admixture. Many IV medications have limited compatibility with 3-in-1 formulations but may be coinfused with a 2-in-1 formulation.25,26 Some medications can be coinfused at the Y-site, few medications can be mixed directly into the PN admixture or coinfused with IVFE, and some cannot be mixed or coinfused with the PN admixture.25,26

**Standardized, Commercially Available (Premixed) PN Formulations**

A standardized, commercially available PN formulation (also referred to as premixed PN) is a product available from a manufacturer that requires fewer compounding steps before administration.27 These products usually contain amino acids and dextrose in a two-chamber bag, with or without electrolytes. Vitamins and trace elements must be manually added. IVFE can be added to create a TNA or infused separately. Potential advantages of premixed
PN include improvements in safety (both decreased compounding errors and microbiologic contamination) and reduced costs. The safety advantages are logically related to fewer manual manipulations of the system, but clinical trial data are lacking. Cost advantages have been demonstrated in some trials, with others finding no difference or increased costs. Limitations with the use of premixed PN in the United States are related to the limited number of products available, including a lack of formulations containing IVFE (in a three-chamber bag), relatively low amino acid concentration, only 1- and 2-L volumes, limited variability in electrolyte content, and no formulations available for neonates and infants. These limitations may make premixed PN less appropriate for some patients (eg, critically ill, obese, those with organ dysfunction or who require fluid restriction).

### Formulating a PN Admixture and Regimen

After completing a full nutrition assessment, estimating the patient’s daily fluid, energy, and protein requirements (see Table 100–5), and determining if PN is indicated (see Table 100–1), develop an appropriate PN prescription.

### Initiating PN

- Exercise caution when initiating PN to avoid hyperglycemia and fluid and electrolyte abnormalities. After the goal daily PN volume has been determined, initiate PN at a lower infusion rate (eg, ~50% of goal for anywhere from ~6 to 24 hours) on day 1 with no more than 150 to 200 g of dextrose per day (or a maximum dextrose infusion rate of ~2 mg/kg/min for the first 6–24 hours). Then increase PN to goal over the following 18 to 24 hours, provided that glycemic control is maintained and the patient does not experience significant fluid or electrolyte abnormalities. Monitor electrolytes daily and correct as needed. Advance PN more slowly and cautiously in patients with severe malnutrition and monitor for refeeding syndrome (see Complications of PN).

### Cycling PN

PN should be administered over 24 hours in most hospitalized patients to minimize glucose, fluid, and electrolyte abnormalities. However, administering PN via an infusion over less than 24 hours, or cycling PN, may be advantageous in certain patients and situations. Cycling PN typically involves administering the same PN volume over a goal infusion time, usually over 12 to 18 hours, rather than over 24 hours. Begin with PN infusion over

**Patient Encounter, Part 2**

It is now hospital day #3. Given that PG has malnutrition, an enterocutaneous fistula originating from the jejunum with high output (greater than 500 mL/day), increased when the patient drank water, and had recent abdominal surgery, the surgery team decided to manage PG conservatively: control fistula drainage, NPO status, and begin parenteral nutrition (PN) support today. A peripherally inserted central catheter (PICC) was placed for PN therapy.

**Labs:** Na 134 mEq/L (134 mmol/L); K 3.3 mEq/L (3.3 mmol/L); Cl 91 mEq/L (91 mmol/L); HCO₃ 26 mEq/L (26 mmol/L); BUN 12 mg/dL (4.3 mmol/L); serum creatinine 0.8 mg/dL (71 μmol/L); blood glucose 91 mg/dL (5.1 mmol/L); total Ca 8.4 mg/dL (2.10 mmol/L); ionized Ca 2.38 mEq/L (1.19 mmol/L); Mg 1.5 mg/dL (0.62 mmol/L); phosphorus 2.5 mg/dL (0.81 mmol/L); TG 129 mg/dL (1.46 mmol/L); albumin 2.9 g/dL (29 g/L); WBC count 6300/mm³ (6.3 × 10⁹/L); hemoglobin 12.4 mg/dL (124 g/L or 7.70 mmol/L); hematocrit 35.1% (0.35); platelets 204,000/mm³ (204 × 10⁹/L)

**Determine appropriate nutritional goals for PG (calorie and protein requirements).**

**What other patient data should be collected to help formulate a PN prescription?**
24 hours; then taper the PN infusion to the goal cycle over 2 to 4 days (eg, 24 hours, then 18–20 hours the next day, then 14–16 hours the next day, and then 12 hours the next day). A longer goal cycle (eg, 18 hours) may limit adverse effects related to rate of fluid and dextrose administration (hyper- and hypoglycemia). Titrate the PN infusion rate up over 1 to 2 hours to goal rate to avoid hyperglycemia and taper down over 1 to 2 hours at the end of the cycle to avoid reactive hypoglycemia. Most home infusion pumps can be programmed to cycle a given PN volume automatically over a given time. However, the pharmacist may have to develop an appropriate PN cycle if the infusion pump cannot be programmed for an automatic cycle.

- Cyclic PN has the following potential advantages:
  - It may improve the quality of life of patients receiving home PN by allowing the patient time off of PN to engage in normal activities of daily living.
  - While data are limited, it may help prevent and alleviate PN-associated liver disease by avoiding continuous compulsive nutrient overload on the liver.28

Concerns with cycling PN include hyperglycemia with high infusion rates, reactive hypoglycemia when PN infusion is stopped, and fluid and electrolyte abnormalities. Random capillary blood glucose concentrations should be checked approximately 4 hours into the PN cycle (−2 hours after reaching goal rate), 15 to 60 minutes after PN stops, and intermittently during the PN cycle as needed for glycemic control. During cyclic PN infusion, the potassium infusion rate should not exceed 10 mEq/hour (10 mmol/hour) if the patient is not on a cardiac monitor. If nocturnal cyclic PN infusion interferes with patient’s sleep pattern by causing overdiuresis, the PN cycle can be extended over a longer infusion time or PN can be infused during other times of the day that are most convenient to the patient.

### Transition to Oral or Enteral Nutrition

The goal is to transition the patient to enteral or oral nutrition and taper off PN as soon as indicated. After initiation of enteral or oral nutrition, monitor the patient for glucose, fluid, and electrolyte abnormalities. When oral nutrition intake is inconsistent, perform calorie counts to determine the adequacy of nutrition via the oral route. When the patient is tolerating more than 50% of total estimated daily calorie and protein requirements via the oral or enteral route, decrease PN by about 50%. PN can be stopped when the patient is tolerating at least 75% of total daily calorie and protein requirements via the oral or enteral route, assuming that intestinal absorption is maintained.

### Complications of PN

**KEY CONCEPT** PN therapy is associated with significant complications, both with short- and long-term therapy (Table 100–7). Many complications are related to overfeeding (Table 100–8).

#### Hyperglycemia

Hyperglycemia is one of the most common complications associated with PN therapy. The rate of dextrose oxidation may be reduced in patients with stress and hypermetabolism, patients with diabetes or acute pancreatitis, and patients receiving certain medications (eg, corticosteroids, vasopressors, octreotide, and tacrolimus).29,30 Uncontrolled hyperglycemia can lead to fluid and electrolyte disturbances, hyperglycemic hyperosmolar nonketotic syndrome, hypertriglyceridemia, and an increased risk of infection.31 Hyperglycemia in critically ill patients may be more a reflection of illness severity than from dextrose infusions, provided that the patient is not being overfed with dextrose.32 Critical illness is associated with increased endogenous glucose production (caused by increased glycogenolysis and gluconeogenesis) and insulin resistance. Therefore, critically ill patients have lower tolerance for dextrose infusion compared with non-stressed patients. A portion of daily calories (−20%–30%) can be administered via IVF to help decrease hyperglycemia, provided that the patient does not have hypertriglyceridemia. Overfeeding (with dextrose and with total calories) must always be avoided. Most recent data suggest that moderate glucose control is

**Patient Encounter, Part 3**

The surgical team asks for your recommendations for PN therapy for PG.

**Develop a plan for a complete and balanced PN prescription (including fluid, total calories, dextrose, amino acids, IVF, electrolytes, vitamins, trace elements, and any additives) and explain the rationale supporting your PN formulation and plan.**

**How should this PN admixture be initiated and titrated to goal? Would you recommend any other treatments before initiating PN? (Hint: Is this patient at risk for refeeding syndrome?)**
indicated in critically ill patients (eg, capillary glucose concentrations between ~140 and 180 mg per dL [7.8 and 10.0 mmol/L]).

Refer to the section on “PN Additives: Regular Insulin” regarding management of hyperglycemia with insulin.

**Hypoglycemia**

- Hypoglycemia can occur in patients when PN is interrupted suddenly (reactive hypoglycemia), especially when patients are treated with insulin or as a result of insulin overdosing in PN. It is essential to prevent hypoglycemia and, if it occurs, identify and treat it promptly. Reactive hypoglycemia typically is rare and usually can be avoided by tapering PN over 1 to 2 hours before discontinuation rather than abruptly stopping the infusion (especially if the patient is receiving insulin in PN or if the patient is not receiving oral or enteral nutrition). Reactive hypoglycemia generally occurs within 15 to 60 minutes after stopping PN (especially in neonatal patients), although it can occur later than this after discontinuing PN. Capillary blood glucose concentrations should be monitored about 15 to 60 minutes after stopping PN infusion to detect any potential hypoglycemia. If PN is interrupted abruptly (eg, because of lost IV access), infusing dextrose 10% in water or dextrose 10% NaCl 0.45% in water (to avoid excessive free water) at the same rate as PN should prevent hypoglycemia. In patients with poor venous access, reduce the PN infusion rate by 50% for 1 hour before discontinuing. Another alternative to prevent reactive hypoglycemia is to provide a glucose source via the oral route (by mouth or sublingually) when feasible.

**Hyperlipidemia/Hypertriglyceridemia**

Patients receiving IVFE may be at risk for hyperlipidemia and hypertriglyceridemia. Hyperlipidemia in patients receiving PN may lead to a reduction in pulmonary gas diffusion and pulmonary vascular resistance. Severe hypertriglyceridemia (especially serum triglyceride concentrations exceeding 1000 mg/dL or 11.30 mmol/L) can precipitate acute pancreatitis.

- Hypertriglyceridemia may develop as a result of increased fatty acid synthesis caused by hyperglycemia, impaired IVFE clearance, in patients with history of hyperlipidemia, obesity, diabetes, alcoholism, kidney failure, liver failure, multiorgan failure, sepsis, or pancreatitis, or as a result of medications (eg, propofol, corticosteroids, cyclosporine, and sirolimus). Hyperglycemia is probably the most common cause of hypertriglyceridemia in patients receiving PN. A higher PL:TG ratio has been proposed to cause the appearance of the abnormal lipoprotein X particles in the blood. Lipoprotein X may compete with IVFE particles for metabolism by lipoprotein lipase. It is preferred to use IVFE with a lower PL:TG ratio, especially in patients with hypertriglyceridemia, because they have improved clearance compared with emulsions with a higher PL:TG ratio (see Table 100–2).

Monitor serum triglyceride concentrations regularly during PN therapy (see Table 100–8). If a patient develops hypertriglyceridemia, identify and correct the underlying cause(s) if possible. Prolonging the infusion of IVFE may improve lipid clearance. If a patient is receiving propofol, IVFE should be withheld and the calories from the 10% IVFE in propofol should be taken into account (see Table 100–2). IVFE should be held when the serum is lipemic or when serum triglyceride concentrations are greater than 400 mg/dL (4.52 mmol/L). When this occurs, restart IVFE when the serum triglyceride concentration is approximately 200 to 400 mg/dL (2.26–4.52 mmol/L) (or less) and administer only two to three times per week to prevent EFAD. Avoid completely holding IVFE for more than 3 to 4 weeks due to risk of EFAD.

**Hypercapnia**

- Hypercapnia can develop as a result of overfeeding with dextrose and/or total calories. Excess carbon dioxide production and retention can lead to acute respiratory acidosis. Excess carbon dioxide will also stimulate an increase in respiratory rate, and this increase in respiratory workload could cause respiratory insufficiency that may require mechanical ventilation. Reducing total calorie and dextrose intake would result in resolution of hypercapnia if due to overfeeding.

**Liver Complications**

The incidence of liver complications associated with PN ranges from approximately 7% to 84%, and end-stage liver disease develops in as many as 15% to 40% of adult patients on long-term PN. Patients may develop a mild increase in liver transaminases within 1 to 2 weeks of initiating PN, but this generally resolves as PN continues, provided overfeeding is avoided. Severe liver complications include hepatic steatosis, steatohepatitis, cholestasis, and cholelithiasis.

- Hepatic steatosis is usually a result of excessive administration of carbohydrates or fats, but deficiencies of carnitine, choline, and essential fatty acids may also contribute. Hepatic steatosis can be minimized or reversed by avoiding overfeeding, especially from dextrose and IVFE. Cholestasis is a common and potentially serious complication in PN-dependent patients. Factors that predispose PN patients to cholestasis include overfeeding, bowel rest, long duration of PN, short-bowel syndrome, bacterial overgrowth and translocation, and sepsis. Patients may exhibit increased liver transaminases, increased alkaline phosphatase and gamma-glutamyl transferase concentrations, and mainly increased bilirubin concentrations with jaundice. The most sensitive marker of cholestasis is increased serum conjugated bilirubin concentration of greater than 2 mg/dL (34.2 μmol/L).

Cholestasis generally is reversible if PN is discontinued before permanent liver damage occurs. Serum liver function tests may take up to 3 months to return to normal after discontinuing PN. Steps to prevent cholestasis associated with PN include early enteral or oral feedings, using a balanced PN formulation, avoiding overfeeding, using cyclic PN infusion, and treating and avoiding sepsis. Limiting soy-based IVFE infusion to one or two times weekly at a dose adequate to prevent essential fatty acid deficiency may also decrease serum bilirubin concentrations and improve cholestasis. Pharmacologic treatments include ursodeoxycholic acid (ursodiol), which may improve bile flow and reduce the signs and symptoms of cholestasis. However, ursodiol is only available in an oral dosage form, and absorption may be limited in patients with intestinal resections.

- Cholelithiasis can develop as a result of decreased gallbladder contractility, especially in the absence of enteral or oral intake. Lack of intestinal stimulation reduces secretion of cholecystokinin, a peptide hormone secreted in the duodenum that induces gallbladder contractility and emptying. The best prevention of cholelithiasis is early initiation of enteral or oral feeding.

Monitor liver function tests, including serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, total bilirubin, conjugated bilirubin, unconjugated bilirubin, and γ-glutamyl transferase at the initiation of PN therapy and regularly thereafter during PN therapy. The frequency of monitoring liver function tests depends on the presence or absence of liver disease. This varies from one to two times weekly in the acute setting to once weekly, once monthly, or even one to two times per year in stable home PN patients.
Manganese Toxicity

Manganese accumulation can occur in patients with cholestasis or in patients receiving long-term PN therapy. Neurotoxicity is the most common manifestation (headache, somnolence, weakness, confusion, tremor, muscle rigidity, altered gait, and mask-like face [a Parkinson-like syndrome]), but liver toxicity also may occur. Periodically monitor blood manganese concentrations in patients on long-term PN. Patients with cholestasis receiving PN may require restriction of manganese in PN to prevent accumulation and possible toxicity.

Metabolic Bone Disease

Metabolic bone disease (MBD) is a condition of bone demineralization leading to osteomalacia, osteopenia, or osteoporosis in patients receiving long-term PN. MBD may occur in as many as 40% to 100% of patients receiving long-term PN. Often patients are asymptomatic, although symptoms can include bone pain, back pain, and fractures. Patients often have increased serum alkaline phosphatase concentrations, low to normal parathyroid hormone (PTH) concentrations, normal 25-hydroxyvitamin D and low 1,25 dihydroxyvitamin D concentrations, hypercalcemia or hypocalcemia, and hypercalcuria. Because patients may be asymptomatic, diagnosis can be incidental. Radiographic techniques commonly used in diagnosing bone disease include quantitative computed tomography (CT) and bone mineral density.

Factors that can predispose patients to developing MBD include deficiencies of phosphorus, calcium, and vitamin D; aluminum toxicity; amino acids and hyperosmolar dextrose infusions; chronic metabolic acidosis; corticosteroid therapy; and lack of mobility. Calcium deficiency (caused by decreased intake or increased urinary excretion) is one of the major causes of MBD in patients receiving PN. Provide adequate calcium and phosphate with PN to improve bone mineralization and help to prevent MBD. Administration of amino acids and chronic metabolic acidosis also appear to play an important role. Provide adequate amounts of acetate in PN admixtures to maintain acid–base balance.

Aluminum toxicity appears to play a role in the development of MBD in patients on long-term PN, possibly by impairing calcium bone fixation, inhibiting the conversion of 25-hydroxyvitamin D to the active 1,25 dihydroxyvitamin D, and/or reducing PTH secretion. The FDA issued a rule specifying acceptable aluminum concentrations in large-volume parenterals, indicating that products contains no more than 25 mcg/L (0.93 μmol/L) of aluminum and defined a safe upper limit for parenteral aluminum intake at less than 4 to 5 mcg/kg/day. Pharmacies should use products with the lowest labeled aluminum content for the making of PN. Patients who are chronically dependent on PN should have their serum aluminum concentrations routinely monitored or whenever MBD is suspected or diagnosed.

Encourage patients on long-term PN to engage in regular low-intensity exercise. Yearly bone density measurements also should be performed on patients on long-term PN and when MBD is suspected.

Refeeding Syndrome

Refeeding syndrome describes the metabolic derangements that occur during nutritional repletion of patients who are starved, underweight, or severely malnourished. Hypophosphatemia and hypokalemia (along with associated complications) are the classic signs and symptoms, but refeeding syndrome encompasses a constellation of fluid and electrolyte abnormalities affecting neurologic, cardiac, hematologic, neuromuscular, and pulmonary systems. The most severe cases of refeeding syndrome have resulted in cardiac failure, seizures, coma, and death. The reintroduction of energy substrates, especially carbohydrates, increases metabolism and utilization of glucose as the predominant fuel source. This increases insulin secretion and demand for phosphorylated intermediates of glycolysis (eg, ATP and 2,3-diphosphoglycerate [2,3-DPG]), inhibits fat metabolism, and causes an intracellular shift of phosphorus, potassium, and magnesium. These changes, in combination with preexisting low total body stores of phosphorus, potassium, and magnesium and enhanced cellular uptake of phosphorus during anabolic refeeding, result in hypophosphatemia, hypokalemia, and hypomagnesemia. Vitamin deficiencies (eg, thiamine) also may exist or be precipitated during refeeding. High carbohydrate intake increases the demand for thiamine, which can precipitate thiamine deficiency and cause lactic acidosis and neurologic abnormalities, as well as myocardial dysfunction and congestive heart failure. Other metabolic alterations that may occur include expansion of the extracellular water compartment and fluid intolerance.

The primary goal is preventing refeeding syndrome when initiating PN in high-risk patients (eg, prolonged lack of adequate nutritional Intake, significant weight loss, or moderate to severe malnutrition). When initiating nutrition support, the rule of thumb to prevent refeeding syndrome is to “start low and go slow.” Initiate PN cautiously (eg, ~25%–33% of estimated nutritional requirements on day 1) and gradually increase to goal over 3 to 5 days. Correct electrolyte abnormalities before initiating PN and provide supplemental phosphate, potassium, and magnesium in and/or outside of PN. Doses of IV phosphate up to 0.64 to 1 mmol/kg may be used to treat severe hypophosphatemia (in patients with normal kidney function), and doses can be repeated as needed until serum phosphorus concentration has normalized. Provide supplemental oral or IV thiamine 100 mg/day and folic acid 1 mg/day for about 1 week in addition to the standard multivitamin in PN. Assess patients for fluid balance, signs of edema, fluid overload, and weight gain, and consider minimizing fluid and sodium intake during the first few days of PN. Monitor patients closely for signs and symptoms of refeeding syndrome until they are tolerating PN at goal for a few days:

- Vital signs, mental status, and neurologic and neuromuscular function at least every 4 to 8 hours.
- Pulse oximetry and any electrocardiographic changes when indicated.
- Serum laboratory values (including sodium, potassium, phosphorus, and magnesium) at least once a day.

Infectious Complications

Patients receiving central PN are at increased risk of developing infectious complications caused by bacterial and fungal pathogens. Patients without malnutrition who receive early PN (eg, within 48 hours of ICU admission) may have a higher incidence of infectious complications than patients who do not receive PN or receive late PN initiation (eg, greater than 7 days after ICU admission). Strict aseptic techniques must be used when placing the catheter along with continuous care of the catheter and infusion site. Catheter-related bloodstream infections are a common complication in long-term PN patients, often requiring hospital admission for parenteral antimicrobial therapy and/or removal of the catheter. Contamination of the PN admixture is
possible but rare if protocols are followed for aseptic preparation of PN admixtures.

Mechanical Complications
Mechanical complications of PN are related to venous catheter placement and the equipment used to administer PN. A central venous catheter must be placed by a trained professional, and risks associated with placement include pneumothorax, arterial puncture, bleeding, hematoma formation, venous thrombosis, and air embolism. Over time, the venous catheter may require replacement. Problems with the equipment include malfunctions of the infusion pump, IV tubing sets, and filters.

MONITORING PN THERAPY
When initiating PN, patients should have important baseline laboratory values checked to assess electrolyte status, organ function, and nutritional status. Thereafter, these and other nutritional parameters should be monitored routinely or as indicated (Table 100-9). Random capillary blood glucose concentrations also should be monitored every 6 to 8 hours when initiating PN, and regular insulin should be administered to control blood glucose concentrations as needed.

SUMMARY AND CONCLUSION
PN is an effective and potentially lifesaving method of administering nutrition support to patients who cannot receive adequate oral or enteral nutrition. Administration of PN can be associated with significant adverse effects and metabolic, infectious, and mechanical complications. Optimal design, compounding, and administration of a PN regimen are essential to minimize the risk of adverse effects and complications, and patients must be monitored closely while receiving PN to optimize outcomes.

### Abbreviations Introduced in This Chapter

- AdjBW: Adjusted body weight
- ALT: Alanine aminotransferase
- A.S.P.E.N.: American Society for Parenteral and Enteral Nutrition
- AST: Aspartate aminotransferase
- ATP: Adenosine triphosphate
- CT: Computed tomography
- 2,3-DPG: 2,3-Diphosphoglycerate
- FDA: Food and Drug Administration
- GI: Gastrointestinal
- HIT: Heparin-induced thrombocytopenia
- IBW: Ideal body weight
- IVFE: Intravenous fat emulsions
- kcal: Kilocalorie(s)
- kJ: Kilojoule(s)
- LDH: Lactate dehydrogenase

### Patient Encounter, Part 4

The surgical team plans to initiate PN for PG per your recommendations. Laboratory data were listed previously.

**What monitoring parameters related to PN therapy should you follow in PG after initiating PN? List monitoring parameters and frequency.**

**What potential complications of PN should you monitor for in PG?**

**What special considerations must be made when developing a plan for nutrition support therapy and a PN formulation for patients with severe malnutrition?**
MBD  Metabolic bone disease
mEq  Milliequivalents
mmol  Millimoles
mOsm  Milliosmoles
PL  Phospholipid(s)
PN  Parenteral nutrition
PPN  Peripheral parenteral nutrition
PTH  Parathyroid hormone
TG  Triglyceride
TNA  Total nutrient admixture
TPN  Total parenteral nutrition

REFERENCES

LEARNING OBJECTIVES

Upon completion of this chapter, the reader will be able to:

1. Discuss how gut structure and function impact choice of feeding route and outcome of feeding.
2. Estimate kilocalorie and protein requirements of an enteral feeding candidate and design an enteral nutrition (EN) regimen to meet these.
3. Evaluate patient-specific parameters to determine whether EN is appropriate.
4. Compare clinical efficacy, complications, and costs of EN versus parenteral nutrition (PN).
5. Formulate a monitoring plan for an EN patient.
6. Select appropriate medication administration techniques for an EN patient.

INTRODUCTION

Enteral nutrition (EN) is broadly defined as delivery of nutrients via the gastrointestinal (GI) tract. The terms enteral nutrition and tube feedings are often used synonymously. Formulas for EN usually are delivered in the form of commercially prepared liquid preparations, although some products are produced as powders for reconstitution. Nonvolitional feedings in patients who cannot meet nutritional requirements by oral intake include EN and parenteral nutrition (PN), which are collectively known as specialized nutrition support (SNS).

Several organizations have issued clinical guidelines on the use of EN. These include the American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.), European Society for Clinical Nutrition and Metabolism (ESPEN), and a Canadian team known as Critical Care Nutrition. A.S.P.E.N. and the Society for Critical Care Medicine (SCCM) have jointly issued guidelines for SNS in critically ill patients.

GI TRACT STRUCTURE AND FUNCTION

Anatomy and Absorptive Function

With normal volitional feeding, food is ingested via the mouth. There, the process of breaking down complex foodstuffs into simpler forms that can be absorbed by the small bowel begins. Solid food is chewed in the mouth, and enzymes begin digestion. The trigger for release of many enzymes and GI hormones is the presence of food in specific regions of the GI tract. Food is swallowed and passes through the esophagus and the esophageal sphincter to the stomach, where additional digestive enzymes and acids further break it down. The stomach also serves a mixing and grinding function.

The food, now in a liquid form known as chyme, passes through the pyloric sphincter into the duodenum, where stomach acid is neutralized. Most absorption of digested carbohydrate and protein occurs within the jejunum. Most fat absorption occurs within the jejunum and ileum. In the small bowel, breakdown of macronutrients (ie, carbohydrate, protein, and fat) occurs both within the lumen and at the intestinal mucosal membrane surface. The absorptive units on the intestinal mucosal membrane are infoldings known as villi. These villi are made up of epithelial cells called enterocytes. Projections from these enterocytes called microvilli increase the surface area of the small bowel and make up the brush-border membrane.

Digestive substances secreted by the pancreas play a role in food breakdown. The pancreas secretes large amounts of sodium bicarbonate that neutralize stomach acid. Substances flow from the pancreas through the pancreatic duct. The pancreatic duct typically joins the hepatic duct to become the common bile duct that empties through the sphincter of Oddi into the duodenum. Bile secreted by the liver does not contain digestive enzymes, but bile salts help to emulsify fat and facilitate fat absorption. Bile flows through bile ducts into the hepatic duct and common bile duct. Bile is stored in the gallbladder until needed in the gut to aid fat digestion, at which time it empties through the cystic duct to the common bile duct to the duodenum. Pathways through which carbohydrate, protein, and fat are digested and absorbed through the small bowel are illustrated in Figure 101–1.

Remaining undigested food passes from the ileum through the ileocecal valve to the colon. A major role of the colon is fluid absorption. Some of the water and sodium absorption achieved by the colon is facilitated by short-chain fatty acids (SFCAs) formed from digestion of certain dietary fibers by colonic bacterial enzymes.

Gut Immune Function

The gut plays significant immune roles. The distal small bowel and colon host many bacteria and their endotoxins, and it is important that these organisms not gain access to the internal systems of the body. This function is known globally as the gut barrier function. Normal flora of the gut comprises one component. The normal flora, particularly some anaerobes, helps to prevent overgrowth of potential pathogens. A second component involves...
mechanical factors. These include a mucous layer that prevents adherence of bacteria. Peristalsis of the small bowel prevents stasis of bacteria. Gut-associated lymphoid tissue (GALT), prominent in small bowel, serves as a local immune system. Secretory immunoglobulin A produced at the mucosal surface in response to food in the gut prevents bacteria from invading the surface.

**PATIENT SELECTION**

In general, EN is the preferred route if the gut can be used safely in patients who cannot meet nutritional requirements by oral intake. If the gut functions, EN is usually preferred over PN. The timing of SNS (either EN or PN) is controversial, but definitive guidelines for these therapies state that SNS should be started when intake has been inadequate for 7 to 14 days or if inadequate oral intake is anticipated for at least 7 to 14 days. Prior nutritional status of the patient should be considered. Previously well-nourished patients can better afford not being fed for longer periods than previously poorly nourished patients. Patients in the intensive care unit (ICU) probably benefit from early EN started within 24 to 48 hours of admission to the ICU. Ethical questions come into play when consideration is given to starting (or stopping) EN in seemingly futile situations. Methods for assessing nutritional status and designing SNS regimens are covered in Chapter 100. Generally, nonobese hospitalized patients require 20 to 35 total kcal/kg of body weight/day (84–147 kJ/kg body weight/day) and 1 to 2 g protein/kg of body weight/day. Obese patients are often fed hypocaloric, high-protein diets; guidelines state to start feedings at 1.2 g protein per kg and less than 14 kcal/kg actual body weight (59 kJ/kg actual body weight).

**Indications**

Many potential indications for EN exist. PN was used extensively in the past for many of these conditions.

Advances in EN technology now allow many patients with these conditions to receive EN. EN is administered in both institutional and home settings.

### Contraindications and Precautions

- EN should not be used or should be used with extreme caution in certain conditions (Table 101–2). It is possible to use EN in some patients with these conditions depending on severity of illness, location of abnormality, and experience of practitioners delivering care. Feeding in the setting of hemodynamically unstable patients is particularly controversial; some clinicians avoid enteral feedings in this setting for fear of worsening intestinal ischemia, whereas others believe early feeding may facilitate intestinal perfusion and be beneficial. Others might avoid jejunal feedings in this setting but would proceed with cautious gastric feedings.

### Enteral versus Parenteral Feeding

With advent of the technique of PN by large central vein in the late 1960s, this modality quickly became popular. PN was incorporated quickly into care of patients such as critically ill patients. The relative ease of PN administration, along with the perception that critically ill patients had prolonged high-energy expenditures, led to complications of overfeeding. Dextrose overfeeding led to complications, including hyperglycemia, carbon dioxide overproduction leading to delays in weaning from mechanical ventilation, and liver abnormalities owing to hepatic steatosis.

The pendulum began to swing toward EN in the late 1980s and early 1990s as clinical studies showed better clinical outcomes with EN compared to PN. Some potential advantages of EN over PN are included here. First, EN is expected to preserve the gut barrier function better than PN. This could prevent translocation of bacteria and endotoxin from the gut lumen into the lymphatic system and systemic circulation, thus preventing infections. Some studies support that EN is associated with fewer infectious complications than PN. EN is cited frequently as having a better overall safety profile than PN. Whereas EN is associated with more severe complications, such as pneumonia, EN formulas typically are cheaper and less labor intensive to prepare than PN, although some specialty EN formulas approach the cost of PN formulas. Depending on the method of feeding tube placement, EN costs can mount if the tube must be placed by a radiologist or gastroenterologist rather than a nurse or if the tube must be replaced.

Arguments in support of EN over PN have been questioned. Part of this questioning relates to the question of whether EN is beneficial compared with PN or whether PN as commonly administered may be detrimental. Overfeeding and hyperglycemia occur easily with PN, and the potential harm of hyperglycemia, especially in critical care populations, has been demonstrated, although the exact range optimal for glycemic control in ICU patients remains controversial. A study published in 1991 demonstrated that there were more infectious complications in patients randomized to receive PN compared with those randomized to receive no SNS; there was no difference in noninfectious complications between the two groups. Only in severely malnourished perioperative patients were fewer noninfectious complications seen with PN; in these patients, no difference in infectious complications was seen between groups. Whether EN truly prevents infections and improves clinical outcomes or whether PN is detrimental continues to be debated and probably depends upon specific patient population. At present, EN is preferred by most experts over PN when the gut is functional. In Europe (more so than in North America), PN has been used to supplement EN during the first week of intensive care therapy when EN is not yet being tolerated at full rates. This approach is currently discouraged by American and Canadian ICU guidelines. Recent randomized controlled trials relating to this topic have yielded disparate results.

### ROUTES OF ACCESS

There are several access sites for EN (Figure 101–2). Nasogastric (NG), orogastric (OG), nasoduodenal (ND), and nasojejunal (NJ) routes generally are for short-term use (less than 1 month), whereas gastrostomy, percutaneous endoscopic gastrostomy (PEG), jejunostomy, and percutaneous endoscopic jejunostomy (PEJ) tubes are preferred for longer-term treatment. Both advantages and disadvantages exist for each EN route (Table 101–3).

### Gastric Feeding

Gastric feedings are used commonly. They require an intact gag reflex and normal gastric emptying for safety and success. Certain patients, such as those who have suffered head trauma, may not empty their stomachs efficiently and therefore may not be good candidates for gastric feedings. In these patients, it may be impossible to achieve a gastric tube feeding rate to provide adequate nutrients. In addition, pooling of formula in the stomach could increase risk of aspirating feeding formula into the lungs. The NG route is used most commonly for short-term enteral access. The major advantage of this route is that the tube can be placed quickly and inexpensively by the nurse at the bedside.

Gastrostomy tubes, in which an incision is made directly through the abdominal wall, are indicated for patients who can tolerate gastric feedings but in whom long-term feedings are anticipated. The most commonly placed gastrostomy tubes are either placed by interventional radiology or are PEG tubes placed endoscopically. Gastrostomy tubes also can be placed laparoscopically or during an open procedure by a surgeon. Placement of a gastrostomy tube either endoscopically or surgically is more expensive than bedside OG or NG placement but can result in placement of a larger bore tube.

An advantage of feeding into the stomach is that feedings can be delivered either intermittently or continuously. When feeding directly into the small bowel continuous feedings must be used. Intermittent feedings into the small bowel result in GI intolerance in most patients.

Postpyloric Feedings

**KEY CONCEPT** For patients intolerant of gastric feedings or in whom the risk of aspiration is high, feedings delivered with the tip of the tube in the jejunum are preferred. This bypasses the problem of poor gastric emptying and adds another barrier (pyloric sphincter) through which tube feedings must traverse before aspiration into the lungs. However, postpyloric feedings do not preclude the possibility of aspiration. Many patients with this complication are aspirating their own nasopharyngeal secretions.

Nasoduodenal and NJ feeding tubes can be placed by trained, experienced nurses at the bedside. Although such placements typically take more time than NG or OG placements, this is still a relatively inexpensive method of placement. bedside electromagnetic transmitter devices (eg, CORTRAK, Corpak Medsystems) may be helpful in achieving postpyloric tube placement. In some institutions, ND or NJ placements are done in radiology by a radiologist using fluoroscopy to visualize tube advancement. This procedure increases cost of EN therapy. NJ tubes generally are preferred over ND tubes; placement of the tube tip distal to the ligament of Treitz (located near the junction of the duodenum and the jejunum) may reduce risk of aspiration. Alternatively, during a laparotomy, the surgeon can place an ND or NJ tube.

Surgically placed jejunostomy tubes are placed through an incision in the abdominal wall, precluding the need for a tube down the nose or mouth. These tubes frequently are placed during laparotomy following abdominal trauma. Alternatively, jejunal access can be obtained by placing a jejunal extension through a PEG tube; the resulting tube is sometimes referred to as a PEGJ tube or G-J tube. Another option is to place a PEJ tube directly; this is more technically difficult than PEG placement. Tubes with both gastric and jejunal lumens are sometimes used, the gastric lumen for suctioning stomach contents and the jejunal lumen for delivery of feedings.

**METHODS OF DELIVERY**

Enteral feedings are delivered by several different methods. Continuous infusion must be used when duodenal or jejunal feedings are administered. For gastric feedings, bolus or intermittent feedings could be administered instead of continuous feedings. Each method has advantages and disadvantages. In many hospitals, EN is delivered most commonly as a continuous infusion at a constant rate regulated by an infusion pump. A variation of continuous infusion is cyclic feeding, in which a constant rate is maintained over a certain number of hours daily; this method of administration is used commonly in long-term care or home settings. Sometimes EN is administered overnight.

Intermittent feedings are used commonly in long-term care or home settings. Patients frequently are started with continuous feedings; transitioned to intermittent feedings given several times a day over about 30 to 45 minutes for each feeding; and eventually changed to bolus feedings administered over less than 10 minutes per feeding. An advantage of intermittent feedings is that they may be administered by gravity flow adjusted with a roller clamp, although some institutions may use an infusion pump. Bolus feedings can be administered using a 60-mL syringe, although in some circumstances, an infusion set and pump may be used. Intermittent and bolus feedings often are given in amounts of 240 to 480 mL per feeding, corresponding to one to two cans of formula.

**EN FORMULAS**

One advantage of EN over PN is the availability in the United States of certain nutrients in some EN formulations (eg, glutamine, fish oils) that are not available for parenteral use. A number of EN formulas are marketed commercially. Hospitals and long-term care facilities usually limit formulations of EN formulas, stocking only a limited number of products.

**Polymeric versus Oligomeric Formulas**

A major criterion for categorizing EN products is whether macronutrients (particularly protein) are more intact (polymeric) or present in simpler forms (oligomeric). **KEY CONCEPT** Standard EN formulas are polymeric; these are appropriate for most patients. Oligomeric formulas should be reserved for patients with GI dysfunction.

Polymeric formulas typically contain intact proteins (most commonly casein). They have low osmolality of 300 to 500 mOsm/kg. These usually supply essential vitamins and minerals in amounts similar to the Adequate intakes (AI) or Recommended Dietary Allowances (RDA) for these nutrients when the formula is delivered in amounts adequate to meet macronutrient requirements of most patients. Many polymeric formulas are inexpensive relative to oligomeric formulas. Most modern formulas are lactose and gluten free. Products designed for use as oral supplements generally are polymeric and often have sucrose or other simple sugars added to improve taste.

Oligomeric formulas are also known as chemically defined formulas. These can be subcategorized based on whether the formula contains all free amino acids (elemental formulas) or peptides (peptide based) as the protein source. Some formulas contain a combination of free amino acids and small peptides. Dipeptides and tripeptides are absorbed more efficiently than free amino acids. Oligomeric formulas may be better tolerated than polymeric formulas for patients with defects in GI function and may be particularly useful with severe pancreatic dysfunction or significantly decreased GI surface area. However, adaptation of the bowel is better when intact nutrients are supplied to patients with short bowel syndrome, so those patients should be transitioned to intact nutrients as soon as possible.

Oligomeric formulas typically are more expensive than polymeric formulas and have higher osmolality. However, osmolality of these products usually does not exceed 700 mOsm/kg, a value less than that of many oral medications or a regular diet. Sometimes enteral feedings are diluted to deliver extra water required by the patient; this practice generally is discouraged because of potential risk of formula contamination. Instead, it is better to give extra water as boluses through the tube. If medications are administered through the feeding tube, generous amounts of water should be used to flush the tube before and after each medication; this practice helps provide extra fluid and prevent problems with tube occlusion.

Oligomeric formulas are less palatable than polymeric formulas and are not designed for use as oral supplements. Many oligomeric formulas provide some fat calories as medium-chain triglycerides (MCTs), a fat source that is more readily absorbed and metabolized than long-chain triglycerides (LCTs) typically found in polymeric formulas. The MCTs do not require bile salts or pancreatic enzymes for absorption. Some elemental formulas contain a low proportion of fat (less than 10% of total calories), which makes them useful in certain situations where fat needs to be restricted. The carbohydrate source in oligomeric formulas
is also less complex than in polymeric formulas, consisting of oligosaccharides rather than hydrolyzed starch.

**Fiber Content**

Another distinguishing factor of enteral formulas is whether or not they contain fiber. Both soluble and insoluble fibers may be included. Insoluble fiber exerts an effect on gut motility by drawing water into the intestine and decreasing transit time, thus preventing constipation. Soluble fiber can help to lower blood cholesterol levels, regulate blood sugar, and prolong gastric emptying. Soluble fiber may also help control diarrhea. Cellulose gum is an example source of insoluble fiber. Oat fiber and guar gum provide primarily soluble fiber. Soy fiber provides primarily insoluble fiber but also some soluble fiber and is the most commonly used fiber source in tube feeding products. Fiber has been useful for regulating gut motility in some but not all clinical studies; it certainly can be useful in selected patients.9 Some patients may experience GI discomfort secondary to gas production with introduction of fiber.

**Fructooligosaccharides** (FOS) are a form of fiber that pass through the stomach and small bowel undigested and are fermented by colonic bacteria to the SCFAs butyrate, propionate, and acetate. The SCFAs serve as a fuel source for colonocytes and also serve other important functions.20 The FOS are thus prebiotics that serve as fermentable substrates for normal flora of the colon. The SCFAs are not added directly to EN products because they would be absorbed completely before reaching the colon; rather, FOS are added, allowing bacterial degradation to form SCFAs. Products containing FOS are often avoided postoperatively due to increased gas, bloating, and abdominal distension with these products.

**Caloric Density**

Enteral feeding formulas can be categorized based on caloric density. Standard caloric density is 1 to 1.3 kcal/mL (4.2–5.4 kJ/mL). More calorically dense formulas containing 1.5 to 2 kcal/mL (6.3–8.4 kJ/mL) are available and have a higher osmolality. Fluid-overloaded patients may benefit from more calorically dense formulas. As caloric content of a formula increases, the amount of free water decreases.

**Protein Content**

Protein content is an important factor in choosing an EN formula. Standard protein content in EN formulas is up to about 20% of total calories as protein. High-protein formulas containing 25% or more of total calories as protein are available for highly stressed patients with elevated protein needs. So are low-nitrogen formulas containing less than 10% of total calories as protein for use in patients requiring protein restriction. A wide range of protein is available, from about 35 to 95 g/L.

**Carbohydrate Content**

The most common carbohydrate source in tube feeding products is maltodextrin, a partially hydrolyzed starch that is easily digestible. Corn syrup solids are another hydrolyzed starch found in many products. Products containing simple sugars (often those intended for oral use) tend to be higher in osmolality.

**Fat Content**

Both MCTs and LCTs are used in tube feeding products. Corn, soy, and safflower oils are standard sources of fat, providing mainly ω-6 polyunsaturated fatty acids (PUFAs). Some newer EN products contain higher quantities of ω-3 PUFAs from sources such as fish oil (ie, docosahexanoic acid [DHA] and eicosapentaenoic acid [EPA]). Other formulas contain higher quantities of monounsaturated fatty acids (MUFAs) from canola oil and high-oleic safflower or sunflower oils. The essential fatty acid (EFA) content (mainly linoleic acid) of EN formulas is important because EFA deficiency can be induced if at least 1% to 4% of total calories are not supplied as EFAs. MCT oil does not contain EFAs.

**Vitamin, Mineral, and Electrolyte Content**

Most EN products contain vitamins and minerals, including major electrolytes, in amounts adequate to deliver the RDA or AI when a standard volume of formula is delivered daily. Some specialty formulas (eg, renal formulas) may have altered amounts of certain micronutrients.

**Specialty Formulas**

Specialty formulas designed for use in specific clinical situations generally are more expensive than standard polymeric formulas. Robust clinical trial data supporting use of specialty formulas in niche populations typically remain lacking in terms of improved patient outcomes.

**Stress and Trauma Formulas**

Historically, formulas aimed specifically for highly stressed, critically ill patients, were enriched with branched-chain amino acids (BCAAs). The rationale was that skeletal muscle BCAAs are preferentially used for energy in critical illness. Provision of BCAAs might limit breakdown of muscle in these patients. Clinical data failed to support or refute benefit of these formulas unequivocally in terms of clinical outcomes.

The newer generation of enteral feeding formulas marketed for use in these populations covers a broad spectrum of characteristics (Table 101–4). Whereas some are polymeric, others are oligomeric to address malabsorption that may accompany high stress. Some formulas marketed for use in critical illness are calorically dense (1.5–2 kcal/mL [6.3–8.4 kJ/mL]) to address fluid restrictions seen in this population, and others are less calorically dense. Most products contain generous amounts of protein to address requirements of highly stressed patients (nonprotein kilocalorie to nitrogen ratios typically between 75:1 and 125:1 [nonprotein energy to nitrogen ratio between about 300 and 500 kJ/g N]). Many products contain ingredients purported to increase immune function; the term immunonutrition is sometimes attached to these products.

Immune-enhancing ingredients present in some enteral feeding products include arginine, glutamine, ω-3 fatty acids, nucleic acids, and antioxidants. Few products contain all of these (see Table 101–4). Arginine is an important substrate for nitric oxide (NO) synthesis, and small amounts of NO have beneficial effects on immune function under certain conditions. Arginine has been purported to have a positive influence on lymphocyte and macrophage function. Glutamine is considered to be conditionally essential in critical illness and is a preferred fuel source for enterocytes of the small bowel. Supplementation with glutamine, either parenterally or enterally, may help maintain integrity of gut mucosa, preventing translocation of bacteria and endotoxin from the gut lumen into the lymphatic system and systemic circulation. However, a recent trial showed increased mortality with glutamine supplementation...
of patients with multiorgan failure. The ω-3 fatty acids, primarily from fish oils, are included in many immunonutrition products. Metabolites of ω-6 fatty acids include mediators such as prostaglandins, leukotrienes, and thromboxanes that are primarily proinflammatory and increase coagulation. Conversely, mediators produced from ω-3 fatty acids are less proinflammatory and decrease coagulation. Limited data support nucleic acids as immunomodulators. Quantities of antioxidants (particularly vitamin C, vitamin E, and β-carotene) higher than traditionally found in standard enteral formulas are added to some immunonutrition formulas to protect body systems, including the immune system, from damage by oxygen-free radicals.

**Use of enteral immunonutrition in certain clinical settings is now widely accepted.** Commercial immunonutrition products and/or specific ingredients found in these products have generally been found to have no benefit in terms of mortality rates. However, infection rates, length of stay, and length of time on a ventilator may be decreased with these products. The 2009 A.S.P.E.N./SCCM ICU Guidelines support use of these formulas in major elective surgery, trauma, burns, head and neck cancer, and mechanically ventilated patients. The best timing (initiation and duration) of delivery remains to be determined. There is some concern that supplementation with arginine may be detrimental in septic patients.

### Pulmonary Formulas

Enteral feeding formulas designed for use in patients with chronic obstructive pulmonary disease or receiving mechanical ventilation contain higher amounts of fat (40%–55% of total kilocalories) than most formulas. The rationale for high fat content is that burning of fat for energy is associated with less carbon dioxide production compared with burning of carbohydrate. Less carbon dioxide production theoretically would be advantageous in patients with retention of this substance and might facilitate weaning from mechanical ventilation. Because part of the market targeted by the manufacturers of these products comprises mechanically ventilated patients, these products are included in Table 101–4. Carbon dioxide retention owing to carbohydrate administration was a problem previously when feeding was overzealous. However, at conservative calorie levels, standard enteral formulas usually can be given without fear of excess carbon dioxide production.

One formula, Oxepa (Nestle), has been studied specifically in critically ill patients with acute respiratory distress syndrome (ARDS), acute lung injury (ALI), and sepsis. This formula contains high quantities of the ω-3 fatty acids (EPA) and γ-linolenic acid (GLA). GLA is metabolized to a prostaglandin with vasodilatory properties. EPA is converted to prostaglandins and leukotrienes that are less proinflammatory than those derived from ω-6 fatty acids. This formula contains large quantities of antioxidants. Patients receiving this formula had improved outcomes, including fewer days of mechanical ventilation, compared with patients receiving a high-fat enteral feeding product as a control. Another study using a standard enteral feeding product as a control did not show clear benefit in septic patients with ARDS or ALI. However, a third study demonstrated benefit from Oxepa in patients with early sepsis even when using a standard enteral feeding control product. Timing and duration of use for optimum benefit remain to be determined.

Diabetic Formulas

Similar to pulmonary formulas, formulas designed for patients with diabetes or stress-induced hyperglycemia are relatively high in fat and low in carbohydrates (Table 101–5). These formulas typically contain fiber (primarily soluble) because it plays some role in glycemic control. They also may contain fructose and MUFAs. Data support improved blood sugar control with use of these formulas in patients with diabetes. Whether or not a diabetic EN formula is chosen, avoidance of overfeeding and maintenance of good glycemic control with insulin or other hypoglycemic medications are important in these populations.

Renal Formulas

Products designed for use in renal failure have high caloric density (1.8–2 kcal/mL [7.5–8.4 kJ/mL]) to decrease administered fluid (Table 101–6). The products vary in amounts of nutrients of interest in renal failure patients such as protein, potassium, phosphorus, and magnesium. Products low in protein (20–35 g/L) may be appropriate in chronic renal failure patients not yet receiving dialysis. On the other hand, removal of nitrogen by dialysis, coupled with the hypercatabolic, hypermetabolic condition seen in many acute renal failure patients, makes use of higher protein formulas (80–90 g/L) appropriate in these situations. Potassium, phosphorus, and magnesium contents of EN formulas designed for use in renal failure tend to be lower than standard formulas because these renally excreted electrolytes accumulate during renal failure.

Historically, elemental formulas designed for renal failure were enriched with essential amino acids (EAs) and contained lesser amounts of nonessential amino acids (NEAs) than standard formulas. Theoretically, EAAs could combine with urea nitrogen in the synthesis of NEAs, leading to a decrease in blood urea nitrogen (BUN). The only situation in which such formulas may be appropriate is in patients with chronic renal failure who are not candidates for dialysis. Even in this setting, use of these products should be limited to no more than 2 or 3 weeks. These formulas have been supplanted largely by polymeric formulas with protein content similar to standard EN formulas. Many dialysis patients tolerate standard, high-protein EN formulas, although electrolytes must be monitored closely.

Hepatic Formulas

Specialized formulas for patients with hepatic insufficiency are limited in number. These are enriched with BCAAs while containing a reduced quantity of aromatic amino acids (AAAs) and methionine compared with standard formulas. These changes address high levels of AAAs and low levels of BCAAs found in the blood of patients with hepatic insufficiency. Theoretically, these products might help patients with hepatic encephalopathy (HE). Hepatic formulas have low AAA content, and this distinguishes them from the BCAA-enriched formulas historically used in patients with critical illness and stress. Improvement in mortality attributable to these products has not been consistent.

The A.S.P.E.N./SCCM guidelines for the ICU recommend against the use of protein restriction to reduce risk of development of HE. These guidelines recommend use of standard EN formulas for ICU patients with acute or chronic liver disease but state that the hepatic specialty formulas may be useful in improving coma grade in HE patients refractory to standard treatment with locally acting antibiotics and lactulose. An example of a specialized hepatic formula is Hepatic-Aid II (Hormel Health Labs), a product supplied as a powder for reconstitution that requires vitamin, mineral, and electrolyte supplementation. A second product is NutriHep (Nestle), supplied as a liquid formula containing the recommended amounts of key vitamins, minerals, and electrolytes.

Wound Healing Formulas

Tube feeding and oral supplement formulas designed for use in patients with wounds or decubitus ulcers typically supply high

Causes
Large quantities of sorbitol present in oral liquid medications related cause of diarrhea is the sorbitol content of medications. Acutely ill patients, including those receiving EN, are frequently very sick. Along these lines, antibiotic therapy is a major cause of diarrhea in acutely ill patients, including those receiving EN. A medication-related cause of diarrhea is the sorbitol content of medications. Large quantities of sorbitol present in oral liquid medications (often considered the dosage form of choice for administration through a feeding tube) can cause diarrhea. Unfortunately, sorbitol content of many medications is not listed on their labeling, and manufacturers frequently reformulate preparations to contain varying amounts of excipients, such as sorbitol.

Determining cause of diarrhea is important to know how to address the problem. Whereas C. difficile colitis should be treated

Patient Encounter, Part 1
LT is an obese 55-year-old woman with a history of diabetes mellitus and chronic obstructive pulmonary disease admitted with multiorgan failure and septic shock with a suspected pulmonary source. She meets criteria for acute respiratory distress syndrome (ARDS) and prerenal azotemia. She is placed on mechanical ventilation; started on aggressive fluid resuscitation, vasopressor therapy, and antibiotics; and systemic corticosteroid therapy. She is started on propofol for sedation while on the ventilator.

LT responds somewhat slowly to the sepsis protocol and on day 3 is still requiring both norepinephrine and vasopressin for blood pressure support. The dietitian assesses her nutritional needs. Her dry weight is 102 kg; height is 64 inches (163 cm); body mass index is 38 kg/m².

Is there any concern regarding starting EN at this time?
If EN is not appropriate at this time, should PN be initiated?

(continued on next page)

Modular Components
Single nutrient components are frequently administered through feeding tubes to augment the composition of the EN formula. Protein modules are probably the most commonly used. These may be supplied by the manufacturer as a powder that must be reconstituted with water or as a liquid product. Another modular component is fiber. These components are typically given as a bolus through the feeding tube rather than being added to the feeding formula.

MONITORING AND COMPLICATIONS
Although complications of EN generally are considered less serious than those of PN, some complications nevertheless can be dangerous or can lead to impaired delivery of desired nutrient load. Complications can be divided into four categories: GI, technical, infectious, and metabolic. The first three categories, along with common causes, are listed in Table 101–7. Patients on EN must be monitored for prevention of complications (Table 101–8). Monitoring of many parameters can become less frequent as patient condition stabilizes. Monitoring for efficacy of EN is also important.

GI Complications
GI complications are the most common complications of EN limiting the amount of feeding that patients receive. Although diarrhea frequently is blamed on feeding formula or the method of EN administration, other possible causes usually exist (see Table 101–8). In the inpatient setting, patients receiving EN frequently are very sick. Along these lines, Clostridium difficile colitis must be considered as a possible cause of diarrhea, especially in patients receiving antimicrobial therapy or proton pump inhibitors. Antibiotic therapy is a major cause of diarrhea in acutely ill patients, including those receiving EN. A medication-related cause of diarrhea is the sorbitol content of medications. Large quantities of sorbitol present in oral liquid medications

GI, gastrointestinal.

### Technical Complications

Technical or mechanical complications are encountered frequently in EN patients. Tube occlusion most commonly is related to formula occlusion or medication administration through the tube. An important practice to help prevent medication-related occlusion is adequate water flushing of the tube before, between, and after each medication is given through the tube. If intermittent feedings are used, water flushing after each feeding is recommended. Tube occlusion can increase cost of EN if the tube has to be removed and replaced. Clearing of occlusions using water or pancreatic enzymes plus sodium bicarbonate can be attempted, and special devices and kits (eg, DeClogger, Bionix) are available.

Tube displacement is a potentially significant complication. This may be seen in an agitated patient pulling at the tube, or in some cases, the tube tip migrates spontaneously. If the tip of the tube is positioned in the tracheobronchial tree and feeding is delivered to this area, pneumonia, pneumothorax, and other problems could potentially occur. Location of the feeding tube tip should be confirmed initially by chest radiograph after placement and before use. For ongoing assessment of tube placement, auscultation and measurement of aspirate pH can be used.

Endoscopic and surgical feeding tubes can cause erosion of the exit site caused by leakage of gastric or intestinal contents onto the skin. This complication must be addressed by good wound care and repair or replacement of the access device. Similarly, NG, ND, and NJ tubes can be complicated by nasopharyngeal irritation or necrosis. This is one reason why such tubes should be considered for short-term use only.

### Infectious Complications

Infectious complications of EN include aspiration pneumonia and infections related to delivery of contaminated EN formula. Although GI infections owing to industrial contamination of enteral formulas have been reported uncommonly, these formulas are more commonly seeded with organisms during the processes of transferring from can to delivery bag with ready-to-use formulas and during the process of reconstitution with powdered formulas. The so-called closed systems of delivery, wherein the formulas come from the manufacturer premixed

EN, enteral nutrition.

with an appropriate antibiotic, medication-related diarrhea can be addressed by removal of the offending agent. Likewise, diarrhea secondary to malabsorption sometimes can be addressed by changing to an oligomeric EN formula. Antiperistaltic agents (eg, loperamide) may be useful in some noninfectious diarrhea.

On the other hand, constipation may occur in patients receiving EN, especially the elderly. Increased provision of fluid or fiber may be useful. Constipation may be drug related, in which case discontinuation or replacement of the offending drug may be beneficial.

Impaired gastric emptying is seen commonly in EN patients receiving gastric feedings and may be associated with nausea and vomiting. Impaired emptying may be related to disease process (eg, diabetic gastroparesis or sequelae to head injury) or to drug therapy, most notably narcotics. Gastric residual checks frequently are measured in patients receiving gastric feedings (see Table 101–8). To accomplish this, a syringe is attached to the feeding device, and as much liquid as possible is aspirated into the syringe. Debate is ongoing as to what constitutes a significant gastric aspirate, with numbers between 200 and 500 mL most commonly defended; a recent study indicated that residual checks are not necessary. Approaches to the patient with delayed gastric emptying might include changing to a formula containing less fat because dietary fat is associated with slower gastric emptying. Metoclopramide often is given to patients receiving gastric feedings to facilitate gastric emptying. Erythromycin is an alternative medication that may be useful, although it is associated with drug–drug interactions. Patients with consistently high residuals are considered to be at higher risk of aspirating feedings into their lungs and should be considered for transition to postpyloric feedings. Postpyloric feedings may help relieve EN-related nausea and vomiting and are preferred for patients without an intact gag reflex. An important practice to help prevent aspiration is elevation of the head of the bed to at least 30 degrees during continuous feedings and during and for 30 to 60 minutes after intermittent and bolus feedings.

#### Technical Complications

Technical or mechanical complications are encountered frequently in EN patients. Tube occlusion most commonly is related to formula occlusion or medication administration through the tube. An important practice to help prevent medication-related occlusion is adequate water flushing of the tube before, between, and after each medication is given through the tube. If intermittent feedings are used, water flushing after each feeding is recommended. Tube occlusion can increase cost of EN if the tube has to be removed and replaced. Clearing of occlusions using water or pancreatic enzymes plus sodium bicarbonate can be attempted, and special devices and kits (eg, DeClogger, Bionix) are available.

Tube displacement is a potentially significant complication. This may be seen in an agitated patient pulling at the tube, or in some cases, the tube tip migrates spontaneously. If the tip of the tube is positioned in the tracheobronchial tree and feeding is delivered to this area, pneumonia, pneumothorax, and other problems could potentially occur. Location of the feeding tube tip should be confirmed initially by chest radiograph after placement and before use. For ongoing assessment of tube placement, auscultation and measurement of aspirate pH can be used.

Endoscopic and surgical feeding tubes can cause erosion of the exit site caused by leakage of gastric or intestinal contents onto the skin. This complication must be addressed by good wound care and repair or replacement of the access device. Similarly, NG, ND, and NJ tubes can be complicated by nasopharyngeal irritation or necrosis. This is one reason why such tubes should be considered for short-term use only.

#### Infectious Complications

Infectious complications of EN include aspiration pneumonia and infections related to delivery of contaminated EN formula. Although GI infections owing to industrial contamination of enteral formulas have been reported uncommonly, these formulas are more commonly seeded with organisms during the processes of transferring from can to delivery bag with ready-to-use formulas and during the process of reconstitution with powdered formulas. The so-called closed systems of delivery, wherein the formulas come from the manufacturer premixed
in a delivery bag, should help decrease possibility of formula contamination. Practice recommendations from A.S.P.E.N. state that sterile water should be used for formula reconstitution, medication dilution, tube flushing, and additional water provision in acute or chronically ill patients requiring EN. This recommendation can be difficult to implement, especially in home care.

Metabolic Complications

Metabolic complications of EN most commonly include disorders of fluid and electrolyte homeostasis and hyperglycemia. More severely ill patients require more frequent monitoring (see Table 101–8). Both dehydration and fluid overload can occur. Careful monitoring of fluid inputs and outputs as well as body weight is important. Dehydration may be caused by either excessive fluid losses or inadequate fluid intake. The trend in the ratio of BUN to serum creatinine can be useful in helping monitor fluid status; a ratio greater than 15:1 (60:1 for SI mmol/L:mmol/L) may be an indicator of dehydration; high ratios may also be a result of high protein provision by the feeding. Attention should be paid to free-water content of EN formulas. Free-water content varies from about 65% to 85%; percentage-free water typically drops as caloric density of the formula rises. If dehydration develops, switching to a less calorically dense formula or using larger water flushes is appropriate. Fluid overload is reflected by increases in weight, lower extremity edema, and pulmonary rales and particularly may be a problem in patients with renal or cardiac insufficiency. Use of a more calorically dense EN formula may be helpful, and diuretic therapy may be necessary. Fluid imbalances often are associated with abnormalities of sodium homeostasis that should be addressed in concert with fluid imbalance.

Hypokalemia, hypomagnesemia, and hypophosphatemia are some of the most common electrolyte abnormalities in sick, hospitalized patients. These can occur in context of the refeeding syndrome which occurs in chronically malnourished patients aggressively started on feeding. Although classically associated with PN, refeeding syndrome can also occur with aggressive EN. Careful monitoring of electrolytes, coupled with a feeding regimen increased gradually to goal rate over a period of several days, should help protect at-risk patients from this complication. Hypokalemia and hypomagnesemia also are associated with excessive losses through the GI tract or urine and are associated with various medications, including diuretics. Repletion may be accomplished enterally in nonsymptomatic patients or parenterally if the patient is symptomatic or the abnormality is severe. Enteral repletion with magnesium and phosphate can cause diarrhea. Hyperkalemia, hypermagnesemia, and hyperphosphatemia are less common and usually are associated with renal insufficiency. Hyperkalemia also is associated with medications, including potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers.

Although hyperglycemia is less common with EN than PN, it can occur. Many severely ill patients (eg, septic, highly stressed) receiving EN have a metabolic milieu promoting hyperglycemia. For ICU patients with hyperglycemia receiving continuous EN, an IV insulin drip may be the most effective way to achieve good glycemic control. Scheduled intermediate or long-acting insulin plus correctional regular or rapid acting insulin is preferred after stabilization on the feeding regimen. Administration of a higher fat, lower carbohydrate EN formula may be useful in selected patients.

Monitoring for Efficacy and Outcome Evaluation

A useful physical measurement of EN efficacy in the long-term patient is body weight. Depending on the clinical situation, the goal may be weight gain, weight maintenance, or weight loss. Whereas day-to-day fluctuations in weight generally reflect fluid changes, week-to-week variations are more useful in determining if caloric provision is appropriate.

The amount of EN actually administered is often less than the amount ordered owing to interruptions in therapy. It is imperative to monitor volume of feedings actually received and to make adjustments in rates or amounts of EN as necessary.

Biochemical markers have been used historically to help interpret EN adequacy. Use of visceral proteins such as albumin or prealbumin is limited by the effects of inflammation on serum levels of these biomarkers. In the acute phase of illness characterized by a proinflammatory state, proteins known as acute-phase reactants are preferentially synthesized. One of these measured clinically is C-reactive protein (CRP). In some patients with significant illness, prealbumin may not rise, even though the patient is receiving appropriate EN, until CRP begins to fall. Collection of urine to measure nitrogen balance can help analyze adequacy of caloric and protein provision.

In patients with wounds (eg, decubitus ulcers), a goal of therapy is to facilitate wound healing. Monitoring status of the wound becomes part of ongoing nutritional assessment. In debilitated patients, particularly on long-term EN, measures of functional status such as grip strength and ability to perform activities of daily living become important components of nutritional assessment.

MEDICATION ADMINISTRATION IN PATIENTS RECEIVING EN

Medication Administration Through Feeding Tubes

If a patient receiving EN is alert and can swallow oral medications, then medications should be given by mouth. Many patients are not able to receive medications by this route, and the feeding tube may be considered as a delivery route. Effects of medication administration through feeding tubes on the delivery of both the drug and the EN formula nutrients have been inadequately studied.

Patient Encounter, Part 2

On day 4, vasopressor requirements are minimal and enteral feeding is initiated at a low rate via nasogastric tube. Propofol is changed to dexmedetomidine on day 5. Gastric residuals range from 0 to 20 mL over the next 2 days as the tube feeding is advanced to goal rate. Blood sugar readings rise to above 200 mg/dL (11.1 mmol/L), necessitating initiation of an insulin drip on day 7; on day 9, insulin glargine subcutaneous is added as the insulin drip is titrated off.

How does propofol affect the initial EN prescription?

Design an enteral feeding regimen, including choice of formula and goal rate, appropriate for this patient at this time.

What are this patient’s risk factors for hyperglycemia, and is the approach to blood sugar management rational?
Compatibility of medication with EN formula is of concern when administering medications through feeding tubes. An important technical complication of EN is tube occlusion, related most commonly to medication administration. Not only must compatibility of medication and EN formula be considered, but interactions between medications and the feeding tube itself must be considered. Strict protocols for flushing the tube before, between, and after administration of medications are important. The best fluid for flushing is warm water. Between 10 and 30 mL of water should be used as a flush before and after any medication administration through a feeding tube. Medications should be administered one at a time sequentially rather than being mixed together for simultaneous administration down the tube; about 5 mL of water should be used as a flush between medications. This should help prevent interactions between drugs within the tube itself that could lead to occlusion.

Different dosage forms present unique challenges for administration through feeding tubes. Certain solid dosage forms should not be crushed because crushing would alter release characteristics. For example, controlled-release, extended-release, and sustained-release preparations should not be crushed, nor should sublingual dosage forms. Enteric-coated dosage forms generally are designed to protect acid-labile medications from stomach acid; when these dosage forms reach the small bowel with its higher pH, the drug is released into an environment in which it is more stable. Alternatively, enteric-coated dosage forms protect the stomach from medications that could cause irritation. Thus, crushing the enteric coating defeats the purpose of the dosage form and could lead to decreased efficacy or increased adverse events.

Medications available commercially as compressed tablets can be crushed for administration through tubes. After crushing, the fine powder should be mixed with 10 to 30 mL of fluid (usually warm water) for administration. A powdered dosage form inside a hard-gelatin capsule can be poured out and mixed with water for administration through tubes. Soft-gelatin capsules can be dissolved in warm water. Some enteric-coated and delayed-release microencapsulated products can be opened and individually coated particles administered through the tube without crushing if the tube has a large enough diameter.

If a liquid dosage form of a medication exists, it would seem rational to use this for administration through a feeding tube. This may decrease potential for tube clogging but may in some instances decrease tolerability of medication administration. Sorbitol is an excipient found in many liquid medications in amounts sufficient to cause diarrhea. If diarrhea secondary to sorbitol is suspected, contact with the manufacturer to ascertain sorbitol content may be necessary.

Another potential problem with administration of liquid medications through feeding tubes is high osmolality of some products. Dilution of hypertonic medications with 30 to 60 mL of water or administration of smaller doses more frequently may help prevent diarrhea. Although administration of IV medications through feeding tubes may be entertained, these dosage forms frequently are hypertonic and contain problematic excipients when given via the GI tract.

It is generally not recommended to mix medications directly into EN formula because physical incompatibilities might lead to tube occlusion. Limited data currently available indicate that acidic syrups and elixirs may be most harmful, causing physical incompatibility when admixed with EN formulas. It would seem logical that medications considered absorbed better in the fasted state either should be given between feedings on an intermittent feeding schedule or feedings should be held before and after medication administration. However, not all studies have supported this notion; therefore, this issue deserves further study.

Location of feeding tube tip is important when considering medication administration. This is particularly true if the medication acts locally in the GI tract. For example, sucralfate and antacids act locally in the stomach; therefore, administration through a duodenal or jejunal tube is illogical. Likewise, for medications requiring acid for best absorption, administration directly into the duodenum or jejunum may result in suboptimal absorption. Absorption of drugs when administered directly into the small bowel, especially the jejunum, is a topic where more research would be useful.

### Problem Medications

#### Phenytoin

Certain medications present challenges when administered through feeding tubes. The medication studied most thoroughly is phenytoin. Most studies have shown significant decreases in phenytoin absorption when administered enterally to patients receiving EN. Several mechanisms have been proposed for this interaction. Liberal dilution of phenytoin suspension before its administration down the tube may improve its delivery. Many institutions hold tube feedings for 1 or 2 hours before and after administration of phenytoin, although some EN patients subjected to this routine still require high dosages of phenytoin to achieve therapeutic serum concentrations. Holding feeding around medication administration can make meeting nutritional requirements difficult with continuous feedings, especially if phenytoin is administered several times daily. Diligent monitoring of phenytoin serum concentrations is necessary for the patient on EN receiving this medication. In some cases, use of IV phenytoin or another anticonvulsant medication may be prudent.

#### Warfarin

EN formulas contain vitamin K, which can antagonize the pharmacologic activity of warfarin. Vitamin K content of EN formulas has been adjusted down over several decades, resulting in products that contain amounts of vitamin K unlikely to affect anticoagulation by warfarin significantly. However, inadequate warfarin anticoagulation in EN patients receiving formulas containing minimal vitamin K has been reported. A component of certain tube feedings, perhaps protein, may bind warfarin and result in suboptimal activity. One small study indicated a better response in terms of the international normalized ratio (INR) when feedings were held for 1 hour before and after warfarin compared with administration of the drug without

### Patient Encounter, Part 3

LT is extubated on day 13. Concern regarding her swallowing strength leads to a speech pathology consult. She is switched to a standard formula tube feeding. On day 14, an order to advance oral diet as tolerated is written following the speech pathology assessment.

**Was the switch to a standard tube feeding formula rational?**

**How should the transition from EN to oral feedings be accomplished?**
holding feedings. When tube feedings are started, changed, or discontinued, INR should be monitored closely.

► Fluoroquinolones
Absorption of antimicrobial agents such as fluoroquinolones and tetracyclines that can be bound by divalent and trivalent cations potentially could be compromised by administration with EN formulas containing these cations. Fluoroquinolones (eg, levofloxacin and ciprofloxacin) have been best studied in this regard, and results of studies are not consistent. Some institutions hold tube feedings for 1 to 2 hours or more before and after enteral dosages of fluoroquinolones. Not all fluoroquinolones are affected by the interaction, suggesting that a mechanism other than chelation by divalent cations may also be significant. Because ciprofloxacin absorption has been shown to be decreased with jejunal administration, this drug probably should not be given by jejunal tube.

SUMMARY AND CONCLUSION
EN is an important method of feeding patients who cannot or should not eat enough to meet nutrient requirements for a prolonged time. When the GI tract can be used safely, EN is preferred over PN. Various types of enteral access devices are available. Whereas tubes inserted through the nose often are adequate for patients expected to receive EN for a short time, more permanent devices are preferred for longer-term patients. Choice of whether to feed into the stomach or postpylorically is patient specific. Although numerous EN formulas are available, many products are very similar, making a limited formulary feasible.

Data supporting many specialized types of EN formulas are limited. Although complications of EN tend to be less serious than those of PN, adverse effects encountered can be significant, and diligent ongoing monitoring is necessary. Although medications can be administered through feeding tubes, various factors must be taken into account in each individual patient.

Abbreviations Introduced in This Chapter

AAA  Aromatic amino acid(s)
AI  Adequate intake
ALI  Acute lung injury
ARDS  Acute respiratory distress syndrome
A.S.P.E.N.  American Society for Parenteral and Enteral Nutrition
BCAA  Branched-chain amino acid(s)
BUN  Blood urea nitrogen
CRP  C-Reactive protein
DHA  Docosahexanoic acid
EAA  Essential amino acid(s)
EFA  Essential fatty acid(s)
EN  Enteral nutrition
EPA  Eicosapentaenoic acid
ESPEN  European Society for Clinical Nutrition and Metabolism
FOS  Fructooligosaccharide
GALT  Gut-associated lymphoid tissue
GI  Gastrointestinal
GLA  y-Linolenic acid
HE  Hepatic encephalopathy
IBD  Inflammatory bowel disease
ICU  Intensive care unit
INR  International normalized ratio
LCT  Long-chain triglyceride
MCT  Medium-chain triglyceride
MUFA  Monounsaturated fatty acid
ND  Nasoduodenal
NEAA  Nonessential amino acid
NG  Nasogastric
NJ  Nasojugal
NO  Nitric oxide
OG  Orogastro
PEG  Percutaneous endoscopic gastrostomy
PEJ  Percutaneous endoscopic jejunostomy
PN  Parenteral nutrition
PUFA  Polyunsaturated fatty acid
RDA  Recommended Dietary Allowance

SCFA  Short-chain fatty acid
SNS  Specialized nutrition support

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of overweight and obesity.
2. Identify parameters used to diagnose obesity and other objective information that indicates the severity of disease.
3. Identify desired therapeutic goals for patients who are overweight or obese.
4. Recommend appropriate nonpharmacologic and pharmacologic therapeutic interventions for overweight or obese patients.
5. Implement a monitoring plan that will assess both the efficacy and safety of therapy initiated.

INTRODUCTION

Overweight and obesity are terms used to describe weight measurements greater than what is considered healthy for a given height. Body mass index (BMI), waist circumference (WC), comorbidities, and readiness to lose weight are used in the assessment of overweight or obese patients. The primary modality in defining overweight and obesity is the BMI, a measure of body fat based on height and weight. BMI should be used to identify adults at increased risk for cardiovascular disease (CVD) and other obesity-related disorders. Evaluation of the patient’s risk status involves not only calculation of the BMI but also the measurement of WC and determination of obesity-related comorbidities and presence of CVD risk factors.

ETIOLOGY AND EPIDEMIOLOGY

Obesity is a multifactorial, complex disease that occurs because of an interaction between genotype and the environment. Although the etiology is not completely known, it involves overlapping silos of social, behavioral, and cultural influence; pathophysiology; metabolism; and genetic composition. The majority of overweight or obese individuals are adults, but these diseases are also prevalent in children between 2 and 19 years of age. While the prevalence of obesity appears to be leveling off, approximately 35% of US adults 20 years of age and older are currently considered obese. The prevalence of obesity in men and women of various racial and ethnic origins differ. Thirty-six percent of non-Hispanic white adults are considered obese, where approximately 40% of Mexican Americans and 50% of non-Hispanic black Americans are obese.

Thirty-two percent of children and adolescents aged 2 through 19 years are considered either overweight or obese. The prevalence of obesity among this age group remains unchanged at 17%. Overweight children typically mature to overweight adults, but most obese adults were not overweight as children. Overweight and obesity, when present in young adults, may be a better predictor of prevalence. Adulthood overweight and obesity contribute to an increased risk of death in the presence of hypertension, dyslipidemia, diabetes mellitus, CVD, stroke, sleep apnea, gallbladder disease, osteoarthritis, and certain cancers. Psychosocial functioning also may be hindered because obese patients may be at risk for discrimination if negatively stereotyped. Pediatric obesity is also associated with significant health-related problems and is therefore considered a risk factor for much of the adult obesity-related morbidity and mortality.

PATHOPHYSIOLOGY

The key factor in the development of overweight and obesity is the imbalance that occurs between energy intake and energy expenditure. The extent of obesity is determined by the length of time this imbalance has been present. Energy intake is affected
by environmental influences, including social, behavioral, and cultural factors, whereas genetic composition and metabolism affect energy expenditure.50

Energy Intake

Food intake is regulated by various receptor systems. Stimulation of the following receptors increases and decreases food intake, respectively.

► Increase Food Intake
  - Serotonin 1A subtype (5-HT<sub>1A</sub>)
  - Noradrenergic α₂
  - Cannabinoid 1 (CB₁)

► Decrease Food Intake
  - Serotonin 2C subtype (5-HT<sub>2C</sub>)
  - Noradrenergic α₁ or β₂
  - Histamine subtypes 1 and 3 (H₁ and H₃)
  - Dopamine 1 and 2 (D₁ and D₂)

Identification of appetite-associated receptors is useful in the development of pharmacologic agents, however not all are targeted by currently approved anti-obesity medications. In addition to receptor-modulated food consumption, higher levels of the protein leptin are associated with decreased food intake.11 In contrast, elevated levels of neuropeptide Y increase food intake.11

It is debatable whether obesity is related to total calorie intake or composition of macronutrients. Of the three macronutrients (ie, carbohydrate, protein, and fat), fat has received the most attention, given its desirable texture and its ability to augment the flavor of other foods. Food high in fat promotes weight gain, in comparison with the other macronutrients, because fat is more energy dense. When compared with carbohydrate and protein, more than twice as many calories per gram are contained in fat. In addition, fat is stored more easily by the body compared with protein and carbohydrate.12

Energy Expenditure

A person’s metabolic rate is the primary determinant of energy expenditure. The metabolic rate is enhanced after food consumption and is directly related to the amount and type.13

Physical inactivity may predispose an individual to overweight and obesity. In addition, endocrine-related disorders (eg, hypothyroidism and Cushing syndrome) may lower the metabolic rate, further contributing to the development of overweight and obesity.

CLINICAL PRESENTATION AND DIAGNOSIS

BMI, WC, comorbidities, and readiness to lose weight are used in the assessment of overweight or obese patients. Any interaction between a patient and a health care provider presents an opportunity to evaluate the patient’s height and weight; however, these parameters should be measured no less than annually. The BMI should then be calculated and classified based on current cut points for overweight and obesity. The BMI is calculated using the measured weight in kilograms divided by the height in meters squared (kg/m²) for all adult patients regardless of gender. The greater the BMI in overweight and obese individuals, the greater the risk of CVD, type 2 diabetes mellitus and all-cause mortality.14 The BMI distribution changes with age for children just as height and weight. Percentiles specific for age and gender are used to classify pediatric patients as overweight or obese as well as healthy and underweight. The BMI is classified according to Table 102–1. WC should also be determined no less than annually for adult patients by placing a measuring tape at the top of the right iliac crest and proceeding around the abdomen, ensuring that the tape is tight but not constricting the skin. The value is measured after normal expiration.2 Table 102–2 defines high-risk WC.2 Measurement of WC is not recommended for children and adolescents because reference values identifying risk are unavailable.15 After obtaining patient appropriate parameters, further assess the adult patient for the presence of obesity-related comorbidities and cardiovascular risk factors.15

The presence of comorbidities (CVD, type 2 diabetes mellitus, and sleep apnea) and cardiovascular risk factors (cigarette smoking, hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, impaired fasting glucose) requires identification and aggressive management for overall effective treatment of the overweight or obese patient. A patient at very high absolute risk if diagnosed with CVD, type 2 diabetes mellitus, or sleep apnea or if three or more of the risk factors listed in Table 102–3 are present.2 Aggressive disease management should be initiated and not limited to weight loss. If the patient is a child or adolescent and the BMI is greater than the 85th percentile, determine the patient’s risk for future obesity-related problems or presence of obesity-related medical conditions such as sleep, respiratory, gastrointestinal (GI), endocrine, cardiovascular, and psychiatric disorders.15,16

**TREATMENT**

**Desired Outcome**

**KEY CONCEPT** The treatment goals for overweight and obesity are to prevent additional weight gain, reduce and maintain a lower body weight, and control related risks. A 5% to 10% weight loss as derived from the patient’s current weight is the initial goal of obesity management because favorable outcomes on the negative effects of obesity have been documented. A sustained loss in weight of 5% will likely reduce triglyceride and blood glucose values as well as risk for the development of type 2 diabetes mellitus. Greater reductions in weight will reduce blood pressure and improve both low-density and high-density lipoprotein cholesterol. **KEY CONCEPT** Weight loss is indicated for patients with a BMI of 25 to 29.9 kg/m² with one or more indicators of increased CVD risk (eg, elevated WC, prediabetes or type 2 diabetes, hypertension, dyslipidemia, current cigarette smoker) or for any patient with a BMI of 30 kg/m² or greater. Weight loss should occur at a rate of 0.45 to 0.9 kg (1–2 lb) per week, meeting the initial weight loss goal within the first 6 months of therapy. If the patient achieves a 5% to 10% loss in weight, weight loss maintenance strategies should be considered. **KEY CONCEPT** Weight maintenance occurs after successful achievement of weight loss.

It is desirable to achieve a goal of improved long-term physical health for a child or adolescent. A BMI below the 85th percentile is warranted but is difficult to assess in frequent or short time periods. Serial weight measurements may better quantify energy balance. Goals are most likely accomplished through adaptation of lifelong healthy lifestyle habits. In doing so, weight loss or maintenance can be attained for some children. Others may need to incorporate changes that result in a negative energy balance or energy input less than energy output.

**General Approach to Treatment**

**KEY CONCEPT** Treatment of obesity includes comprehensive lifestyle intervention (caloric restricted diet, increased physical activity, and behavioral therapy to facilitate compliance with diet and exercise), pharmacologic treatment, surgical intervention, or a combination of modalities. Before initiating therapy, secondary causes of obesity (eg, hypothyroidism and Cushing syndrome) must be considered. Current treatment with medications that negatively alter weight should be determined and, if present, alternative therapies should be suggested. Table 102–4 provides a list of drugs commonly associated with weight gain. If no secondary cause exists, the presence of other cardiovascular risk factors and

**Patient Encounter 1, Part 1**

A 54-year-old woman presents to your weight loss clinic for an initial evaluation. She reports that her glucose was elevated upon screening while attending a community health fair. She followed up with her primary care provider who recommended weight loss as patient is unwilling to start metformin. She is not currently following any specific diet. She admits to eating foods high in sugar content, especially for breakfast. She routinely skips lunch and then snacks on potato chips, nuts, and sweetened beverages in the late afternoon. She frequently eats fast food for dinner as it is quick and requires no clean-up. Patient is recently divorced (1 year ago) and doesn’t enjoy making dinner for one. This patient is not currently exercising but has adhered to a daily walking regimen in the past. The patient does not smoke or consume alcohol. Her BMI is 30.8 kg/m² and her waist circumference is 39 in (99 cm).

**What classification of overweight and obesity is appropriate for this patient?**

**Does this patient have a high-risk waist circumference?**

**Does she have other risk factors that may contribute to morbidity or mortality?**

**What are the treatment goals for the patient?**

**What additional information do you need to know before creating a treatment plan for this patient?**
comorbidities must be determined to guide clinical decisions. Therapy implemented to minimize associated risk(s) may not enhance weight loss, but weight loss will positively address risk factors. Weight loss therapy should not be initiated in pregnant or lactating patients, decompensated psychiatric patients, or patients in whom reduced caloric intake can exacerbate an acute, serious illness. Four stages have been suggested for the treatment of obesity in children and adolescents. Stage 1 or Prevention Plus is the first step and includes adherence to healthy eating and activity habits. Patients should be encouraged to eat more than or equal to five servings of fruits and vegetables daily, limit consumption of sweetened drinks, decrease television or other screen time behaviors, and increase physical activity to greater than or equal to 1 hour/day. Stage 2 or Structured Weight Management incorporates Prevention Plus habits while setting specific eating and activity goals. Responsibilities include meal planning, observed physical activity or play daily for 1 hour, and documentation of energy consumption and expenditure. Comprehensive Multidisciplinary Interventions (Stage 3) is directed at increasing the intensity of healthy behaviors. To accomplish goals, the child or adolescent should work closely with the primary care provider, registered dietitian, exercise specialist, and behavioral counselor. Stage 4, Tertiary Care Intervention, may be needed for severely obese adolescents. A very low-calorie diet, medication or weight control surgery may be warranted.

Nonpharmacologic Therapy

Given that the imbalance between energy intake and energy expenditure is key factor for developing overweight and obesity, weight loss therapy requires the creation of an energy deficit. This can be achieved through daily caloric restriction and increased physical activity. Both therapeutic strategies are part of a comprehensive lifestyle intervention program as well as behavioral therapy to facilitate compliance and exercise. Comprehensive lifestyle intervention is foundational to weight loss and should be recommended for patients who have never participated in such a program. In addition, a comprehensive lifestyle intervention program is recommended for patients even when adjunctive therapy with medications or bariatric surgery have been implemented.

Reduced-Calorie Diet

Overall energy consumption and expenditure will determine the amount of weight alteration. Techniques to reduce dietary energy intake include adoption of a target energy intake less than that required for energy balance. This can usually be achieved by reducing the energy intake by 500 kcal/day (2093 kJ/day) or greater. Recommend 1200–1500 or 1500–1800 kcals/day (5023–6279 or 6279–7534 kJ/day) for women and men, respectively. The choice of calorie-restricted diet is based on patient preference and current health status. A variety of diets, including but not limited to high protein, low carbohydrate, low fat, Mediterranean and American Heart Association (AHA) Step-1 diet, can result in weight loss if reduction in dietary intake is achieved. The AHA Step-1 diet restricts daily calories to a range of 1000 to 1200 kcal (4186–5023 kcal/day) for women weighing less than 75 kg (165 lb) and 1400 to 1600 kcal (5860–6697 kcal/day) for all others. This daily limit should be considered after assessing a patient’s normal daily caloric intake and ensuring that the initial caloric restriction does not exceed 500 to 1000 kcal (2093–4186 kcal/day). For example, a male patient who consumes 3000 kcal (12,557 kcal/day) should not reduce his daily caloric intake to less than 2000 kcal (8372 kcal/day) when initially implementing a dietary program. Further reduction to the target of 1600 kcal (6697 kcal/day) can be attempted when the patient has reduced calories successfully as initially recommended for a period agreeable by the practitioner and the patient. Diets that are too restrictive in calorie reduction are successful initially but fail in the long term because compliance is difficult to sustain. Therefore, this less aggressive approach promotes gradual weight loss and weight maintenance. Consultation with a dietician is recommended when implementing a healthy meal plan tailored to the individual’s nutritional needs.

Increased Physical Activity

Although diet and exercise contribute to weight loss, combining a reduced-calorie diet with increased physical activity results in greater weight loss compared with either therapy alone. In addition, physical activity can help prevent weight regain and reduce related cardiovascular risks. Slow titration of both the amount and intensity of aerobic physical activity is recommended for most patients. A program that incorporates brisk walking daily is a viable option for most patients. Suggest 10 minutes of physical activity 3 days/week with a target of no less than 30 minutes most days, if not every day. Two hundred to 300 minutes per week of aerobic physical activity are recommended for weight maintenance or prevention of weight regain.

Behavioral

Nonadherence with recommended lifestyle changes may result in unsuccessful weight loss for adults. Eliminating barriers through behavior modification is necessary to gain maximal benefit from both dietary modification and exercise. Successful behavioral therapy includes regular self-monitoring of food intake, physical activity, and weight. Targeted behaviors should be recommended to pediatric patients and their families because healthy habits help prevent excessive weight gain. These include, but are not limited to:

- Limit the consumption of sugar-sweetened beverages.
- Limit the amount of screen time (television, computer, etc) to 2 hours or less per day.

• Limit the number of meals eaten at restaurants, especially those serving fast food.
• Parents should limit portion size when preparing and serving meals.

Pharmacologic Therapy

**KEY CONCEPT** Pharmacotherapy in addition to comprehensive lifestyle intervention can be considered for patients with a BMI of 30 kg/m² or greater, or a BMI of 27 kg/m² or greater with other obesity-related risk factors. Pharmacologic products promoting weight loss are classified according to their mechanisms of action, including the suppression of appetite and the suppression of fat absorption.

Pharmacotherapy was indicated previously for short-term use; however, because obesity-related risks resurface with weight regain, long-term treatment may be necessary to minimize these sequelae. **KEY CONCEPT** Weight will likely be regained if lifestyle changes are not continued indefinitely. Four drugs are currently approved for long-term use in promoting weight loss and preventing weight regain.

> Orlistat

Orlistat promotes and maintains weight loss by acting locally in the GI tract. It inhibits pancreatic and gastric lipases, as well as triglyceride hydrolysis. As a result, undigested triglycerides are not absorbed, causing a caloric deficit and weight loss.21

Several studies have reported significant weight loss for adult patients receiving orlistat 120 mg three times a day compared with placebo.22,23 Weight maintenance or prevention of weight regain has also been documented with continued orlistat use.22,24

Orlistat (120 mg three times daily) in combination with diet, exercise, and behavior modification resulted in a significant reduction in BMI and WC in adolescents. In addition, orlistat-treated subjects exhibited minimal weight increase after 1 year.25

The safety and efficacy of orlistat have not been determined beyond 4 years of use. Because orlistat acts locally in the GI tract, common side effects reported include oily spotting, flatus with discharge, fecal urgency, fatty or oily stools, oily evacuation, increased defecation, and fecal incontinence.21 Other adverse events include bloating, abdominal pain, dyspepsia, nausea, vomiting, diarrhea, and headache.26 Liver injury information is contained within orlistat’s product label and includes signs, symptoms, and when to seek medical attention for severe liver disease. Signs and symptoms include itching, yellowing of the eyes or skin, dark urine, decreased appetite and light-colored stools. Orlistat should be stopped if the patient complains of these signs and symptoms. In addition, liver function tests, including aspartate transaminase (AST) and alanine aminotransferase (ALT), should be assessed.27

Orlistat reduces the absorption of some fat-soluble vitamins and β-carotene. Daily intake of a multivitamin containing fatsoluble vitamins, as well as β-carotene, is recommended. Patients should take the multivitamin 2 hours before or after the dose of orlistat.21 Because the availability of vitamin K may decline in patients receiving orlistat therapy, close monitoring of coagulation status should occur with concomitant administration of warfarin.21 Hypothyroidism has been observed in patients taking both orlistat and levothyroxine. Patients should take levothyroxine 4 hours before or after the orlistat dose and be monitored for changes in thyroid function. Administration of orlistat in conjunction with cyclosporine can result in decreased cyclosporine plasma levels. To avoid this interaction, cyclosporine should be taken 2 hours before or after the dose of orlistat. Additionally, cyclosporine levels should be monitored more frequently.21

Pregnant or lactating women should not take orlistat because no data exist to establish safety. Orlistat is contraindicated in patients with chronic malabsorption syndrome or cholestasis.21

Initiate orlistat 120 mg three times a day with a well-balanced but reduced-caloric meal containing no more than 30% of calories from fat. Orlistat may be taken during or up to 1 hour after the meal. If a meal is missed or contains little fat, the dose of orlistat may be omitted. Doses above 360 mg/day provide no greater benefit and thus are not recommended.21

> Lorcaserin

Lorcaserin, a 5-HT₄ agonist, promotes satiety and decreases food consumption; however, the exact mechanism is unknown. The safety and effectiveness of lorcaserin has been established in adults, however, no data exists for patients under the age of 18; therefore, pediatric use is not recommended.28,29

Common adverse reaction noted in the trials include headache, dizziness, fatigue, nausea, dry mouth, and constipation. Almost 30% of diabetic patients taking lorcaserin experienced hypoglycemia. Blood glucose should be monitored closely in patients taking an antidiabetic medication and lorcaserin.29

Because lorcaserin is a serotonergic drug, serotonin syndrome may occur if taken with other drugs affecting the serotonergic neurotransmitter systems including triptans, monoamine oxidase inhibitors (MAOI), selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, tricyclic antidepressants, bupropion, lithium, antipsychotics, St. John’s Wort, tryptophan, and dextromethorphan. If serotonin syndrome symptoms occur (agitation, hallucinations, tachycardia, hyperthermia, muscle rigidity, nausea/vomiting and diarrhea), discontinue lorcaserin immediately and initiate supportive care.28

Lorcaserin is contraindicated during pregnancy (Pregnancy Category X). Because it is unknown whether lorcaserin is excreted in human milk, the nursing mothers should avoid use while nursing or decide not to nurse.28

Initiate lorcaserin 10 mg twice daily in addition to a calorie-restricted diet and increased physical activity. The drug should be discontinued if the patient has not achieved a 5% weight loss by week 12 of treatment. Doses greater than 20 mg daily are not recommended and may result in the development of euphoria, altered mood, and hallucinations. Due to the potential for psychic dependence and abuse, lorcaserin is a federally controlled substance (CIV).28

> Phentermine-topiramate

Phentermine-topiramate is an extended-release combination product approved for weight loss. Phentermine decreases food intake by increasing norepinephrine and dopamine release in the central nervous system (CNS). Topiramate is an antiepileptic drug whose exact mechanism of action is unknown. It is thought to increase satiety and suppress appetite through multiple pathways.30

The safety and effectiveness of phentermine-topiramate have not been established in pediatric patients; therefore, its use is not recommended.30

Common adverse reactions include paresthesias, dizziness, dysgeusia, insomnia, constipation, and dry mouth. Phentermine-topiramate use is associated with increased heart rate. Monitor resting heart rate frequently and have patients report the presence of palpitations. Topiramate can increase a patient’s risk for suicidal thoughts and behaviors. Patients should be monitored for worsening depression, thoughts of suicide, and unusual mood or behavior. Topiramate is also associated with acute myopia and secondary angle closure glaucoma. Patients should...
report decreased visual acuity and/or ocular pain. Phentermine-topiramate can cause mood disorders (depression and anxiety) and insomnia. Most resolve spontaneously but dose reduction or discontinuation of drug may be necessary. Cognitive impairment is also associated with use of phentermine-topiramate; patients should proceed with caution when operating hazardous machinery including driving a car until the extent of impairment is known. An increase in serum creatinine and decrease in both potassium and bicarbonate have been reported. Monitoring of serum electrolytes and creatinine are recommended at baseline and during therapy.30

Because topiramate is a known teratogen, use of phentermine-topiramate during pregnancy is contraindicated. All women of childbearing potential should have a documented negative pregnancy result before this drug is initiated and monthly while on therapy. Phentermine-topiramate may be excreted in human milk; nursing mothers should avoid use or discontinue nursing.30

Coadministration of phentermine-topiramate and MAOI could result in a hypertensive crisis. Do not initiate phentermine-topiramate within 14 days of MAOI discontinuation. Phentermine-topiramate used in patients taking an oral contraceptive may cause irregular bleeding but not an increased risk of pregnancy. Advise patients to not discontinue the oral contraceptives if spotting occurs. Alcohol can potentiate the CNS depressant effect; avoid concomitant use.30

Initiate phentermine-topiramate at a dose of 3.75 mg/23 mg daily for 14 days then increase to 7.5 mg/46 mg daily. Discontinue drug or increase the dose of phentermine-topiramate if a 3% weight loss is not achieved in 12 weeks. If the decision is made to increase the dose, recommend 11.25 mg/69 mg daily for 14 days then increase to 15 mg/92 mg daily. Discontinue drug if a 5% weight loss is not achieved after 12 weeks at the highest drug dose. Due to the potential for drug abuse, phentermine-topiramate is a federally controlled substance (CIV).30

**Naltrexone-Bupropion**

Naltrexone-bupropion is an extended-release combination product approved for chronic weight management. The exact mechanisms by which this opioid antagonist/antidepressant combination product decreases food intake and weight are not fully known but involve two separate areas of the brain (hypothalamus and mesolimbic dopamine circuit).31

The safety and effectiveness of naltrexone-bupropion have not been established in patients less than 18 years; therefore, its use is not recommended.31

Patients taking this combination weight loss product should be monitored for emergence or worsening of suicidal thoughts and behaviors and neuropsychiatric reactions. Common adverse reactions include nausea, constipation, headache, vomiting, dizziness, and insomnia. This combination product is contraindicated in patients with elevated blood pressure, seizure disorders or in patients taking antiepileptics, in patients taking chronic opioids and in patients taking MAOI or discontinued MAOI use within 14 days. Bupropion inhibits CYP2D6 and can therefore increase the concentration of antidepressants, antipsychotics and β-blockers. When taken with a CYP2B6 inhibitor (eg, clopidogrel), the concentration of bupropion increases. Reduce maximum daily dose by half in these patients. CYP2B6 inducers may reduce bupropion efficacy.31

Naltrexone-bupropion is contraindicated during pregnancy as weight loss offers no benefit during pregnancy and potential for fetal harm (Pregnancy Category X). This drug is not recommended for nursing mothers.31

Each extended-release tablet contains 8 mg of naltrexone and 90 mg of bupropion. Patients should be advised to not cut, crush, or chew tablets. Patients should also avoid taking naltrexone-bupropion with high-fat meals to minimize the risk of enhanced bupropion absorption and subsequent seizure occurrence. To further reduce the risk of seizures, the dose must be titrated slowly. Initiate drug at one tablet every morning for 1 week, then one tablet twice daily (morning and evening) for 1 week, then two tablets in the morning and one tablet in the evening for 1 more week and then two tablets twice a day thereafter. If the patient has not lost 5% of baseline body weight following 12 weeks of maintenance therapy, naltrexone-bupropion should be discontinued.31

**Phentermine**

As monotherapy, this drug is indicated for short-term use—no more than a few weeks—in addition to lifestyle modifications.32 An average weight loss of 3.6 kg (7.9 lb) was demonstrated for patients treated with phentermine compared with placebo.26

Safety and efficacy have not been determined in pediatric patients less than 16 years of age.32

Common adverse reactions seen with phentermine use include heart palpitations, tachycardia, elevated blood pressure, stimulation, restlessness, dizziness, insomnia, euphoria, dysphoria, tremor, headache, dry mouth, constipation, and diarrhea. Phentermine should be avoided in patients with CVD, hypertension, hyperthyroidism and agitated states. Because phentermine is related to the amphetamines, the potential for abuse is high.32

Phentermine use should be avoided in patients concomitantly receiving or having received a MAOI within the preceding 14 days due to the potential for causing hypertensive crisis. Alcohol is not recommended for patients prescribed phentermine.32

The use of phentermine is contraindicated in pregnant patients as weight loss offers no benefit during pregnancy and risk of fetal harm (Pregnancy Category X). Owing to the potential for severe adverse effects in nursing infants, a decision to stop the drug or discontinue nursing must be made.32

Phentermine is available as an immediate- and a sustained-release product. In conjunction with a healthy lifestyle, 30 to 37.5 mg of phentermine is administered once daily, typically before breakfast or 1 to 2 hours after the morning meal. The dosage should be individualized; some patients may be managed adequately at 15 to 18.75 mg/day, but a dose of 18.75 mg twice daily may be used to minimize side effects, excluding insomnia. To lessen the risk of insomnia, dosing phentermine in the evening should be avoided.32

**Diethylpropion**

This sympathomimetic amine exhibits similar pharmacologic activity as the amphetamines, resulting in CNS stimulation and appetite suppression and is indicated for short-term use in conjunction with a reduced-calorie diet and physical exercise.33 The safety and effectiveness of diethylpropion have not been established in patients younger than 16 years; therefore, its use is not recommended.33

Use of diethylpropion for a period longer than 3 months is associated with an increased risk for development of pulmonary hypertension. When used as directed, reported common CNS adverse effects included overstimulation, restlessness, dizziness, insomnia, euphoria, dysphoria, tremor, headache, jitteriness, anxiety, nervousness, depression, drowsiness, malaise, mydriasis, and blurred vision. In addition, diethylpropion can decrease
Surgical Intervention

Surgical options for obesity may produce a loss of two-thirds of excessive weight after 2 years that is sustained long term. Additionally, favorable outcomes for obesity-related comorbid conditions are observed after surgery. When evaluating the various types of surgery available, long-term data suggests the average weight loss from gastric bypass after 15 years is 27%, which is significantly higher than banding (around 14%) and conventional therapy (2%). Risk versus benefit must be considered as complications are inherent to any surgical procedure. The more common bariatric surgery complications are respiratory problems, wound formation, wound infections, hernia development, deep venous thrombosis, and pulmonary embolism. No differences were observed in mortality rates among various surgical procedures. Postoperative weight loss is much greater compared with pharmacologic therapies, but no comparative trials exist.

Bariatric surgery is an alternative offered to adolescents because it results in substantial weight loss and medical health improvement, but also has the potential for serious complications. Patients with a BMI greater than or equal to 40 kg/m² and an associated medical condition or BMI greater than or equal to 35 kg/m² with obesity-related comorbidities are considered as candidates for surgery.

All patients undergoing bariatric surgery should be part of an comprehensive program of health education, diet, exercise, and behavioral modification before and after surgery. Patients must understand and commit to a substantial change in eating patterns to maintain long-term weight reduction. Postoperatively, health care providers should also make considerations for medication management as these procedures may alter drug and nutrient absorption.

Medications should be transitioned to crushed or liquid formulations initially and until appropriate to restart solid dosage forms (likely variable).
OUTCOME EVALUATION

Successful management of overweight and obesity is determined by the ability the treatment plan has to (a) prevent weight gain, (b) reduce and maintain a lower body weight, and (c) decrease the risk of obesity-related comorbidities. Because weight is necessary to calculate the BMI, measure the patient’s weight and WC. Obesity management may encompass more than weight loss or maintenance in the presence of other conditions; assess other pertinent parameters at baseline. This includes presence of hypertension, type 2 diabetes mellitus, hyperlipidemia, CVD, sleep apnea, hypothyroidism, osteoarthritis, gallbladder disease, gout, or cancer. Measure blood pressure and heart rate before implementation of any therapy, and assess basic metabolic panel, liver function tests, complete blood count, fasting lipid profile, full thyroid function tests, and other laboratory studies at baseline and as clinically indicated. Additionally, obtain an electrocardiogram if recent results are unknown. When considering various approaches to behavioral therapy for weight loss, in-person, high-intensity (defined as a minimum of 14 sessions within 6 months) behavioral therapy is the most effective. Sessions can be conducted by a pharmacist or trained interventionist for an individual or groups of patients. During each session, assess compliance with comprehensive lifestyle intervention, as well as measure weight, blood pressure, and heart rate. Measure WC intermittently. Identify presence of adverse drug reactions or drug interactions if weight loss medications have been initiated.

When the patient has achieved the recommended weight loss, he or she then enters the weight maintenance phase, which includes continued contact for education (no less than monthly), guidance, and risk factor assessment. Self-weighing, at least weekly, is associated with better weight maintenance over time. Counsel patient to address small weight gains before they become larger.

If weight loss is not attained, further assess why the goals of therapy are unmet. Direct the interaction toward determining the motivation to lose weight, balance between caloric intake and physical activity, adherence to behavioral therapy, and determination of psychological stressors present. Refer patient to a nutrition professional or for evaluation for bariatric surgery. If adjunctive pharmacotherapy has not been initiated, consider antiobesity drugs approved for long-term use.
Patient Encounter 2, Part 3: CVD Risk Reduction 12-Week Follow-up Clinic Visit

The patient present for his 12-week follow-up visit in the CVD Risk Reduction Clinic. He states that he has been adhering to the Step-1 diet and currently jogs on a treadmill 30 minutes a day 2 days a week.

SH: Continues to drink three to four beers nightly

Meds: Lisinopril 10 mg orally every morning

ROS: (–) Heartburn, regurgitation; (–) chest pain, nausea, vomiting, diarrhea, change in appetite, shortness of breath, or cough

VS: BP 126/74 mmHg, P 84 beats/min, RR 16 breaths/min, T 98.5°F (36.9°C), Wt 221 lb (100.2 kg), Ht 65 in (165 cm)

Waist Circumference: 45 in (114)

PE:

General: Well developed, in no acute distress

HEENT: Conjunctiva clear

CV: Regular rhythm, no S₃ or S₄ noted

Lungs: CTA bilaterally

Abd: Obese, soft, non-tender, non-distended; (+) bowel sounds

Neuro: Normal gait, normal speech

Ext: (–) Edema

Labs: Na 142 mEq/L (142 mmol/L); K 4.7 mEq/L (4.7 mmol/L); Cl 107 mEq/L (107 mmol/L); CO₂ 23 mEq/L (23 mmol/L); BUN 18 mg/dL (6.4 mmol/L); creatinine 1.0 mg/dL (88 μmol/L); glucose 84 mg/dL (4.7 mmol/L); TC 218 mg/dL (5.64 mmol/L); LDL 155 mg/dL (4.01 mmol/L); HDL 34 mg/dL (0.88 mmol/L); TG 145 mg/dL (1.64 mmol/L); AST 20 U/L (33 μkat/L); ALT 32 U/L (0.53 μkat/L)

Calculate the patient’s BMI.

What is the best weight loss option for the patient?

Patient Care Process

**Patient Assessment:**
- Measure weight and height.
- Calculate BMI.
- Classify BMI to identify patients at increased risk for CVD/other obesity-related conditions.
- Review medical history for secondary causes of weight gain.
- Conduct a medication history to identify drug therapy contributing to weight gain.
- Review laboratory data to identify secondary causes of weight gain, identify CVD risks and obesity-related comorbidities and to ensure safe use of medication.
- Assess current lifestyle and history of weight gain/loss over time.
- Assess need to lose weight (candidates include obese patients or overweight patients with at least one indicator of increased CVD risk:
  - Elevated WC, prediabetes or diabetes, hypertension, dyslipidemia, current cigarette smoker
- Assess readiness to make lifestyle changes.
- Determine weight loss goals.

**Therapy Evaluation:**
- Implement comprehensive lifestyle intervention strategies (restricted caloric-diet, increased physical activity, and behavioral therapy) with or without adjunctive therapies.
- If patient is already receiving an antiobesity medication, assess efficacy, safety, adherence, and potential drug interactions.
- Manage CVD risk factors such as hypertension, dyslipidemia, etc.

**Care Plan Development:**
- Implement comprehensive lifestyle intervention. If antiobesity drug is warranted, choose a medication for chronic obesity management that is deemed safe based on patient-specific parameters.
- Educate the patient regarding a comprehensive lifestyle intervention program, one that includes a balance between caloric intake and energy expenditure as well as suggest methods to modify behavior.
- Encourage self-weighing, at least weekly, for better weight loss and maintenance over time.

**Follow-Up Evaluation:**
- In 2 weeks, assess weight, blood pressure, heart rate, and adherence with comprehensive lifestyle intervention. Assess weight log.
- Patients should be reassessed in person no less than 14 times within a 6-month period.
- Once weight loss is achieved, continue contact with patient no less than monthly. Address small weight gains and continued adherence with comprehensive lifestyle intervention. Continually assess risk for CVD and address when necessary.
Abbreviations Introduced in This Chapter

ALT  Alanine aminotransferase
AST  Aspartate transaminase
BMI  Body mass index
CB  Cannabinoid receptor
CNś  Central nervous system
CVD  Cardiovascular disease
D1  Dopamine 1
D2  Dopamine 2
GI  Gastrointestinal
5-HT₁A  Serotonin 1A subtype
H₁  Histamine subtype 1
H₃  Histamine subtype 3
5-HT₂C  Serotonin 2C subtype
MAOİ  Monoamine oxidase inhibitor

CONVERSION FACTORS

SI Units
SI (le Système International d’Unités) units are used in many countries to express clinical laboratory and serum drug concentration data. Instead of using units of mass (eg, micrograms), the SI system uses moles (mol) to represent the amount of a substance. A molar solution contains 1 mole (the molecular weight of the substance in grams) of the solute in 1 L of solution. The following formula is used to convert units of mass to moles (mcg/mL to μmol/L or, by substitution of terms, mg/mL to mmol/L or ng/mL to nmol/L).

»» Micromoles per Liter

\[ \text{Micromoles per liter (μmol/L)} = \frac{\text{drug concentration (mcg/mL) } \times 1000}{\text{molecular weight of drug (g/mol)}} \]

»» Milliequivalents

An equivalent weight of a substance is the weight that will combine with or replace 1 g of hydrogen; a milliequivalent is 1/1000 of an equivalent weight.

Milliequivalents per Liter

\[ \text{Milliequivalents per liter (mEq/L)} = \frac{\text{weight of salt (g)} \times \text{valence of ion} \times 1000}{\text{molecular weight of salt}} \]

Weight of salt (g) = \[\frac{\text{mEq/L} \times \text{molecular weight of salt}}{\text{valence of ion} \times 1000}\]

*The atomic/molecular weight of phosphorus is only 31; that of sulfur is only 32.1.

Anion Gap

The anion gap is the concentration of plasma anions not routinely measured by laboratory screening. It is useful in the evaluation of acid–base disorders. The anion gap is greater with increased plasma concentrations of endogenous species (eg, phosphate, sulfate, lactate, and ketoacids) or exogenous species (eg, salicylate, penicillin, ethylene glycol, ethanol, and methanol). The formulas for calculating the anion gap are as follows:

\[
\text{Anion gap} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-)
\]

or

\[
\text{Anion gap} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)
\]

where the expected normal value for the first equation is 11 to 20 mmol/L and for the second equation is 7 to 16 mmol/L. Note that there is a variation in the upper and lower limits of the normal range.

Temperature

- Fahrenheit to Centigrade: \((°F – 32) \times 5/9 = °C\)
- Centigrade to Fahrenheit: \((°C \times 9/5) + 32 = °F\)
- Centigrade to Kelvin: \(°C + 273 = °K\)

Weights and Measures

- **Metric Weight Equivalents**
  - 1 kilogram (kg) = 1000 grams
  - 1 gram (g) = 1000 milligrams
  - 1 milligram (mg) = 0.001 gram
  - 1 microgram (mcg, μg) = 0.001 milligram
  - 1 nanogram (ng) = 0.001 microgram
  - 1 picogram (pg) = 0.001 nanogram
  - 1 femtogram (fg) = 0.001 picogram

- **Metric Volume Equivalents**
  - 1 liter (L) = 1000 milliliters
  - 1 deciliter (dL) = 100 milliliters
  - 1 milliliter (mL) = 0.001 liter
  - 1 microliter (μL) = 0.001 milliliter
  - 1 nanoliter (nL) = 0.001 microliter
  - 1 picoliter (pL) = 0.001 nanoliter
  - 1 femtoliter (fL) = 0.001 picoliter

- **Apothecary Weight Equivalents**
  - 1 scruple (⊙) = 20 grains (gr)
  - 60 grains (gr) = 1 dram (⊙)
  - 8 drams (⊙) = 1 ounce (⊙)
  - 1 ounce (⊙) = 480 grains (gr)
  - 12 ounces (⊙) = 1 pound (lb)

- **Apothecary Volume Equivalents**
  - 60 minims (m) = 1 fluidram (fl ⊙)
  - 8 fluidrams (fl ⊙) = 1 fluid ounce (fl ⊙)
  - 1 fluid ounce (fl ⊙) = 480 minims (m)
  - 16 fluid ounces (fl ⊙) = 1 pint (pt)

**Conversion Equivalents**

- 1 gram (g) = 15.43 grains (gr)
- 1 grain (gr) = 64.8 milligrams (mg)
- 1 ounce (⊙) = 31.1 grams (g)
- 1 ounce (⊙) = 28.35 grams (g)
- 1 pound (lb) = 453.6 grams (g)
- 1 kilogram (kg) = 2.2 pounds (lb)
- 1 milliliter (mL) = 0.001 liter
- 1 minim (m) = 0.06 milliliter (mL)
- 1 fluid ounce (fl oz) = 29.57 milliliters (mL)
- 1 pint (pt) = 473.2 milliliters (mL)
- 1 US gallon = 3.78 liters (L)
- 1 Canadian gallon = 4.55 liters (L)
- 0.1 milligram = 1/650 grain
- 0.12 milligram = 1/540 grain
- 0.15 milligram = 1/430 grain
- 0.2 milligram = 1/320 grain
- 0.3 milligram = 1/220 grain
- 0.4 milligram = 1/160 grain
- 0.5 milligram = 1/130 grain
- 0.6 milligram = 1/110 grain
- 0.8 milligram = 1/80 grain
- 1 milligram = 1/65 grain

**Metric Length Conversion Equivalents**

- 2.54 cm = 1 inch
- 30.48 cm = 1 foot
- 1 m = 3.28 feet
- 1.6 km = 1 mile

ANTHROPOMETRICS

**Creatinine Clearance Formulas**

- **Formulas for Estimating Creatinine Clearance in Patients with Stable Renal Function**

  - **Cockcroft-Gault Formula**
    
    Adults (age 18 years and older):  
    
    \[
    \text{CrCl} \text{ (men)} = \frac{140 - \text{age}}{\text{SCr} \times 72} \times \text{weight}
    \]
    
    \[
    \text{CrCl} \text{ (women)} = 0.85 \times \text{above value}^\text{*}
    \]

  *Some studies suggest that the predictive accuracy of this formula for women is better without the correction factor of 0.85.
where CrCl is creatinine clearance (in mL/min), SCr is serum creatinine (in mg/dL [or μmol/L divided by 88.4]), age is in years, and weight is in kilograms.

**Traub-Johnson Formula**
Children (age 1–18 years):

\[
CrCl = \frac{0.48 \times \text{height} \times \text{BSA}}{\text{SCr} \times 1.73}
\]

where BSA is body surface area (in m²), CrCl is creatinine clearance (in mL/min), SCr is serum creatinine (in mg/dL [or μmol/L divided by 88.4]), and height is in centimeters.

**Formula for Estimating Creatinine Clearance From a Measured Urine Collection**

\[
CrCl (\text{mL/min}) = \frac{U \times V}{P \times T}
\]

where \(U\) is the concentration of creatinine in a urine specimen in mg/dL, \(V\) is the volume of urine in mL, \(P\) is the concentration of creatinine in serum at the midpoint of the urine collection period in mg/dL, and \(T\) is the time of the urine collection period in minutes (eg, 6 hours = 360 minutes; 24 hours = 1440 minutes). Procedures for obtaining urine specimens should stress the importance of complete urine collection during the collection time period.

**IDMS-Traceable MDRD Equation (Used for Creatinine Methods with Calibration Traceable to IDMS)**

For creatinine in mg/dL:

\[
X = 175 \times \text{creatinine}^{-1.154} \times \text{age}^{-0.203} \times \text{constant}
\]

For creatinine in μmol/L:

\[
X = 175 \times (\text{creatinine}/88.4)^{-1.154} \times \text{age}^{-0.203} \times \text{constant}
\]

where \(X\) is the glomerular filtration rate, constant for white men is 1 and for women is 0.742, and constant for African Americans is 1.212.

**Ideal Body Weight**

IBW is the weight expected for a non-obese person of a given height. The IBW formulas below and various life insurance tables can be used to estimate IBW. Dosing methods described in the literature may use IBW as a method in dosing obese patients.

**Adults (age 18 years and older):**

\[
\begin{align*}
\text{IBW (men)} & = 50 + (2.3 \times \text{height in inches over 5 ft}) \\
\text{IBW (women)} & = 45.5 + (2.3 \times \text{height in inches over 5 ft})
\end{align*}
\]

where IBW is in kilograms.

**Children (age 1–18 years) under 5-feet tall:**

\[
\text{IBW} = \frac{\text{height}^2 \times 1.65}{1000}
\]

where IBW is in kilograms and height is in centimeters.

**Children (age 1–18 years) 5 feet or taller:**

\[
\begin{align*}
\text{IBW (males)} & = 39 + (2.27 \times \text{height in inches over 5 ft}) \\
\text{IBW (females)} & = 42.2 + (2.27 \times \text{height in inches over 5 ft})
\end{align*}
\]

where IBW is in kilograms.

**REFERENCES**

Appendix B: Common Medical Abbreviations

These are the abbreviations used commonly in medical practice both in verbal communication and in the medical record.

</tbody>
</table>
AVR  aortic valve replacement
BBB  bundle branch block; blood–brain barrier
BC  blood culture
BCOP  Board Certified Oncology Pharmacist
BCP  birth control pill
BCPP  Board Certified Psychiatric Pharmacist
BCPS  Board Certified Pharmacotherapy Specialist
BE  barium enema
BG  blood glucose
bid  twice daily (bis in die)
BKA  below-knee amputation
BM  bone marrow; bowel movement; an isoenzyme of creatine phosphokinase
BMC  bone marrow cells
BMD  bone mineral density
BMI  body mass index
BMP  basic metabolic panel
BMR  basal metabolic rate
BMT  bone marrow transplantation
BP  blood pressure
BPD  bronchopulmonary dysplasia
BPH  benign prostatic hyperplasia
bpm  beats per minute
BR  bed rest
BS  bowel sounds; breath sounds; blood sugar
BSA  body surface area
BUN  blood urea nitrogen
Bx  biopsy
C&S  culture and sensitivity
CA  cancer; calcium
CABG  coronary artery bypass grafting
CAD  coronary artery disease
CAH  chronic active hepatitis
CAM  complementary and alternative medicine
CAPD  continuous ambulatory peritoneal dialysis
CBC  complete blood count
CBD  common bile duct
CBG  capillary blood gas; corticosteroid-binding globulin
CC  chief complaint
CCA  calcium channel antagonist
CCB  calcium channel blocker
CCE  clubbing, cyanosis, edema
CCK  cholecystokinin
CCU  coronary care unit
CF  cystic fibrosis
CFS  chronic fatigue syndrome
CFU  colony-forming unit
CHD  coronary heart disease
CHF  congestive heart failure; chronic heart failure
CHO  carbohydrate
CI  cardiac index
CIWA  Clinical Institute Withdrawal Assessment
CK  creatine kinase
CKD  chronic kidney disease
CLL  chronic lymphocytic leukemia
CM  costal margin
CMG  cystometrogram
CML  chronic myelogenous leukemia
CMV  cytomegalovirus
CN  cranial nerve
CNS  central nervous system
C/O  complains of
CO  cardiac output; carbon monoxide
COLD  chronic obstructive lung disease
COPD  chronic obstructive pulmonary disease
CP  chest pain; cerebral palsy
CPAP  continuous positive airway pressure
CPK  creatine phosphokinase; (BB, MB, and MM are isoenzymes)
CPP  cerebral perfusion pressure
CPR  cardiopulmonary resuscitation
CrCl  creatinine clearance
CRF  chronic renal failure; corticotropin-releasing factor
CRH  corticotropin-releasing hormone
CRI  chronic renal insufficiency; catheter-related infection
CRNA  Certified Registered Nurse Anesthetist
CRNP  Certified Registered Nurse Practitioner
CRP  C-reactive protein
CRTT  Certified Respiratory Therapy Technician
CSF  cerebrospinal fluid; colony-stimulating factor
CT  computed tomography; chest tube
cTnI  cardiac troponin I
CTZ  chemoreceptor trigger zone
CV  cardiovascular
CVA  cerebrovascular accident
CVC  central venous catheter
CVP  central venous pressure
Cx  culture; cervix
CXR  chest x-ray
CYP  cytochrome P450
DBP  diastolic blood pressure
D&C  dilatation and curettage
D_5W  5% dextrose in water
D&C  discharge
D/C  discontinuance
DCC  direct-current cardioversion
DI  diabetes insipidus
DIC  disseminated intravascular coagulation
Diff  differential
DJD  degenerative joint disease
DKA  diabetic ketoacidosis
dL  deciliter
DM  diabetes mellitus
DNA  deoxyribonucleic acid
DNR  do not resuscitate
DO  Doctor of osteopathy
DOA  dead on arrival; date of admission; duration of action
DOB  date of birth
DOE  dyspnea on exertion
DOT  directly observed therapy
DPGN  diffuse proliferative glomerulonephritis
DPI  dry powder inhaler
DRE  digital rectal examination
DRG  diagnosis-related group
DS  double strength
D/t  due to
DTP  diphtheria–tetanus–pertussis
DTR  deep tendon reflex
DVT  deep vein thrombosis
Dx  diagnosis
EBV  Epstein-Barr virus

<tr>
<td>IM</td>
<td>intramuscular; infectious mononucleosis</td>
</tr>
<tr>
<td>INH</td>
<td>isoniazid</td>
</tr>
<tr>
<td>INR</td>
<td>international normalized ratio</td>
</tr>
<tr>
<td>IOP</td>
<td>intraocular pressure</td>
</tr>
<tr>
<td>IP</td>
<td>intraperitoneal</td>
</tr>
<tr>
<td>IPG</td>
<td>impedance plethysmography</td>
</tr>
<tr>
<td>IPN</td>
<td>interstitial pneumonia</td>
</tr>
<tr>
<td>IRB</td>
<td>institutional review board</td>
</tr>
<tr>
<td>ISA</td>
<td>intrinsic sympathomimetic activity</td>
</tr>
<tr>
<td>ISH</td>
<td>isolated systolic hypertension</td>
</tr>
<tr>
<td>IT</td>
<td>intrathecal</td>
</tr>
<tr>
<td>ITP</td>
<td>idiopathic thrombocytopenic purpura</td>
</tr>
<tr>
<td>IU</td>
<td>international units (this can be dangerous abbreviation because it may be read as “IV” for “intravenous”)</td>
</tr>
<tr>
<td>IUD</td>
<td>intrauterine device</td>
</tr>
<tr>
<td>IV</td>
<td>intravenous; Roman numeral four; symbol for class 4 controlled substances</td>
</tr>
<tr>
<td>IVC</td>
<td>inferior vena cava; intravenous cholangiogram</td>
</tr>
<tr>
<td>IVDA</td>
<td>intravenous drug abuse</td>
</tr>
<tr>
<td>IVDU</td>
<td>injection drug use; intravenous drug use</td>
</tr>
<tr>
<td>IVF</td>
<td>intravenous fluids</td>
</tr>
<tr>
<td>IVIG</td>
<td>intravenous immunoglobulin</td>
</tr>
<tr>
<td>IVP</td>
<td>intravenous pyelogram; intravenous push</td>
</tr>
<tr>
<td>JODM</td>
<td>juvenile-onset diabetes mellitus</td>
</tr>
<tr>
<td>JRA</td>
<td>juvenile rheumatoid arthritis</td>
</tr>
<tr>
<td>JVD</td>
<td>jugular venous distension</td>
</tr>
<tr>
<td>JVP</td>
<td>jugular venous pressure</td>
</tr>
<tr>
<td>K</td>
<td>potassium</td>
</tr>
<tr>
<td>kcal</td>
<td>kilocalorie</td>
</tr>
<tr>
<td>KCl</td>
<td>potassium chloride</td>
</tr>
<tr>
<td>KOH</td>
<td>potassium hydroxide</td>
</tr>
<tr>
<td>KUB</td>
<td>kidney, ureter, and bladder</td>
</tr>
<tr>
<td>KVO</td>
<td>keep vein open</td>
</tr>
<tr>
<td>L</td>
<td>liter</td>
</tr>
<tr>
<td>LABA</td>
<td>long-acting beta agonist</td>
</tr>
<tr>
<td>LAD</td>
<td>left anterior descending; left axis deviation</td>
</tr>
<tr>
<td>LAO</td>
<td>left anterior oblique</td>
</tr>
<tr>
<td>LBBB</td>
<td>left bundle branch block</td>
</tr>
<tr>
<td>LBP</td>
<td>low-back pain</td>
</tr>
<tr>
<td>LDH</td>
<td>lactate dehydrogenase</td>
</tr>
<tr>
<td>LDL</td>
<td>low-density lipoprotein</td>
</tr>
<tr>
<td>LE</td>
<td>lower extremity</td>
</tr>
<tr>
<td>LES</td>
<td>lower esophageal sphincter</td>
</tr>
<tr>
<td>LFT</td>
<td>liver function test</td>
</tr>
<tr>
<td>LHRH</td>
<td>luteinizing hormone-releasing hormone</td>
</tr>
<tr>
<td>LLE</td>
<td>left lower extremity</td>
</tr>
<tr>
<td>LLL</td>
<td>left lower lobe</td>
</tr>
<tr>
<td>LLQ</td>
<td>left lower quadrant (abdomen)</td>
</tr>
<tr>
<td>LMD</td>
<td>local medical doctor</td>
</tr>
<tr>
<td>LMP</td>
<td>last menstrual period</td>
</tr>
<tr>
<td>LMWH</td>
<td>low-molecular-weight heparin</td>
</tr>
<tr>
<td>LOS</td>
<td>length of stay</td>
</tr>
<tr>
<td>LP</td>
<td>lumbar puncture</td>
</tr>
<tr>
<td>LPN</td>
<td>Licensed Practical Nurse</td>
</tr>
<tr>
<td>LPT</td>
<td>Licensed Physical Therapist</td>
</tr>
<tr>
<td>LR</td>
<td>lactated Ringer's</td>
</tr>
<tr>
<td>LS</td>
<td>lumbosacral</td>
</tr>
<tr>
<td>LT</td>
<td>levothyroxine</td>
</tr>
<tr>
<td>LUQ</td>
<td>left upper quadrant</td>
</tr>
<tr>
<td>LUTS</td>
<td>lower urinary tract symptoms</td>
</tr>
<tr>
<td>LVH</td>
<td>left ventricular hypertrophy</td>
</tr>
<tr>
<td>MAP</td>
<td>mean arterial pressure</td>
</tr>
<tr>
<td>MAR</td>
<td>medication administration record</td>
</tr>
<tr>
<td>MB-CK</td>
<td>a creatine kinase isoenzyme</td>
</tr>
<tr>
<td>mcg</td>
<td>microgram</td>
</tr>
<tr>
<td>MCH</td>
<td>mean corpuscular hemoglobin</td>
</tr>
<tr>
<td>MCHC</td>
<td>mean corpuscular hemoglobin concentration</td>
</tr>
<tr>
<td>MCV</td>
<td>mean corpuscular volume</td>
</tr>
<tr>
<td>MD</td>
<td>Medical Doctor</td>
</tr>
<tr>
<td>MDI</td>
<td>metered-dose inhaler</td>
</tr>
<tr>
<td>MDRD</td>
<td>modification of diet in renal disease</td>

Inflammation of the middle ear accompanied by fluid in the middle ear space and signs or symptoms of an acute ear infection.

Abscess: A purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells.

Absence: A primary-generalized seizure characterized by sudden and brief (i.e., several seconds in duration) loss of consciousness without muscle movements.

Acanthosis nigricans: Increased thickness and hyperpigmentation of the outer cell layers of the skin; typically observed at areas of flexure.

Acaricide: A chemical that kills mites and ticks.

Acetaldehyde: A hepatotoxic metabolic by-product of alcohol.

Acetylcholine: The neurotransmitter responsible for transmitting messages between certain nerve cells in the brain.

Acetone: A compound in red blood cells that affects oxygen binding to and release from hemoglobin.

Ablation: Destruction of part or all of an organ or structure.

Acute coronary syndrome (ACS): Ischemic chest discomfort at rest most often accompanied by ST-segment elevation, ST-segment depression, or T-wave inversion on the 12-lead electrocardiogram; caused by plaque rupture and partial or complete occlusion of the coronary artery by thrombus. Acute coronary syndromes include myocardial infarction and unstable angina.

Addiction: A primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over substance use, compulsive use, continued use despite harm, and craving.

Adenoma: A non-malignant tumor of the epithelial tissue that is characterized by glandular structures.

Adenomatous polyposis coli (APC): A gene associated with familial adenomatous polyposis (FAP), an inherited disorder characterized by the development of myriad polyps in the colon, often occurring in adolescents and young adults ages 15 to 25.

Adverse drug reaction (ADR): Any unexpected, unintended, undesired, or excessive response to a medication that requires discontinuing or changing the medication, or modifying the dose (except for minor dosage modifications). May necessitate hospital admission and/or supportive treatment; prolong stay in a health care facility; significantly complicate diagnosis; negatively affect prognosis; or result in temporary or permanent harm, disability, or death.

Adrenergic receptor: A receptor for norepinephrine and epinephrine.

Adrenergic fibers: Nervous fibers that secrete norepinephrine and epinephrine.

Aerophagia: The act of swallowing air.

Aeronautic: Concerning the science of aviation.

Aeronastronautics: The science of aviation.

Aeroallergen: An airborne substance that causes an allergic response.

Afterload: The force against which a ventricle contracts that is contributed to by the vascular resistance, especially of the arteries, and by the physical characteristics (mass and viscosity) of the blood.

Ageism: Discrimination against aged persons.
Air embolus: An obstruction in a small blood vessel caused by air that is introduced into a blood vessel and is carried through the circulation until it lodges in a smaller vessel.

Akathisia: Motor or subjective feelings of restlessness, often characterized by the urge to move limbs and inability to sit still.

Akinesthesia: Lack of movement.

Albuminuria: The presence of albumin (greater than 30 mg/day) in the urine, which is an early sign of chronic kidney disease (CKD).

Aldosterone: A hormone produced in and secreted by the zona glomerulosa of the adrenal cortex. Aldosterone acts on the kidneys to reabsorb sodium and excrete potassium. It is also a part of the renin-angiotensin-aldosterone system that regulates blood pressure and blood volume.

Alkalosis: A decrease in the concentration of carbon dioxide in the blood or a rise above normal in pCO₂.

Alkalosis: Any pathologic state that leads to alkalemia.

Allodynia: Pain that results from a stimulus that does not normally cause pain.

Allograft: Tissue or organ transplanted from a donor of the same species but different genetic makeup; recipient’s immune system must be suppressed to prevent rejection of the graft.

Allograft survival: After the transplant procedure, the transplanted organ continues to have some degree of function, from excellent to poor.

All recognize: Recognition of the foreign antigens present on the transplant organ or the donor’s antigen presenting cells.

Alopecia: Hair loss.

Alzheimer disease: Type of dementia with insidious onset and gradual progression that causes problems with memory, learning, thinking, and behavior. Symptoms eventually become severe enough to interfere with daily tasks, including self-care.

Ambulatory esophageal reflux monitoring: A telemetry capsule containing a tiny camera is swallowed, or a transnasal catheter is inserted to determine how often reflux is occurring as well as the incidence of abnormal esophageal acid exposure. The telemetry capsule provides about 48 hours of data, whereas the transnasal catheter provides about 24 hours of data.

Amenorrhea: Abnormal cessation or absence of menses.

Ampulla of Vater: Dilation of the duodenal wall at the opening of the fused pancreatic and common bile ducts.

Amylin: A 37-amino acid polypeptide hormone that is secreted from the β cells of the pancreas in response to nutrients. Mechanisms of action include slowing gastric emptying, suppressing postmeal glucagon secretion, and suppressing appetite.

Amyloid: Any of a group of chemically diverse proteins that are composed of linear non-branching aggregated fibrils.

Anaphylactic/anaphylaxis: Immediate, severe, potentially fatal hypersensitivity reaction induced by an antigen.

Anaphylactoid: An anaphylactic-like reaction, similar in signs and symptoms but not mediated by IgE. The drug causing this reaction produces direct release of inflammatory mediators by a pharmacological effect.

Anastomosis: The connection of two hollow organs to restore continuity after resection.

Anemia: Reduction in the concentration of hemoglobin that results in reduced oxygen-carrying capacity of the blood.

Anemia of chronic kidney disease: A decline in red blood cell production caused by a decrease in erythropoietin production by the progenitor cells of the kidney. As kidney function declines in chronic kidney disease, erythropoietin production also declines, resulting in decreased red blood cell production. Other contributing factors include iron deficiency and decreased red blood cell lifespan, caused by uremia.

Anergy: A reduction or lack of an immune response to a specific antigen.

Aneurysm: A blood-filled bulge which forms in the wall of a weakened blood vessel; if ruptured, may result in bleeding, shock, and/or other negative health outcome including mortality.

Angina: Discomfort in the chest or adjacent areas caused by decreased blood and oxygen supply to the myocardium (myocardial ischemia).

Angioedema: Swelling similar to urticaria (hives), but the swelling occurs beneath the skin instead of on the surface. Characterized by deep swelling around the eyes and lips and sometimes of the hands and feet. If it proceeds rapidly, it can lead to airway obstruction and suffocation, and should therefore be treated as a medical emergency.

Angiogenesis: The formation of new blood vessels. Increased blood flow to deliver nutrients is required for tumor growth.

Angiography: Examination of the blood vessels using x-rays after injection of a radiopaque substance.

Anterior circulation: Blood supply to the anterior portion of the brain supplied by the internal carotid arteries, anterior cerebral artery, and middle cerebral artery.

Anterograde amnesia: Memory loss affecting the transfer of new information or events to long-term storage.

Antiangiogenic: Preventing or inhibiting the formation and differentiation of blood vessels.

Anticoagulant: Any substance that inhibits, suppresses, or delays the formation of blood clots. These substances occur naturally and regulate the clotting cascade. Several anticoagulants have been identified in a variety of animal tissues and have been commercially developed for medicinal use.

Antiproteinase: A substance that inhibits the enzymatic activity of a proteinase.

Anuria: Urine output of less than 50 mL over 24 hours.

Aphakic: The absence of a lens in the eye.

Aphasia: Impairment of language affecting the ability to speak and to understand speech.

Aphthous ulcer: A small superficial area of ulceration within the gastrointestinal mucosa, typically found in the oral cavity.

Apoptosis: Programmed cell death as signaled by the nuclei in normally functioning cells when age or state of cell health and condition dictates.

Arcuate scotoma: An arc-shaped area of blindness in the field of vision.

Arteriovenous malformation: A tangle of blood vessels, usually in the brain, that results in abnormal connections between arteries and veins; if ruptured, may result in hemorrhage.

Arthrocentesis: Puncture and aspiration of a joint. Certain drugs can be injected into the joint space for a local effect.

Articular: Related to a joint or joints.

Ascites: Accumulation of fluid within the peritoneal cavity.

Asterixis: A flapping tremor of the arms and hands that is seen in patients with end-stage liver disease.

Astringent: A substance that causes tissues to constrict, resulting in a drying effect of the skin.
Atelectasis: Decreased or absent air in a partial or entire lung, with resulting loss of lung volume.

Atherosclerosis: Accumulation of lipids, inflammatory cells, and cellular debris in the subendothelial space of the arterial wall.

Atherosclerotic cardiovascular disease: Disease in which plaque builds up in vessels.

Atonic seizure: A primary-generalized seizure characterized by loss of consciousness and muscle tone.

Atoxic: A genetic disposition to develop type I hypersensitivity reactions against common environmental antigens. It is seen commonly in patients with allergic rhinitis, asthma, and atopic dermatitis.

Atresia: Congenital absence of a normal opening or normally patent lumen.

Atrophic urethritis: An inflammation of the vagina (and the outer urinary tract) due to a lack of estrogen.

Attenuation: Loss of intensity or virulence.

Aura: Visual, but sometimes sensory, motor or verbal disturbance usually occurring before a migraine or seizure.

Auspitz sign: Pinpoint bleeding that occurs when a psoriatic scale or lesion is peeled off of the skin.

Autologous: A transplant using one’s own stem cells.

Autologous hematopoietic stem cell transplant: A procedure in which blood-forming stem cells (cells from which all blood cells develop) are removed, stored, and later given back to the same person.

Automaticity: Ability of a cardiac fiber or tissue to spontaneously initiate depolarizations.

Avolition: Inability to initiate and persist in goal-directed activities.

Azoospermic: Having no living spermatozoa in the semen, or failure of spermatogenesis.

B2 microglobulin: A low-molecular weight protein that may be elevated in multiple myeloma.

Bacille Calmette-Guérin vaccine: A tuberculosis vaccine prepared from an attenuated strain of the closely related species Mycobacterium bovis, used for immunization against tuberculosis in many countries, but not in the United States.

Bacteremia: Bacteria in the bloodstream.

Bacteriuria: Presence of bacteria in urine.

Barium enema: A diagnostic test using an x-ray to view the lower gastrointestinal tract (colon and rectum) after rectal administration of barium sulfate, a chalky liquid contrast medium.

Barrett esophagus: Disorder in which the cells of the lower esophagus are damaged, most often a result of longstanding reflux.

Basal ganglia: Cluster of nerve cells deep in the brain that coordinate normal movement.

β-hydroxybutyric acid: A ketone body that is elevated in ketosis, is synthesized in the liver from acetyl-CoA, and can be used as an energy source by the brain when blood glucose is low.

Bence-Jones proteins: Light chained immunoglobulins found in the urine.

Bilateral salpingo-oophorectomy: Surgical excision (removal) of both ovaries.

Bile acids: The organic acids in bile. Bile is the yellowish-brown or green fluid secreted by the liver and discharged into the duodenum where it aids in the emulsification of fats, increases peristalsis, and retards putrefaction.

Biliary sludge: A deposit of tiny stones or crystals made up of cholesterol, calcium bilirubinate, and other calcium salts. The cholesterol and calcium bilirubinate crystals in biliary sludge can lead to gallstone formation.

Bioavailability: The amount of an agent that is absorbed orally relative to an equivalent dose administered intravenously.

Biopsy: The removal of cells or tissue for examination.

Bladder hypotonicity: Low elastic tension of the bladder.

Blast: An immature cell.

Blastospores: An asexual reproductive sphere formed by budding, often seen with yeast.

Blood urea nitrogen (BUN): A waste product in the blood produced from the breakdown of dietary proteins. The kidneys filter blood to remove urea and maintain homeostasis; a decline in kidney function results in an increase in BUN.

Body mass index (BMI): A calculation utilized to correct weight changes for height and is a direct calculation regardless of gender. It is the result of the weight in kilograms divided by the height in meters squared. If nonmetric measurements are used, it is the result of the weight in pounds multiplied by 703 and then that quantity divided by the product of height in inches squared.

Bone remodeling: The constant process of bone turnover involving bone resorption followed by bone formation.

Bouchard nodes: Hard, bony enlargement of the proximal interphalangeal (middle) joint of a finger or toe.

Brachial plexus: Collection of nerves that arises from the spine at the base of the neck from nerves that supply parts of the shoulder, arm, forearm, and hand.

Brachytherapy: A form of radiotherapy where a sealed radiation source is placed inside or next to the area requiring treatment.

Bradycardia: Slower than normal heart rate.

Bradykinesia: Slow movement.

Breakpoint: The concentration of an antimicrobial agent that can be achieved in serum after a normal or standard dose of that antimicrobial agent.

Bronchiectasis: Chronic dilation of bronchi or bronchioles as a result of inflammatory disease or obstruction associated with heavy sputum.

Bronchoalveolar lavage: Diagnostic procedure in which a scope is passed through the nose or mouth into the lungs and fluid is squirted into an area of lung then recollected for examination.

Bullectomy: Surgical removal of one or more bullae (air spaces in the lung measuring more than one centimeter in diameter in the distended state).

Bursitis: An inflammation of the bursa, the fluid-filled sac near the joint where tendons and muscles pass over bone.

Cancer survivorship: The process of living with, throughout, and beyond cancer. Begins at cancer diagnosis and includes people who are/are not receiving treatment to manage disease or to decrease the risk of recurrence.

Capillary leak: Loss of intravascular volume into the interstitial space within the body.

Carcinogenesis: The actual formation of a cancer, whereby normal cells are transformed into cancer cells.

Carcinoma: A malignant growth that arises from epithelium, found in skin or the lining of body organs. Carcinomas tend to infiltrate into adjacent tissue and spread to distant organs.

Carcinomatosis: Condition of having widespread dissemination of carcinoma (cancer) in the body.

Cardiac cachexia: Physical wasting with loss of weight and muscle mass caused by cardiac disease; a wasting syndrome that causes weakness and a loss of weight, fat, and muscle.

Cardiac index: Cardiac output normalized for body surface area (cardiac index = cardiac output/body surface area).

Cardiac output: The volume of blood ejected from the left side of the heart per unit of time [cardiac output (L/min) = stroke volume × heart rate].

Cardiac remodeling: Genome expression resulting in molecular, cellular, and interstitial changes and manifested clinically as
changes in size, shape, and function of the heart resulting from cardiac load or injury.

**Carotid bruit**: Abnormal sound heard when auscultating a carotid artery caused by turbulent blood flow, usually due to the presence of atherosclerotic plaques.

**Carotid endarterectomy**: Removal of a thrombus from the carotid artery.

**Carotid intima-media thickness**: A measurement of the surface between the intima and media. This is a well-validated measure of the progression of atherosclerosis. Increasing measurements over time correlate with increasing atherosclerosis, whereas a decrease in the measurement is indicative of atherosclerotic regression.

**Carotids**: The two main arteries in the neck.

**Castrate resistant**: Prostate cancers resistant to hormonal therapy.

**Cataplexy**: A sudden loss of muscle control with retention of clear consciousness that follows a strong emotional stimulus (e.g., elation, surprise, or anger) and is a characteristic symptom of narcolepsy.

**Causalgia**: Persistent burning pain, allodynia, and hyperpathia following a traumatic nerve lesion.

**Cavitory lesions**: A spherical, air-containing lesion found on radiograph or computed tomography. The lesion usually has a thick wall and can be found within an area of a surrounding infiltrate or mass.

**CD4 and CD8**: Proteins predominately found on the surface of T cells.

**Central pain**: Pain that results from a lesion or dysfunction in the central nervous system.

**Cephalic**: Of or relating to the head.

**Cervicitis**: Inflammation of the cervix.

**Chemoprevention**: The use of drugs, vitamins, or other agents to reduce the risk or delay the development or recurrence of cancer.

**Chemoreceptor trigger zone (CTZ)**: Located in the area postrema of the fourth ventricle of the brain. It is exposed to cerebrospinal fluid and blood and is easily stimulated by circulating toxins to induce nausea and vomiting.

**Chemosis**: Edema of the bulbar conjunctiva.

**Cheyne-Stokes respiration**: Pattern of breathing with gradual increase in depth (and sometimes in rate) to a maximum, followed by a decrease resulting in apnea; the cycles ordinarily are 30 seconds to 2 minutes in duration, with 5 to 30 seconds of apnea.

**Chimeric**: An individual, organ, or substance composed of substances with different genetic origins.

**Chloasma**: Melasma characterized by irregularly shaped brown patches on the face and other areas of the skin, often seen during pregnancy or associated with the use of oral contraceptives.

**Chlorpromazine equivalents**: Approximate dose equivalent of a first-generation antipsychotic to 100 mg of chlorpromazine (relative potency).

**Cholecystitis**: Inflammation of the gallbladder.

**Cholelithiasis**: Formation of stones in the gallbladder (gallstones).

**Cholestasis**: Reduced or lack of flow of bile, or obstruction of bile flow.

**Cholelithiasis**: A mass of keratinized epithelial cells and cholesterol resembling a tumor that forms in the middle ear or mastoid region.

**Cholinesterase inhibitor**: Medication class that inhibits the acetylcholinesterase enzyme from breaking down acetylcholine, thereby increasing both the level and duration of action of the neurotransmitter acetylcholine.

**Choreo**: A type of dyskinesia with rhythmic dance-like movement. The increase in motor activity may be associated with fidgetiness, twitching, or flinging movements.

**Chronic acid-base disorder**: An acid-base disturbance that has been present for hours to days.

**Chronic kidney disease (CKD)**: A progressive, irreversible decline in kidney function that occurs over a period of several months to years.

**Chronic stable angina**: Manifestation of ischemic heart disease that typically results when an atherosclerotic plaque progresses to occlude at least 70% of a major coronary artery. Patients typically present with a sensation of chest pressure or heaviness that is provoked by exertion and relieved with rest or sublingual nitroglycerin.

**Chronotropic**: Pertaining to the heart rate.

**Chvostek sign**: Noted when a tap on the patient’s facial nerve adjacent to the ear produces a brief contraction of the upper lip, nose or side of the face.

**Chylothorax**: The presence of lymphatic fluid (chyle) in the pleural cavity.

**Circadian rhythm**: 24-hour cycles of behavior and physiology that are generated by endogenous biologic clocks (pacemakers).

**Circulatory shock**: A condition wherein the circulatory system is inadequately supplying the oxygen and vital metabolic substrates to cells throughout the body.

**Cirrhosis**: Hepatic fibrosis and regenerative nodules that have destroyed the architecture of the liver, scarring the liver tissues. Progressive scarring of the liver resulting in non-functional hepatocytes.

**Clonal expansion**: An immunologic response in which lymphocytes stimulated by antigen proliferate and amplify the population of relevant cells.

**Closed comedo**: A plugged hair follicle of sebum, keratinocytes, and bacteria that remains beneath the surface of the skin. Also referred to as a “whitehead.”

**Clotting cascade**: A series of enzymatic reactions by clotting factors leading to the formation of a blood clot. The clotting cascade is initiated by several thrombogenic substances. Each reaction in the cascade is triggered by the preceding one and the effect is amplified by positive feedback loops.

**Clotting factor**: Plasma proteins found in the blood that are essential to the formation of blood clots. Clotting factors circulate in inactive forms but are activated by their predecessor in the clotting cascade or a thrombogenic substance. Each clotting factor is designated by a Roman numeral (e.g., factor VII) and by the letter “a” when activated (e.g., factor VIIa).

**Clubbing**: Proliferation of soft tissues, especially in the nail bed, which results in thickening and widening of finger and toe extremities.

**Coalescence**: Fusion of smaller lipid emulsion particles forming larger particles, resulting in destabilization of the emulsion.

**Cognitive function**: Executive function and mental processing such as understanding, perception, reasoning, language, and awareness. Executive function involves organization, self-regulation, attention, and problem solving.

**Coitus**: Sexual intercourse.

**Collateral damage**: The development of resistance occurring in a patient’s nontargeted flora that can cause secondary infections.

**Colloids**: Intravenous fluids composed of water and large-molecular weight molecules used to increase volume in
patients with hypovolemic shock via increased intravascular oncotic pressure.

**Colonoscopy:** Visual examination of the colon using a lighted, lens-equipped, flexible tube (colonoscope) inserted into the rectum.

**Colony-forming units:** Number of viable colonies of bacteria, yeast, or mold per unit of measurement (e.g., milliliter or gram).

**Colorectal cancer:** The development of malignant cells in the lining or epithelium of the first and longest portion of the large intestine.

**Combined androgen blockade:** The combination of both androgen receptor (AR) antagonism and inhibition or suppression of androgen production.

**Comedolytic:** An agent that is able to break up or destroy a comedo.

**Comorbidities:** Multiple disease states occurring concurrently in one patient.

**Complete response:** In cancer, disappearance of all targeted lesions.

**Complex partial seizures:** Seizures that are localized in a specific area of the brain, but there is an alteration in the patient’s level of consciousness.

**Complex regimen:** Taking medications 3 or more times per day, or 12 or more doses per day.

**Complicated acid-base disorder:** The presence of two or more distinct acid-base disorders.

**Concreteness:** Inability to think in abstract terms. It may be a primary developmental defect or secondary to organic mental disorder or schizophrenia.

**Congenital adrenal hyperplasia:** A rare inherited condition resulting from a deficiency in cortisol and aldosterone synthesis with resulting excess androgen production. The clinical presentation depends on the variant of the condition but typically manifests as abnormalities in sexual development and/or adrenal insufficiency.

** Conjunctival injection:** Erythema of the conjunctiva.

**Conjunctivitis:** Inflammation of the conjunctiva.

**Conjunctivitis medicamentosa:** A drug-induced form of allergic conjunctivitis resulting from overuse of topical ocular vasoconstrictors.

**Consolidation:** Cancer treatment given after induction therapy to consolidate the gains obtained, further reduce the number of cancer cells, and enhance the likelihood of a durable complete remission.

**Contiguous spread:** Infection that involves bone that has come from adjacent tissues.

**Continuous positive airway pressure:** A technique of assisting breathing by maintaining the air pressure in the lungs and air passages constant and above atmospheric pressure throughout the breathing cycle.

**Convection:** The movement of dissolved solutes across a semi-permeable membrane by applying a pressure gradient to the fluid transport.

**Conversion (transformation):** Mutated cell becomes malignant.

**Cor pulmonale:** Right-sided heart failure caused by lung disease.

**Corneal arcus:** Accumulation of lipid on the cornea.

**Coronary artery bypass graft:** Surgical intervention to improve coronary blood flow by removing a vein from the leg and attaching one end to the aorta and the other end to the coronary artery distal to the atherosclerotic plaque. Alternatively, an artery from the inside of the chest wall may be used to bypass the coronary occlusion.

**Coronary artery disease:** Narrowing of one or more of the major coronary arteries, most commonly by atherosclerotic plaques. May be referred to as coronary heart disease.

**Coronary heart disease:** Narrowing of one or more of the major coronary arteries, most commonly by atherosclerotic plaques. May be referred to as coronary artery disease.

**Corpus luteum:** The small yellow endocrine structure that develops within a ruptured ovarian follicle and secretes progesterone and estrogen.

**Corticotropin-releasing hormone:** A hormone released by the hypothalamus that stimulates release of adrenocorticotropic hormone by the anterior pituitary gland.

**Cortisol:** An adrenal gland hormone responsible for maintaining homeostasis of carbohydrate, protein, and fat metabolism.

**Cosyntropin:** A synthetic version of adrenocorticotropic hormone.

**Counterirritant:** A substance that elicits a superficial inflammatory response with the objective of reducing inflammation in deeper, adjacent structures.

**C-peptide:** A peptide which is made when proinsulin is split into insulin and C-peptide. They split before proinsulin is released from endocytic vesicles within the pancreas, one C-peptide for each insulin molecule. C-peptide is the abbreviation for “connecting peptide.” It is used to determine if a patient has type 1 or type 2 diabetes mellitus.

**Creaming:** Aggregation of lipid emulsion particles that then migrate to the surface of the emulsion; can be reversed with mild agitation.

**Creatinine:** A waste product in the blood produced from the breakdown of protein by-products generated by muscle in the body or ingested in the diet. The kidneys filter blood to remove creatinine and maintain homeostasis; a decline in kidney function results in an increase in creatinine.

**Creatinine clearance:** Rate at which creatinine is filtered across the glomerulus; estimate of glomerular filtration rate.

**Crepitus:** A grating sound or sensation typically produced by friction between bone-on-cartilage or bone-on-bone contact.

**Cretinism:** Obsolete term for congenital hypothyroidism.

**Cross-allergenicity:** Sensitivity to one drug and then reacting to a different drug with a similar chemical structure.

**Cyst abscess:** Neutrophilic infiltration of the intestinal glands (crypts of Lieberkühn); a characteristic finding in patients with ulcerative colitis.

**Cryptogenic (cause unknown) epilepsies:** A seizure disorder that results from an underlying neurologic disorder that is often ill-defined, and other neurologic functions are often abnormal or developmentally delayed.

**Crystalloids:** Intravenous fluids composed of water and electrolytes (e.g., sodium, chloride, etc.) used as intravascular volume expanders for patients with hypovolemic shock.

**Cutis laxis:** Hypereflacidity of the skin with loss of elasticity.

**Cyanosis:** A dark blue or purple discoloration of the skin and mucous membranes due to deficient oxygenation of the blood.

**Cyclic citrullinated peptide (CCP):** A circular peptide (a ring of amino acids) containing the amino acid citrulline. Autoantibodies directed against cyclic citrullinated peptide provide the basis for a test of importance in rheumatoid arthritis.

**Cylooxxygenase:** An enzyme that catalyzes the conversion of arachidonic acid to prostaglandins and consists of two isoforms, generally abbreviated COX-1 and COX-2.

**Cystitis:** Inflammation of the urinary bladder.
Cystocele: Hernial protrusion of the bladder, usually through the vaginal wall.

Cytokines: Regulatory proteins, such as interleukins and lymphokines, that are released by cells of the immune system and act as intercellular mediators in the generation of an immune response. Soluble glycoproteins released by the immune system which act through specific receptors to regulate immune responses.

Cytomegalovirus (CMV) disease: The term used when patients who are already infected with CMV present with the classically associated symptoms that resemble a viral infection and may include fever, malaise, arthralgias, and others.

Cytomegalovirus (CMV) infection: The term used when a patient has anti-CMV antibodies in the blood, when CMV antigens are detected in infected cells, or when the virus is isolated from a culture.

Decolonization: Eradication of targeted bacterial species normally found on a person’s body but which have the potential to cause invasive disease.

Deep vein thrombosis: A disorder of thrombus formation causing obstruction of a deep vein in the leg, pelvis, or abdomen.

De-escalation: Decreasing antimicrobial regimen spectrum of activity to provide coverage against specific antimicrobial-sensitive pathogens recovered from culture.

Delayed peak response: The peak effects of a dose of medication take longer than expected to manifest.

Delirium: Transient brain syndrome presenting as disordered attention, cognition, psychomotor behavior, and perception.

Delirium tremens (DTs): Symptom of alcohol withdrawal characterized by hallucinations, delirium, severe agitation, fever, elevations of blood pressure and heart rate, and possible cardiac arrhythmias.

Denervation: Loss of nerve supply.

Dennie-Morgan line: A line or fold below the lower eyelids;

Dermatophyte: Any microscopic fungus that grows on the skin, scalp, and nails. May cause infections.

Desensitization: A process in which a drug to which a patient is allergic is administered in small, incremental doses to induce a state of temporary tolerance.

Desquamation: Peeling or shedding of the epidermis (superficial layer of the skin) in scales or flakes.

Detumescence: The return of the penis to a flaccid state.

Diabetes insipidus: Polyuria due to the failure of renal tubules to reabsorb water in response to antidiuretic hormone.

Diabetic ketoacidosis: A reversible but life-threatening short-term complication primarily seen in patients with type 1 diabetes caused by the relative or absolute lack of insulin that results in marked ketosis and acidosis.

Dialysate: The physiologic solution used during dialysis to remove excess fluids and waste products from the blood.

Dialysis: The process of removing fluid and waste products from the blood across a semi-permeable membrane to maintain fluid, electrolyte, and acid-base balance in patients with kidney failure.

Diaphoresis: Sweating or profuse perspiration, generally as a symptom of a disease or an adverse drug effect.

Diarthrodial joint: A freely moveable joint (e.g., knee, shoulder). Contrast with amphiarthrodial joint (a slightly movable joint; e.g., vertebral joint) and synarthrodial joint (an unmovable joint; e.g., fibrous joint).

Diastolic dysfunction: Abnormal filling of the ventricles during diastole.

Diffusion: The movement of a solute across the dialyzer membrane from an area of higher concentration (usually the blood) to a lower concentration (usually the dialysate).

Dilated cardiomyopathy: Ability of the heart to pump blood is decreased because the left ventricle is enlarged and weakened.

Diphasic dyskinesia: The motor fluctuations occur while the plasma levodopa concentrations are rising and when they are falling. In each dosing interval, the patient may experience improvement, dyskinesia and improvement (IDI) or dyskinesia, improvement, dyskinesia (DID).

Direct current cardioversion: The process of administering a synchronized electrical shock to the chest, the purpose of which is to simultaneously depolarize all of the myocardial cells, resulting in restoration of normal sinus rhythm.

Disease-free survival: Length of time after treatment during which no disease is found.

Disease progression: In cancer, at least a 20% increase in the sum of the longest diameter of target lesions from baseline, including new lesions discovered during treatment.

Disseminated erythrosquamous papules: Widespread or whole body red, scaly psoriatic lesions.

Disseminated intravascular coagulopathy: Abnormal overactivity of proteins in the blood that form blood clots; over time, clotting proteins are reduced which then increases risk for serious bleeding.

DNA mismatch repair (dMMR) genes: Genes that control an intrinsic intracellular mechanism which corrects nucleotide insertion errors made during DNA replication, by exciting the mismatched base pairs that escaped correction by the proofreading activities of DNA polymerases and replacing the mismatched bases with the correct ones.

Door-to-needle time: Time from arrival in hospital to administration of treatment in appropriate patients.

Downregulation: The process of reducing or suppressing a response to a stimulus.

Druen: Tiny yellow or white deposits of extracellular material in the eye.

D-test: Double disk diffusion microbiological testing which indicates the presence or absence of macrolide-induced resistance to clindamycin.

Ductus arteriosus: Shunt connecting the pulmonary artery to the aortic arch that allows most of the blood from the right ventricle to bypass fetal lungs.

Duodenal enterocyte: Cells lining the duodenum, which is the first of three parts of the small intestine.

Dysarthria: Speech disorder due to weakness or incoordination of speech muscles; speech is slow, weak, and imprecise.

Dysesthesia: An unpleasant abnormal sensation.

Dysgeusia: Taste disturbance or dysfunction of the sense of taste.

Dyskinesia: Abnormal involuntary movements, which include dystonia, chorea, and akathisia.

Dyslipidemia: Elevation of the total cholesterol, low-density lipoprotein cholesterol, or triglyceride concentrations, or a decrease in high-density lipoprotein cholesterol concentration in the blood.

Dysmenorrhea: Crampy pelvic pain occurring with or just prior to menses. “Primary” dysmenorrhea implies pain in the setting of normal pelvic anatomy, while “secondary” dysmenorrhea is secondary to underlying pelvic pathology.

Dyspareunia: Painful sexual intercourse due to medical or psychological causes.

Dysphagia: Difficulty in swallowing.

Dysphonia: Impairment of the voice or difficulty speaking.
Dysphoria: An unhappy or depressed feeling.
Dyspnea: Shortness of breath or difficulty breathing.
Dystonia: A type of dyskinesia. The movement is slow and twisting. It may be associated with painful muscle contractions or spasms.
Dysuria: Difficulty or pain in urination.
Ebstein anomaly: Congenital heart defect in which the opening of the tricuspid valve is displaced toward the apex of the right ventricle of the heart.
Eburbation: A condition in which bone or cartilage becomes hardened and denser.
Ecchymosis: Passage of blood from ruptured blood vessels into subcutaneous tissue causing purple discoloration of the skin.
Echocardiogram: An ultrasound test with high-frequency sound waves to produce a graphic image of the interior heart to evaluate the heart’s structures and movement.
Ectopic pregnancy: Presence of a fertilized ovum outside of the uterine cavity.
Effector cells: Cells that become active in response to initiation of the immune response.
Ejection fraction: The fraction of the volume present at the end of diastole that is pushed into the aorta during systole.
Electrocardiogram: A noninvasive recording of the electrical activity of the heart.
Electroconvulsive therapy: Administration of electric current to the brain through electrodes placed on the head to induce seizure activity in the brain; used in the treatment of certain mental disorders.
Electroencephalograph: A diagnostic test where electrodes are placed on the scalp and electrical activity in the brain is measured and recorded.
Electroencephalography: The recording of brain waves via electrodes placed on the scalp or cortex.
Embolism: The sudden blockage of a vessel caused by a blood clot or foreign material which has been brought to the site by the flow of blood.
Embolization: The process by which a blood clot or foreign material dislodges from its site of origin, flows in the blood, and blocks a distant vessel.
Emesis: Vomiting; a reflexive rapid and forceful oral expulsion of upper gastrointestinal contents due to powerful and sustained contractions in the abdominal and thoracic musculature.
Endometritis: Inflammation of the endometrium.
Endoscopic evaluation: Visual inspection of the inside of hollow organs with an endoscope; used mainly for diagnostic purposes; refers to procedures such as gastroscopy, duodenoscopy, colonoscopy, and sigmoidoscopy.
Endoscopy: A diagnostic tool used to examine the inside of the body using a lighted, flexible instrument called an endoscope.
Endothelial cell: A single layer of cells surrounding the lumen of arteries.
End-stage liver disease: Liver failure that is usually accompanied by complications such as ascites or hepatic encephalopathy.
Enteral nutrition: Delivery of nutrients via the gastrointestinal tract, either by mouth or by feeding tube.
Enthesitis: Inflammation of the sites where tendons, ligaments, or fascia attach to bone.
Enuresis: Incontinence at night.
Epilepsy: A neurological disorder characterized by recurring motor, sensory, or psychic malfunction with or without loss of consciousness or convulsive seizures.
Epistaxis: Nasal hemorrhage with blood drainage through the nostrils; a nosebleed.
Erectile dysfunction: Condition defined as the inability to achieve or maintain an erection sufficient for sexual intercourse.
Erythema multiforme: A rash characterized by papular (small raised bump) or vesicular lesions (blisters), and reddening or discoloration of the skin often in concentric zones about the lesion.
Erythematous: Flushing of the skin caused by dilation of capillaries. Erythema is often a sign of inflammation and infection.
Erythrocyte sedimentation rate: Non-specific test to indirectly measure degree of inflammation in the body due to conditions such as infections, cancers, or autoimmune diseases.
Erythrodermic psoriasis: Generalized erythema covering nearly the entire body surface area. Fever and malaise are common but, while quite rare, can be severe and even fatal; it is usually associated with a worsening of other forms of psoriasis.
Erythropoiesis stimulating agents: Agents developed by recombinant DNA technology that have the same biological activity as endogenous erythropoietin to stimulate erythropoiesis (red blood cell production) in the bone marrow. The currently available agents in the United States are epoetin alfa and darbepoetin alfa.
Erythropoietin: A hormone primarily produced by the progenitor cells of the kidney that stimulates red blood cell production in the bone marrow. Lack of this hormone leads to anemia.
Esophageal varices: Dilated blood vessels in the esophagus.
Essential fatty acid deficiency: Deficiency of linoleic acid, linolenic acid, and/or arachidonic acid, characterized by hair loss, thinning of skin, and skin desquamation. Long-chain fatty acids include trienes (containing 3 double-bonds [e.g., 5,8,11-eicosatrienoic acid {or Mead acid}, trienoic acids]) and tetaenes (containing 4 double-bonds [e.g., arachidonic acid]). Biochemical evidence of essential fatty acid deficiency includes a triene:tetraene greater than 0.2 and low linoleic or arachidonic acid plasma concentrations.
Euphoria: A feeling of happiness and excitement.
Euthymia: Normal mood.
Euthyroid: State of normal thyroid function or hormone activity.
Euvolemia: The state of proper fluid balance.
Exantheme: Eruption of the skin.
Exanthem: A rash characterized by papular (small raised bump) or vesicular lesions (blisters), and reddening or discoloration of the skin often in concentric zones about the lesion.
Erythematous: Flushing of the skin caused by dilation of capillaries. Erythema is often a sign of inflammation and infection.
Extrapyramidal symptoms (EPS): Adverse drug effects of medications such as phenothiazines. EPS include dystonia ( involuntary muscle contractions), tardive dyskinesia (repetitive, involuntary movements), and akathisia (motor restlessness or anxiety).
Extravasation: Movement of fluid from inside a blood vessel into the surrounding tissues.
Facultative anaerobe: An organism that makes adenosine triphosphate by aerobic respiration if oxygen is present, but switches to fermentation under anaerobic conditions.
Felty syndrome: An extra-articular manifestation of rheumatoid arthritis associated with splenomegaly and neutropenia.
Ferritin: A protein in the body that binds to iron; most of the iron stored in the body is bound to ferritin.

Festivation: Walking with short, rapid, shuffling steps.

Fibrin: An insoluble protein that is one of the principal ingredients of a blood clot. Fibrin strands bind to one another to form a fibrin mesh. The fibrin mesh often traps platelets and other blood cells.

Fibrinolysis: A normal ongoing process that dissolves fibrin and results in the removal of small blood clots; hydrolysis of fibrin.

Fibrinolytic: Possessing the property of preventing blood clot formation.

Fibroadenoma: A benign neoplasm that commonly occurs in breast tissue and is derived from glandular epithelium.

FISH: A laboratory technique used to look at genes or chromosomes in cells and tissues. Pieces of DNA that contain a fluorescent dye are made in the laboratory and added to cells or tissues on a glass slide. When these pieces of DNA bind to specific genes or areas of chromosomes on the slide, they light up when viewed under a microscope with a special light. Also called fluorescence in situ hybridization.

 Fistula: Abnormal connection between two internal organs (e.g., arteriovenous fistula is a connection between an artery and a vein), or between an internal organ and the exterior or skin (e.g., enterocutaneous fistula is a connection between the intestine and the skin).

Fistulogram: X-ray photograph (or radiograph) taken after injection of a contrast material or radiopaque material (material that will not allow passage of x-rays and will be visible in an x-ray photograph [or radiograph]).

Flexural psoriasis: Characterized by lesions found in skin folds. These lesions tend to be erythematous plaques and are often found in the axillary, genital, perineal, intergluteal, and inframammary regions. While shiny, smooth, and deep red in color, there may be skin fissures and the absence of the silvery scales.

Flight of ideas: A nearly continuous flow of rapid speech and thought that jumps from topic to topic, usually loosely connected.

Floppy iris or small pupil syndrome: The iris of the eye becomes flaccid and cannot become dilated.

Flow cytometry: A method of measuring the number of cells in a sample, the percentage of live cells in a sample, and certain characteristics of cells, such as size, shape, and the presence of tumor markers on the cell surface. The cells are stained with a light-sensitive dye, placed in a fluid, and passed in a stream before a laser or other type of light. The measurements are based on how the light-sensitive dye reacts to the light.

Foam cell: Lipid-laden white blood cell.

Forced expiratory volume in 1 second: The volume of air that a patient can forcibly exhale in the first second of forced exhalation after taking a maximal breath.

Forced vital capacity: The maximum volume of air that can be forcibly exhaled after taking a maximal breath.

Fragility fracture: A fracture resulting from a fall from standing height or less amount of trauma.

Frailty: Excess demand imposed upon reduced capacity; a common biological syndrome in the elderly.

Frank-Starling mechanism: Increase in stroke volume in response to an increase in volume of blood filling the heart (i.e., end-diastolic, volume) when all other factors remain constant.

Freelite™ assay: A highly sensitive assay that determines the ratio of serum free light chain kappa to lambda.

Freezing: A sudden but temporary inability to move.

Fremitus: A palpable vibration, as felt by the hand placed on the chest during coughing or speaking.

Friction: Risk factor for pressure ulcers that is created when a patient is dragged across a surface, which can lead to superficial skin damage.

Fructooligosaccharides: Polymers of fructose that reach the colon undigested and are broken down to short chain fatty acids by bacterial enzymes.

Functional gastrointestinal disorder: A term used to describe symptoms occurring in the gastrointestinal tract in the absence of a demonstrated pathologic condition; the clinical product of psychosocial factors and altered intestinal physiology involving the brain–gut interrelationship.

Gadolinium: An intravenous contrast agent used with magnetic resonance imaging.

Gallstone (cholelithiasis): A solid formation in the gallbladder.

Gastritis: Chronic or acute inflammation of the lining of the stomach.

Gastroparesis: A form of autonomic neuropathy involving nerves of the stomach. It may include nausea, vomiting, feeling full, bloating, and lack of appetite. It may cause wide fluctuations in blood sugars due to insulin action and nutrient delivery not occurring at the same time.

Gastroesophageal reflux disease: Congenital abdominal wall defect in which the intestines, and sometimes other organs, develop outside the fetal abdomen through an opening in the abdominal wall.

Gastrectomy: Surgical excision of part or all of the stomach.

Genetic syndrome: Age specific presentations or differential diagnoses, including visual and hearing impairment, malnutrition and weight loss, urinary incontinence, gait impairment and falls, osteoporosis, dementia, delirium, sleep problems, and pressure ulcers; commonly seen conditions in elderly patients.

Gestational diabetes mellitus: Diabetes that occurs during pregnancy which may or may not end at delivery.

Gigantism: A condition of abnormal size or overgrowth of the entire body or of any of its parts.

Glomerular filtration rate: The volume of plasma that is filtered by the glomerulus per unit time, usually expressed as mL/min or mL/min/1.73 m² (and in some areas, in SI units of mL/s or mL/s/m²), which adjusts the value for body surface area. This is the primary index used to describe overall renal function.

Glomerulonephritis: Glomerular lesions that are characterized by inflammation of the capillary loops of the glomerulus.
These lesions are generally caused by immunologic, vascular, or other idiopathic diseases. Leads to high blood pressure and possible loss of kidney function.

**Glucagon:** Hormone involved in carbohydrate metabolism that is produced by the pancreas and released when glucose levels in the blood are low. When blood glucose levels decrease, the liver converts stored glycogen into glucose, which is released into the bloodstream. The action of glucagon is the opposite of insulin.

**Gluconeogenesis:** Formation of glucose from precursors other than carbohydrates especially by the liver and kidney using amino acids from proteins, glycerol from fats, or lactate produced by muscle during anaerobic glycolysis.

**Glutamate:** An excitatory amino acid found in the central nervous system.

**Glycogenolysis:** The process by which glycogen is broken down to glucose in body tissues.

**Goiter:** An enlargement of the thyroid gland, causing a swelling in the front part of the neck.

**Gonioscopy:** Examination of the anterior chamber angle. A gonioscope or Goldman lens is used to perform gonioscopic evaluation.

**Graft-versus-host disease:** Disease caused when cells from a donated stem cell graft attack the normal tissue of the transplant patient. Symptoms include jaundice, skin rash or blisters, a dry mouth, or dry eyes. Also called GVHD.

**Graft-versus-tumor:** An immune response to a person’s tumor cells by immune cells present in a donor’s transplanted tissue, such as bone marrow or peripheral blood.

**Grandiosity:** Exaggerated sense of self-importance, ideas, plans, or abilities.

**Granuloma:** Unique inflammatory response composed of macrophages, giant cells, and other cells of the immune response to wall off infectious pathogens perceived as foreign but cannot be eliminated.

**Gross hematuria:** Visible blood in the urine.

**Gummatous tumor:** A soft, gummy tumor which occurs in the lymph nodes, skin, and other organs. Often located in the arm pit or groin.

**Gut-associated lymphoid tissue:** Lymphoid tissue, including Peyer patches, found in the gut that are important for providing localized immunity to pathogens.

**Guttate psoriasis:** Psoriasis characterized by small lesions, typically found on the trunk and proximal extremities.

**Haptenation:** The process where a drug, usually of low molecular weight, is bound to a carrier protein or cell and becomes immunogenic.

**Hashimoto disease:** Condition in which the immune system attacks the thyroid gland; may result in hypothyroidism. Symptoms may include fatigue, weight gain, pale or puffy face, feeling cold, joint and muscle pain, constipation, dry and thinning hair, heavy menstrual flow or irregular periods, depression, a slowed heart rate, and problems getting pregnant and maintaining pregnancy. Occurs more commonly in women than in men.

**Health literacy:** Degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.

**Heberden nodes:** Hard, bony enlargement of the distal interphalangeal (terminal) joint of a finger or toe.

**Hemarthrosis:** Blood in the joint space.

**Hematuria:** Visible blood in the urine.

**Hematochezia:** Passage of stool that is bright red or maroon, usually because of bleeding from the lower gastrointestinal tract.

**Hematogenous:** Spread through the blood.

**Hematoma:** A localized swelling in an organ or soft tissue that is filled with clotted or partially clotted blood resulting from a break in a blood vessel wall.

**Hematuria:** Presence of blood or red blood cells in urine.

**Hemiparesis:** Weakness on one side of the body.

**Hemisensory deficit:** Loss of sensation on one side of the body.

**Hemithorax:** A single side of the trunk between the neck and the abdomen in which the heart and lungs are situated.

**Hemoptysis:** The expectoration of blood or blood-tinted sputum from the larynx, trachea, bronchi, or lungs.

**Hemorrhagic conversion:** Conversion of an ischemic stroke into a hemorrhagic stroke.

**Hemostasis:** Cessation of bleeding through natural (clot formation or construction of blood vessels), artificial (compression or ligation), or surgical means.

**Heparin-induced thrombocytopenia:** A clinical syndrome of IgG antibody production against the heparin-platelet factor 4 complex occurring in approximately 1% to 5% of patients exposed to either heparin or low-molecular weight heparin. Results in excess production of thrombin, platelet aggregation, and thrombocytopenia (due to platelet clumping), often leading to venous and arterial thrombosis, amputation of extremities, and death.

**Hepatic encephalopathy:** Confusion and disorientation experienced by patients with advanced liver disease due to accumulation of ammonia in the bloodstream.

**Hepatic steatosis:** Accumulation of fat in the liver.

**Hepatocellular carcinoma:** Cancer of the liver.

**Hepatojugular reflex:** Distention of the jugular vein induced by pressure over the liver; it suggests insufficiency of the right heart.

**Hepatorenal syndrome:** Acute kidney injury resulting from decreased perfusion in cirrhosis.

**Hepatotoxicity:** Toxicity to the liver causing damage to liver cells.

**Herniation:** Protrusion of the brain through the cranial wall.

**Heterotopic:** Placing a transplanted organ into an abnormal anatomic location.

**Heterozygous:** Having different alleles at a gene locus.

**Hirsutism:** Excess body hair, especially in females, appearing on the lower abdomen, around the nipples, around the chin and upper lip, between the breasts, and on the lower back.

**Histocompatibility:** Compatibility between the tissues of different individuals, so that one accepts a graft from the other without having an immune reaction.

**Homeostasis:** Impaired capability to withstand stressors and decreased ability to maintain physiological and psychosocial homeostasis; a state commonly found in the elderly.

**Homozygous:** Having identical alleles at a gene locus.

**Hormone receptor-positive:** Tumors that appear to grow in the presence of estrogens; likewise, antiestrogen therapy or estrogen deprivation strategies lead to tumor regression.

**Hospice:** The provision of palliative care during the last six months of life as defined by federal guidelines.

**Hot flashes:** A feeling of warmth that is commonly accompanied by skin flushing and mild to severe perspiration.

**Human leukocyte antigens (HLA):** Groups of genes found on the major histocompatibility complex that contain cell-surface antigen presenting proteins. The body uses HLA to distinguish between self cells and non-self cells.

...pletely normal apart from the occurrence of seizures. be due to genetic alterations. Neurologic functions are com... back loop that controls response to stress. symptoms differ according to the timing of disease onset in... ment. Associated with testosterone deficiency resulting from... symptoms of which is involved in the pathophysiology of narcolepsy.

Hyperprolactinemia: A medical condition of elevated serum prolactin characterized by prolactin serum concentrations greater than 20 ng/mL (20 mcg/L; 870 pmol/L) in men or 25 ng/mL (25 mcg/L; 1087 pmol/L) in women.

Hyperthyroidism: State caused by excess production of thyroid hormone.

Hypertrichosis: Excessive growth of hair.

Hypocretin: A wake-promoting hypothalamic neuropeptide, a defi... that results in a mutated cell. Encounters a normal cell to produce genetic damage, and... "I" (ISI) power to account for differences in thromboplastin clotting time to the clinical laboratory's mean reference value; also known as thrombophilia.

International normalized ratio (INR): The ratio of patient's clotting time to the clinical laboratory's mean reference value; normalized by raising it to the international sensitivity index (ISI) power to account for differences in thromboplastin reagents. Therefore, INR = (Patient's prothrombin time/laboratory's mean normal prothrombin time)$^{\text{ISI}}$.
Intrathecal: Within the meninges of the spinal cord.
Intravesicular: Administration directly into the bladder through the urethra.
Intussusception: The enfolding of one segment of the intestine within another.
Iontophoresis: Introduction of a medication into tissue through use of an electric current.
Ipsilateral: Occurring on the same side.
Ischemic heart disease: Imbalance between myocardial oxygen supply and oxygen demand.
Ischemic penumbra: Ischemic, but still viable cerebral tissue. Typically a rim of mild to moderately ischemic tissue in between normally perfused tissue and the area of evolving infarction; may remain viable for several hours.
Jejunal enterocyte: Cells lining the jejunum, which is a section of the small intestine connecting the duodenum to the ileum.
Jejunostomy: Operative placement of a new opening into the jejunum, usually associated with feeding tube placement.
Juvenile myoclonic epilepsy: An epilepsy syndrome that typically occurs during teenage years and consists of generalized tonic-seizures and myoclonic jerks. Absence seizures may also occur with this syndrome.
Kegel exercises: Specific exercises that strengthen the pelvic floor muscles and help to prevent and treat stress incontinence.
Keratinization: The sloughing of epithelial cells in the hair follicle.
Keratinocytes: The predominant cell type in the outermost layer of the skin.
Keratitis: Infection of the cornea.
Keratoconjunctivitis sicca: An eye disease caused by eye dryness, which results from either decreased tear production or increased tear film evaporation. Also known as dry eye syndrome.
Ketosis: An abnormal increase of ketone bodies present in conditions of reduced or disturbed carbohydrate metabolism.
Korotkoff sounds: The noise heard over an artery by auscultation when pressure over the artery is reduced below the systolic arterial pressure.
Kyphosis: Abnormal curvature of the spine resulting in protrusion of the upper back; hunchback.
Lactose intolerance: Inability to digest milk and some dairy products, resulting in bloating, cramping, and diarrhea; caused by enzymatic lactase deficiency.
Lagophthalmos: Poor closure of the upper eyelid.
Lamina cribrosa: A series of perforated sheets of connective tissue that the optic nerve passes through as it exits the eye.
Laminectomy: A surgical procedure to remove the back of one or more vertebrae, usually to give access to the spinal cord or to relieve pressure on nerves.
Laparoscopic adjustable gastric banding: A surgical procedure for weight loss that elicits its effectiveness through gastric volume limitation. The procedure involves inserting a silicone band lined with an inflatable donut-shaped balloon around the neck of the stomach to be filled with isotonic liquid thereby limiting food intake.
Laparoscopy: Abdominal exploration or surgery employing a type of endoscope called laparoscope.
Laparotomy: Surgical opening of the abdominal cavity
Latent autoimmune diabetes in adults (LADA): A slow, progressive form of type 1 diabetes mellitus for which a patient does not require insulin for a number of years. In its early stages, LADA typically presents as type 2 diabetes mellitus and is often misdiagnosed as such. However, LADA more closely resembles type 1 diabetes mellitus and shares common physiological characteristics of type 1 diabetes mellitus for metabolic dysfunction, genetics, and autoimmune features. LADA does not affect children and is classified distinctly as being separate from juvenile diabetes.
Left shift: Refers to an increase in the number of immature neutrophils (also referred to as bands). A left shift usually indicates infection or inflammation. The term originated in the days in which lab reports were written by hand and the bands were written on the left-hand side of the lab report. Also known as bandemia.
Lennox-Gastaut syndrome: An epilepsy syndrome that often appears early in life that consists of a distinct EEG pattern, mild to severe developmental delay, and multiple seizure types.
Leukocytic vasculitis: Acute cutaneous vasculitis characterized by purpura (especially of the legs) and histologically by exudation of neutrophils and sometimes fibrin around dermal venules, with extravasation of red blood cells.
Leukopenia: A condition in which the number of circulating white blood cells are abnormally low due to decreased production of new cells, possibly in conjunction with medication toxicities.
Lewy bodies: Abnormal masses inside nerve cells. Their structure and composition vary depending on location.
Lhermitte sign: Tingling or shock-like sensation passing down the arms or trunk when the neck is flexed.
Libido: Conscious or unconscious sexual desire.
Ligament of Treitz: Landmark in the proximal portion of the jejunum beyond which it is preferred that postpyloric feedings be delivered for minimization of aspiration.
Linea nigra: Dark vertical line that appears on the abdomen during pregnancy.
Linear accelerator: An accelerator in which particles travel in straight lines, not in closed orbits.
Lipophilic: Having affinity for fatty substances.
Lipoprotein lipase: Enzyme located in the capillary endothelium involved in the breakdown of intravenous lipid emulsion particles.
Livedo reticularis: Purple mottling of the skin.
Liver biopsy: A procedure whereby tissue is removed from the liver and used to determine the severity of liver damage.
Locus ceruleus: Nucleus of norepinephrine containing neurons located in the brainstem that are responsible for physiological response to stress and panic.
Lower esophageal sphincter: A manometrically defined zone of the distal esophagus with an elevated basal resting pressure that prevents the reflux of gastric material from the stomach. It relaxes on swallowing to permit the free passage of food into the stomach.
Luteolysis: Death of the corpus luteum.
Lymphadenectomy: A surgical procedure in which the lymph nodes are removed and a sample of tissue is checked under a microscope for signs of cancer.
Lymphangitis: Inflammation of lymphatic channels.
Lymphatic: The network of vessels carrying tissue fluids.
Lymphoproliferative: Of or related to the growth of lymphoid tissue.
Maceration: The softening or breaking down of a solid by leaving it immersed in a liquid.
Macrophages: Large scavenger cells.
Macrovascular: Complications contributed to by diabetes that include myocardial infarctions, strokes, or peripheral vascular disease.
Macula: The central portion of the retina.
Maculopapular: A rash that contains both macules and papules.
A macule is a flat discolored area of the skin, and a papule is a small raised bump. A maculopapular rash is usually a large area that is red and has small, confluent bumps.
Magnetic resonance imaging: A test that uses strong magnet fields to create a high resolution image of body parts.
Major malformation: A defect that has either cosmetic or functional significance to the child.
Manometry: Measurement of pressures and muscle contractions in the esophagus. It helps to localize the lower esophageal sphincter for ambulatory pH monitoring, evaluates peristaltic function in patients considering surgery, and identifies possible motor disorders.
Macrocytosis: Enlargement of red blood cells with near-constant hemoglobin concentration.
Mastalgia: Tenderness of the breast.
Matrix metalloproteinase: Any of a group of enzymes, normally located in the extracellular space of tissue, that function to break down proteins (e.g., collagen) and require zinc or calcium atoms as cofactors for enzymatic activity. Responsible for the degradation of connective tissue.
Meatal stenosis: Narrowing in the opening of the urethra.
Meconium: First intestinal discharge (“stool”) of a newborn infant, usually green in color and consisting of epithelial cells, mucus, and bile.
Melasma: Dark skin discoloration. Patchy skin pigmentation, often seen during pregnancy.
Melena: Abnormally dark black, tarry feces containing blood (usually from gastrointestinal bleeding).
Menarche: The first menstrual cycle.
Meninges: Covering of the brain consisting of three layers.
Menopause: Permanent cessation of menses following the loss of ovarian follicular activity.
Menorrhagia: Menstrual blood loss of greater than 80 mL per cycle; a more practical definition is heavy menstrual flow associated with problems of containment of flow, unpredictably heavy flow days, or other associated symptoms.
Mesial temporal lobe epilepsy: A common epilepsy syndrome manifested by seizures arising from the mesial temporal lobe of the brain, and is often associated with an anatomical change, described as hippocampal sclerosis.
Mesocortical pathway: A neural pathway that connects the ventral tegmentum to the cortex, particularly the frontal lobes. It is one of the major dopamine pathways in the brain.
Mesothelioma: A benign or malignant tumor affecting the lining of the chest or abdomen. Commonly caused by exposure to asbestos fibers.
Metabolic acidosis: A condition in the blood and tissues that is a consequence of an accumulation of lactic acid resulting from tissue hypoxia and anaerobic metabolism. It may also be caused by a decrease in the concentration of alkaline compounds (typically bicarbonate).
Metabolic alkalosis: Alkalosis that is caused by an increase in the concentration of alkaline compounds (typically bicarbonate).
Metabolic syndrome: Constellation of cardiovascular risk factors related to hypertension, abdominal obesity, dyslipidemia, and insulin resistance diagnosed by the presence of at least three of the following criteria: increased waist circumference, elevated triglyceride concentrations, decreased high-density lipoprotein (HDL) cholesterol or active treatment to raise HDL cholesterol, elevated blood pressure, or active treatment with antihypertensive therapy, or elevated fasting glucose or active treatment for diabetes.
Metastasis: Cancer that has spread from the original site of the tumor.
Micelles: Microscopic particles of digested fat and cholesterol.
Microalbuminuria: Urinary excretion of small but abnormal amounts of albumin. Confirmed spot urine albumin to creatinine ratio of 30 to 300 mg/g (3.4 to 34 mg/mmol creatinine) is consistent with microalbuminuria. Considered an early sign of chronic kidney disease.
Microcytosis: A condition in which the erythrocytes are smaller than normal.
Micrognatia: Abnormal smallness of the jaws.
Micrographia: Small handwriting, often seen in patients with Parkinson disease.
Micrometastases: Deposits of tumor cells in distant organs that cannot be detected by any imaging techniques available.
Microsatellite instability (MSI): The condition of genetic hypermutability that results from impaired DNA mismatch repair (MMR). The presence of MSI represents phenotypic evidence that MMR is not functioning normally.
Micvascular pulmonary emboli: An obstruction in the small blood vessels in the lung caused by material (e.g., blood clot, fat, air, foreign body) that is carried through the circulation until it lodges in another small vessel.
Migraine: A headache that usually affects one side of the head or a portion of the head, accompanied by nausea, vomiting, sensitivity to light, and sensitivity to noise.
Miolysis: The destruction of muscle tissue.
Miosis: Pupil constriction.
Mixed acid-base disorder: See Complicated disorder.
Mixed mood episodes: Symptoms of mania and depression occurring simultaneously or in close juxtaposition.
Mobitz type I: A type of second degree AV nodal block.
Mobitz type II: A type of second degree AV nodal block.
Möbius syndrome: Rare congenital neurological disorder characterized by facial paralysis and affects eye movement.
Monocytes: A variety of white blood cells.
Monoparesis: Slight or incomplete paralysis affecting a single extremity or part of one.
Monosodium urate: A crystallized form of uric acid that can deposit in joints leading to an inflammatory reaction and the signs and symptoms of gout.
Morphology: The science of the form and structure of organisms (plants, animals, and other forms of life).
Motor tics: An involuntary brief spasmodic muscular movement or contraction, usually of the face or extremities.
Mucositis: Inflammation of mucous membranes, typically within the oral and esophageal mucosa. Usually associated with certain chemotherapy agents and radiation therapy involving mucosal area.
Mucous colitis: A condition of the mucous membrane of the colon characterized by pain, constipation, or diarrhea (sometimes alternating), and passage of mucus or mucous shreds.
**Multiparity**: Condition of having given birth to multiple children.
**Muscularis mucosa**: The thin layer of smooth muscle found in most parts of the gastrointestinal tract.
**Mydriasis**: Pupil dilation.
**Myelin**: A protein and phospholipid sheath that surrounds the axons of certain neurons. Myelinated nerves conduct impulses more rapidly than non-myelinated nerves.
**Myeloablative preparative regimen**: A regimen consisting of a single agent or combination of agents expected to destroy the hematopoietic cells in the bone marrow and resulting in profound pancytopenia within one to three weeks from the time of administration. The resulting pancytopenia is long-lasting, usually irreversible, and in most instances fatal, unless hemato poiesis is restored by infusion of hematopoietic stem cells.
**Myelodysplastic syndrome**: One of a group of disorders characterized by abnormal development of one or more of the cell lines that are normally found in the bone marrow.
**Myeloproliferative disorder**: A group of diseases of the bone marrow in which excess cells, usually lymphocytes, are produced.
**Myelosuppression**: Reduction in white blood cells, red blood cells, and platelets.
**Myocardial infarction**: The formation of an infarct, an area of tissue death, due to a local lack of oxygen. Myocardial cell death secondary to prolonged ischemia.
**Myocarditis**: Inflammation of the heart muscle.
**Myoclonic**: A primary-generalized seizure characterized by a single and very brief (< 1 sec) jerk of the body, head, or arms.
**Myoglobinuria**: The presence of myoglobin in urine.
**Myonecrosis**: Necrotic damage to muscle tissue.
**Myopathy**: Any disease of the muscle causing weakness, pain, and tenderness.
**Myringotomy**: A surgical incision in the tympanic membrane to relieve pressure and drain fluid from the middle ear.
**Myxedema**: Hypothyroidism characterized by a relatively hard edema of subcutaneous tissue, with increased content of proteoglycans in the fluid; characterized by somnolence, slow mentation, dryness and loss of hair, increased fluid in body cavities such as the pericardial sac, subnormal temperature, hoarseness, muscle weakness, and slow return of a muscle to the neutral position after a tendon jerk.
**Nail psoriasis**: Nail psoriasis can be characterized by pitting, onycholysis, hyperkeratosis, and an oil-drop sign.
**Nasal scotoma**: An area of blindness in the nasal portion of peripheral vision.
**Nascent**: Immature.
**Nasolacrimal occlusion**: The closing of the tear duct to decrease systemic absorption of a drug.
**Nausea**: The subjective feeling of a need to vomit.
**Necrosectomy**: Surgical excision of necrotic tissue; debridement.
**Necrotizing enterocolitis**: Medical condition seen in premature infants, where portions of the bowel undergo necrosis.
**Negative feedback**: A self-regulating process that responds to influences of an original signal resulting in stabilization or reductions in the effect of fluctuations.
**Nelson syndrome**: A condition characterized by the aggressive growth of a pituitary tumor and hyperpigmentation of the skin.
**Neoadjuvant therapy**: Therapeutic strategy that precedes primary treatment modality (usually surgery). The goals are to “down-stage” tumors so that the surgical field is smaller or to transform a patient from a nonsurgical candidate to one that is surgical. Neoadjuvant therapy may improve overall survival. Strategies usually involve the use of systemic therapy with or without radiation.
**Neovascular maculopathy**: Proliferation of blood vessels in the macula.
**Nephrolithiasis**: A condition marked by the presence of renal calculi (stones) in the kidney or urinary system.
**Nephron**: The working unit of the kidney that filters blood to remove fluid, toxins, and drugs. Each kidney contains approximately 1 million nephrons.
**Nephrostomy**: Surgery to make an opening from the outside of the body to the renal pelvis (part of the kidney that collects urine). This may be done to drain urine from a blocked kidney or blocked ureter into a bag outside the body. It may also be done to look at the kidney using an endoscope (thin, lighted tube attached to a camera), to place anticancer drugs directly into the kidney, or to remove kidney stones.
**Neuritic plaques**: Extracellular deposits of beta amyloid in the gray matter of the brain.
**Neuritis**: Inflammation of a nerve.
**Neurofibrillary tangles**: Aggregates of hyperphosphorylated tau protein; commonly known as a primary marker of Alzheimer disease.
**Neuropathic pain**: Pain resulting from a lesion or dysfunction of the nervous system.
**Neuropathy**: An abnormal and usually degenerative state of the nervous system or nerves. Damage to the small and large nerves due to glycation end products, lack of blood and nutrients to the nerves, or chemical imbalances.
**Neurotransmitters**: Chemicals in the brain that allow the passage of a message between neurons or nerve cells.
**Neutralizing antibodies**: Antibodies that develop in response to a therapeutic agent that decrease the efficacy of the agent.
**Nidus**: A site of origin in which bacteria have multiplied or may multiply; a focus of infection.
**Nitric oxide**: An endogenous vasodilator.
**NMDA antagonist**: Class of medications that work to antagonize the N-methyl-D-aspartate receptor.
**Nociception**: Encoding and processing of noxious stimuli to the nervous system.
**Nociceptors**: Receptors for pain caused by injury from physical stimuli (mechanical, electrical, or thermal) or chemical stimuli (toxins); located in the skin, muscles, or in the walls of the viscera.
**Nocturia**: Excessive urination at night.
**Nocturnal polysomnography**: Electrophysiologic assessment of human sleep minimally composed of electroencephalogram, electrooculogram, and electromyogram that allows determination of sleep stage, breathing events, and muscle movements.
**Nodules**: An abnormal small swelling or aggregation of cells in most parts of the gastrointestinal tract.
**Non-REM sleep**: A state of usually dreamless sleep that occurs regularly during a normal period of sleep with intervening periods of REM sleep and that consists of four distinct sub-stages and low levels of autonomic physiological activity.
Non-ST-segment elevation myocardial infarction: A type of myocardial infarction that is limited to the sub-endocardial myocardium and is smaller and less extensive than an ST-segment elevation myocardial infarction.

Normal flora: Normal colonizing bacteria of a human host.

Nuchal rigidity: Neck stiffness.

Nuclear factor kappa-light-chain-enhancer of activated B cells (NF-kappa-B): A protein complex that controls transcription of DNA, cytokine production, and cell survival.

Nulliparity: Condition of not having given birth to a child.

Nystagmus: Rapid, involuntary movements of the eyes.

Off time: The time when a Parkinson disease patient has poor control of his or her symptoms.

Off-label use: Use of a medication outside the scope of its approved, labeled use.

Oiling out: Continued coalescence of lipid emulsion particles, resulting in irreversible separation of the emulsion (also called “breaking” or “cracking” of the emulsion).

Oligoanovulation: The condition of having few to no ovulatory menstrual cycles.

Oligoclonal immunoglobulin G bands: Small discrete bands in the gamma globulin region of fluid electrophoresis.

Oligohydramnios: Decreased amniotic fluid.

Oligomenorrhea: Abnormally light or infrequent menstruation.

Oliguria: Reduced urine output; usually defined as less than 400 mL in 24 hours or less than 0.5 mL/kg/hour.

Omentectomy: Excision of the double fold of the peritoneum attached to the stomach and connecting it with abdominal viscera (omentum).

On time: The time when the Parkinson disease patient has good control of his or her symptoms.

Oncogenes: Genes, when activated, that cause transformation of normal cells into cancer cells by promoting uncontrolled cell growth and multiplication leading to tumor formation.

Open comedo: A plugged hair follicle of sebum, keratinocytes, and bacteria that protrudes from the surface of the skin and appears black or brown in color. Also referred to as a “blackhead.”

Opsonization: The process by which an antigen is altered so as to become more readily and more efficiently engulfed by phagocytes.

Optic neuritis: Usually monocular central visual acuity loss and ocular/peri orbital pain caused by demyelination of the optic nerve.

Oral glucose tolerance test: Used to measure the body’s response to glucose; may be used to screen for type 2 diabetes and gestational diabetes.

Oral rehydration solution (ORS): A liquid preparation, commercially prepared or made at home using common ingredients according to a formula developed by the World Health Organization, designed to replace fluid loss in persons with diarrhea.

Organification: Binding of iodine to tyrosine residues of thyroglobulin.

Orthopnea: Difficulty in breathing that occurs when lying down and is relieved upon changing to an upright position.

Orthostasis: Characterized by a drop in blood pressure when standing up from sitting or lying down, often causing light-headedness and dizziness.

Orthotopic transplantation: Placing a transplanted organ into the normal anatomic location.

Osmal gap: The difference between the measured serum osmolality and the calculated serum osmolality.

Osteoblast: Cells that secrete the matrix for bone formation.

Osteoclasts: Cells involved in bone resorption.

Osteomalacia: Softening of the bones.

Osteonecrosis: Death of bone tissue.

Osteopenia: Reduced bone density or mass.

Osteophytes: Bony outgrowths (also called bone spurs) into the joint space.

Osteoporosis: Disease of the bones characterized by a loss of bone tissue, resulting in brittle, weak bones that are susceptible to fracture (porous bones).

Ostomy: Surgical operation by which part of the abdominal wall is opened and part of the intestine is connected to the opening for intestinal draining (e.g., colostomy, ileostomy).

Otalgia: Ear pain or earache.

Otitis media with effusion: Fluid in the middle ear space with no signs or symptoms of an acute infection.

Ovulation: Periodic ripening and rupture of mature follicle and the discharge of ovum from the cortex of the ovary.

Pacemaker: A mass of fibers that possess actual or potential automaticity which initiates and determines the rate of spontaneous depolarizations.

Palliative care: The active, total care of patients whose disease is not responsive to curative treatment.

Palliative chemotherapy: Treatment given to control the symptoms of an incurable cancer.

Pancreatic pseudocysts: A cyst-like space not lined by epithelium and contained within the pancreas.

Pancreatitis: Inflammation of the pancreas.

Panhypopituitarism: A clinical disorder characterized by complete deficiency in pituitary hormone production.

Paracentesis: Removal of ascitic fluid from the peritoneal space.

Parenteral nutrition: Delivery of nutrients via the intravenous route.

Paresthesia: An abnormal touch sensation, such as burning or prickling, that occurs without an outside stimulus.

Paroxysmal: Intermittent occurrence, initiating suddenly and spontaneously, lasting minutes to hours, and terminating suddenly and spontaneously.

Partial response: In cancer, at least a 30% decrease in the sum of the longest diameter of target lesions from baseline.

Partial seizures: Seizures that begin in a localized area of the brain.

Peak expiratory flow: The maximum flow rate of air leaving the lungs upon forced exhalation. Individualized best measurements are established for each patient using a handheld peak flow meter.
Pelvic inflammatory disease: Inflammation of the endometrium, uterine tubes, and pelvic peritoneum; often due to a sexually transmitted infection.

Percutaneous coronary intervention: A minimally invasive procedure whereby access to the coronary arteries is obtained through either the femoral or radial artery up the aorta to the coronary ostia. Contrast media is used to visualize the coronary artery stenosis using a coronary angiogram. A guidewire is used to cross the stenosis and a small balloon is inflated to break up atherosclerotic plaque and restore coronary artery blood flow. A stent is often deployed at the site to prevent acute closure and restenosis of the coronary artery. Newer stents are coated with antiproliferative drugs, such as paclitaxel, sirolimus, zotarolimus, or everolimus, which further reduce the risk of restenosis of the coronary artery.

Percutaneous endoscopic gastrostomy: Gastric feeding tube placed via endoscopic technique.

Percutaneous endoscopic jejunostomy: Jejunal feeding tube placed via endoscopic technique.

Perihilar: Around the root or hilum of the lung.

Perimenopause: Also known as the climacteric, is the period of time prior to menopause when hormonal and biological changes and physical symptoms begin to occur and usually lasts for one year after the last menstrual period. The perimenopausal period may last for an average of three to five years.

Perimetry: Measurement of the field of vision.

Peripheral artery disease: Atherosclerosis of the peripheral arteries.

Peripheral resistance: The sum of resistance to blood flow by systemic blood vessels.

Peritonitis: An acute inflammatory reaction of the peritoneal lining to microorganisms or chemical irritation.

Petechiae: Tiny localized hemorrhages from the small blood vessels just beneath the surface of the skin.

Phagocytosis: The process of engulfing and ingesting an antigen by phagocytes.

Pharmacogenomics: The study of inherited genetic variations that dictate different drug responses. Pharmacogenomics explores the ways such variations can be used to predict responses to investigational products and plays an increasingly important role in drug discovery.

Phenotype: The visible or observable properties of an organism that are produced by the interaction of the genotype and the environment. May be used to evaluate the growth of HIV compared to “wild type” virus in the presence of drug to directly measure the amount of drug necessary to suppress viral replication in vitro.

Pheochromocytoma: A tumor arising from chromaffin cells, most commonly found in the adrenal medulla. The tumor causes the adrenal medulla to hypersecrete epinephrine and norepinephrine resulting in hypertension and other signs and symptoms of excessive sympathetic nervous system activity. The tumor is usually benign but may occasionally be cancerous.

Phlebitis: Inflammation of a blood vessel (e.g., vein).

Photochemotherapy: The use of psoralens in addition to ultraviolet rays for patients with a significant amount of body surface area affected (greater than 10%).

Photodynamic therapy: Treatment with drugs that become active when exposed to light.

Photophobia: Intolerance to bright light.

Phototherapy: The use of ultraviolet rays for patients with a significant amount of body surface area affected (greater than 10%).

Physical dependence: A state of adaptation that is manifested by a drug-class specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.

Pilosebaceous unit: A hair follicle and the surrounding sebaceous glands.

Plaque psoriasis: Plaque psoriasis is the most common form of psoriasis and manifests as well-defined, sharply demarcated, erythematous plaques typically covered with silvery scales. These plaques are irregular, round to oval in shape, and are almost always found on the scalp, trunk, buttocks, and limbs.

Plasma cell: Antibody producing cells.

Plasmapheresis: A process of separating cells out from the plasma. This process is used to remove the monoclonal antibodies from the blood.

Pleocytosis: An increased white blood cell count in a bodily fluid, such as cerebrospinal fluid.

Pleuritis: Inflammation of the lining (pleura) around the lungs.

Pneumatic otoscopy: A diagnostic technique involving visualization of the tympanic membrane for transparency, position, and color, and its response to positive and negative air pressure to assess mobility.

Pneumothorax: The presence of air in the pleural cavity, often causing part of the lung to collapse.

Podagra: Gout involving the first metatarsophalangeal joint (great toe).

Polycythemia: An abnormal increase in the number of erythrocytes in the blood.

Polydipsia: Excessive thirst.

Polymerase chain reaction: A laboratory method used to make many copies of a specific DNA sequence.

Polyphagia: Eating excessively large amounts of food at a meal.

Polypharmacy: Taking multiple medications concurrently.

Polyps: Any growth or mass protruding from a mucous membrane.

Polyuria: Excessive excretion of urine resulting in profuse micturition.

Portal hypertension: Increased pressure in blood vessels leading to the liver; usually a result of cirrhosis.

Posterior circulation: Blood supply to the posterior section of the brain through the vertebral, basilar, and posterior cerebral arteries (i.e., brainstem, cerebellum, occipital lobe).

Postpyloric feeding: Delivery of nutrients via a tube placed with its tip past the pyloric sphincter separating the stomach from the duodenum.

Prader-Willi syndrome: A genetic disorder characterized by short stature, mental retardation, low muscle tone, abnormally small hands and feet, hypogonadism, and excessive eating leading to extreme obesity.

Prediabetes: An asymptomatic but abnormal state that precedes the development of clinically evident diabetes.

Preload: The stretched condition of the heart muscle at the end of diastole just before contraction; volume in the left ventricle at the end of diastole estimated by the pulmonary artery occlusion pressure (also known as the pulmonary artery wedge pressure or pulmonary capillary wedge pressure).

Priapism: A prolonged, painful erection lasting more than 4 hours. Considered a medical emergency.

Primary amenorrhea: Absence of menses by age 15 in the presence of normal secondary sexual development or within 5 years of thelarche (if occurs before age 10).

Primary generalized seizures: A seizure where the entire cerebral cortex is involved from the onset of the seizure.
Primary prevention: A program of activities directed at improving general well-being while also involving specific protection for selected diseases.

Prinzmetal angina: Vasospasm or contraction of the coronary arteries in the absence of significant atherosclerosis. Also referred to as variant angina.

Probiotics: Dietary supplements containing potentially beneficial bacteria that promote health by stimulating optimal mucosal immune responses.

Proctitis: Inflammation confined to the rectum in patients with inflammatory bowel disease.

Proctosigmoiditis: Inflammation involving the sigmoid colon and rectum in patients with inflammatory bowel disease.

Progenitor: A primitive cell.

Prognostic factors: Biologic or clinical indicators associated with survival independent of therapy (e.g., over-expression of HER2 is associated with increased risk of relapse and shorter survival).

Progression: In cancer, cell proliferation takes over and the tumor spreads or develops metastases.

Prolapse: A condition whereby organs fall down or slip out of place.

Promotion: Reversible process in cancer; the environment is altered by carcinogens or other factors to favor the growth of the mutated cell over the normal cell.

Proptosis: Forward displacement of the eyeball.

Prostaglandin: Any of a large group of biologically active, carbon-20, unsaturated fatty acids that are produced by the metabolism of arachidonic acid through the cyclooxygenase pathway.

Prostatectomy: An operation to remove the prostate gland and tissues surrounding it.

Prostatic hyperplasia: Enlargement of the prostate.

Protease: Enzyme that cleaves newly synthesized polyproteins into functional units of an infectious HIV virion.

Proteactant: An agent that forms an occlusive barrier between the skin and surrounding moisture.

Proteinase: Any of numerous enzymes that catalyze the breakdown of proteins (also called protease).

Proteinuria: The presence of measurable amounts of protein in the urine, which is often indicative of glomerular or tubular damage in the kidney.

Proteoglycan: Any one of a class of glycoproteins of high molecular weight that are found in the extracellular matrix of connective tissue. They are made up mostly of carbohydate consisting of various polysaccharide side chains linked to a protein and resemble polysaccharides rather than proteins with regard to their properties.

Proteolysis: Degradation of proteins in damaged tissue.

Proteosome: An enzyme complex that degrades intracellular proteins.

Prothrombin: A clotting factor that is converted to thrombin; also known as Factor II.

Prothrombin time: A measure of coagulation representing the amount of time required to form a blood clot after the addition of thromboplastin to the blood sample; also known as Quick test.

Prothrombotic state: A state of high coagulation of the blood.

Protooncogenes: Normal genes that are present in all normal cells and regulate cell function and replication, and through some genetic alteration caused by carcinogens, change into oncogenes.

Pruritus: Localized or generalized itching due to irritation of sensory nerve endings.

Pseudoaddiction: A term used to describe patient behaviors (e.g., “drug-seeking,” “clock watching,” or illicit drug use) that may occur when pain is undertreated. Pseudoaddiction can be distinguished from true addiction in that the behaviors resolve when pain is effectively treated.

Pseudohyphae: Chains of easily disrupted fungal cells; not a true hypha.

Pseudophakic: Refers to presence of a lens after cataract extraction.

Pseudopolyph: An area of hypertrophied gastrointestinal mucosa that resembles a polyp and contains non-malignant cells.

Psoralens: Compounds that act as photosensitizing compounds.

Psoriatic arthritis: Inflammatory arthropathy associated with psoriasis. This condition is characterized by stiffness, pain, swelling, and tenderness around the joints and ligaments.

Pulmonary artery catheter: An invasive device used to measure hemodynamic parameters directly, including cardiac output and pulmonary artery occlusion pressure; calculated parameters include stroke volume and systemic vascular resistance.

Pulmonary artery occlusion pressure: A hemodynamic measurement obtained via a catheter placed into the pulmonary artery used to evaluate patient volume status within the left ventricle.

Pulmonary embolism: A disorder of thrombus formation causing obstruction of a pulmonary artery or one of its branches and resulting in pulmonary infarction.

Pulsus paradoxus: A large fall in systolic blood pressure and pulse volume during inspiration or an abnormal variation in pulse volume during respiration in which the pulse becomes weaker with inspiration and stronger with expiration.

Punding: Stereotypic behavior with repetitive movement or actions. An adverse reaction to dopaminergic therapy.

Purkinje fibers: Specialized myocardial fibers that conduct impulses from the atrioventricular node to the ventricles.

Purpura: A small hemorrhage of the skin, mucous membrane, or serosal surface.

Purulent: Containing, consisting of, or being pus.

Pustular psoriasis: Collection of neutrophils is great enough to be seen clinically. May be generalized or localized. Often characterized by widespread sterile pustules and erythema.

Pyelonephritis: Inflammation of a kidney.

Pyuria: Presence of pus in urine when voided.

Quality indicators: A list of indicators used by long-term care facility administrators and government overseers to identify potential problems in patient care.

Quality of life: Perceived physical and mental health over time.

Radiofrequency catheter ablation: Procedure by which radiofrequency energy is delivered through a catheter positioned at the atrioventricular node for the purpose of destroying one pathway of a reentrant circuit.

Raphe nuclei: Bed of serotonin containing neurons that extend to the hypothalamus, septum, hippocampus, and cingulate gyrus.

Receptor editing: A process that occurs during the maturation of B cells, which are part of the adaptive immune system. This process forms part of central tolerance to attempt to change the specificity of the antigen receptor of self reactive immature B-cells, in order to rescue them from programmed cell death, called apoptosis.

Recombinant activated factor VII: A clotting factor manufactured via recombinant technology used off-label (not Food and Drug Administration approved) to foster clotting in
hemorrhagic shock patients with massive hemorrhage refractory to conventional therapies such as fresh frozen plasma.

**Rectal prolapse:** Externally visible sinking of the rectum through the anal sphincter.

**Recurrence:** A relapse that occurs after a clear-cut recovery.

**Reentry:** Circular movement of electrical impulses, a mechanism of many arrhythmias.

**Refractory period:** The period of time after an impulse is initiated and conducted during which cells cannot be depolarized again.

**Regurgitation:** A passive process without involvement of the abdominal wall and the diaphragm wherein gastric or esophageal contents move into the mouth.

**Relapse:** The return of symptoms, satisfying the full syndrome criteria, after a patient has responded, but prior to recovery.

**REM sleep:** A state of sleep that recurs cyclically several times during a normal period of sleep and is characterized by increased neuronal activity of the forebrain and midbrain, depressed muscle tone, and especially dreaming, rapid eye movements, and vascular congestion of the sex organs.

**Remission:** Patient has no or minimal symptoms of disease. In the case of cancer, in partial remission, some but not all signs and symptoms of cancer have disappeared. In complete remission, all signs and symptoms of cancer have disappeared, although cancer still may be in the body.

**Renal osteodystrophy:** Altered bone turnover that results from sustained metabolic conditions that occur in chronic kidney disease, including secondary hyperparathyroidism, hypophosphatemia, hypocalcemia, and vitamin D deficiency. The disease can be characterized by high bone turnover, low bone turnover, or adynamic disease, or may be a mixed disorder.

**Renin-angiotensin-aldosterone system:** The hormonal system controlled mainly by the kidneys and adrenal glands that regulates blood pressure, blood volume, and electrolyte balance.

**Resorption:** The process of bone breakdown by osteoclasts.

**Respiratory acidosis:** Acidosis that is caused by an accumulation of carbon dioxide.

**Respiratory Disturbance Index:** A summary measure that quantifies the number of apneas, hypopneas, and respiratory effort-related arousals per hour of sleep.

**Response:** Refers to a pre-defined reduction of symptoms from baseline that generally result in significant functional improvement.

**Response inhibition:** Ability to stay on task or the ability to think before acting.

**Restenosis:** Renarrowing of the coronary artery after a percutaneous intervention.

**Restriction fragment length polymorphism:** Variation in the length of a restriction fragment produced by a specific restriction enzyme acting on DNA from different individuals that usually results from a genetic mutation and that may be used as a genetic marker.

**Retching:** A process that follows nausea and consists of diaphragm, abdominal wall, and chest wall contractions and spasmodic breathing against a closed glottis.

**Reticulocytes:** Immature blood cells that mature into erythrocytes.

**Retinopathy:** Occurs when the microvasculature nerve layer that provides blood and nutrients to the retina is damaged, and can cause blindness.

**Retrograde ejaculation:** Semen flows to the bladder instead of the urethra.

**Reverse transcriptase:** Enzyme that generates complementary DNA from an RNA template used in the replication of HIV.

**Rhabdomyolysis:** Destruction of skeletal muscle.

**Rheumatoid factors:** Antibodies reactive with the Fc region of IgG.

**Rhinosinusitis:** Inflammation of the mucous membranes in the nose and sinuses.

**Rhonchi:** Abnormal, rumbling sounds heard on auscultation of an obstructed airway. They are more prominent during expiration and may clear somewhat on coughing.

**Rouleaux formation:** The stacking or aggregation of red blood cells on a peripheral smear when diluted.

**Rubefacient:** A substance that produces redness of the skin.

**Salicylism:** A toxic syndrome caused by excessive doses of acetylsalicylic acid (aspirin), salicylic acid, or any other salicylate product. Signs and symptoms may include severe headache, nausea, vomiting, tinnitus (ringing in the ears), confusion, increased pulse, and increased respiratory rate.

**Scotoma:** A spot in the visual field in which vision is absent or deficient.

**Secondarily generalized seizure:** A partial seizure (simple or complex) that spreads to the entire brain.

**Secondary amenorrhea:** Absence of menses for 3 cycles or 6 months in a previously menstruating woman.

**Secondary hyperparathyroidism:** Increased secretion of parathyroid hormone from the parathyroid glands caused by hyperphosphatemia, hypocalcemia, and vitamin D deficiency that result from decreased kidney function. Secondary hyperparathyroidism can lead to bone disease (renal osteodystrophy).

**Secondary prevention:** Interruption of any disease process before the emergence of recognized signs or diagnostic findings of the disorder.

**Seizure:** A sudden electrical disturbance of the cerebral cortex, when a population of neurons fires rapidly and repetitively for seconds to minutes and electrical discharges are excessively rapid, rhythmic, and synchronous.

**Sentinel lymph node:** The first lymph node to which cancer is likely to spread from the primary tumor.

**Septic emboli:** A detached, traveling intravascular mass of infected tissue.

**Seropositive:** Showing a positive reaction to a test on blood serum for a disease.

**Serum sickness:** A group of symptoms caused by a delayed immune response to certain medications. Arthralgias, fever, malaise, and urticaria may develop usually 7 to 14 days after exposure to the causative antigen.

**Shear stress:** Risk factor for pressure ulcers that is generated when the head of a patient’s bed is elevated and can cause deeper blood vessels to crimp, leading to ischemia.

**Sialorrhea:** Drooling.

**Sick sinus syndrome:** Idiopathic sinus node dysfunction leading to symptomatic sinus bradycardia.

**Sigmoidoscopy:** Visual inspection of the sigmoid colon and rectum with a flexible tube called a sigmoidoscope.

**Simple acid-base disorder:** The presence of a single acid-base disorder, with or without compensation.

**Simple partial seizures:** Seizures in which the patient has a sensation or uncontrolled muscle movement of a portion of their body without an alteration in consciousness.

**Sleep apnea:** The temporary stoppage of breathing during sleep; can be caused by narrowing of the airways resulting from swelling of soft tissue.

**Sleep latency:** The amount of time it takes to fall asleep.
Sleeve gastrectomy: A surgical treatment for weight loss that involves constructing a small pouch in the stomach that empties through a narrow opening into the distal stomach and duodenum.

Slit-lamp biomicroscope: An instrument that allows for the microscopic examination of the cornea, anterior chamber lens and posterior chamber.

Somatic hypermutation: A cellular mechanism by which the immune system adapts to the new foreign elements that confront it (e.g., microbes), as seen during class switching.

Source control: Removal of the primary cause of an infection such as contaminated prosthetic materials (e.g., catheters), necrotic tissue, or drainage of an abscess. Antimicrobials are unlikely to be effective if the process or source that led to the infection is not controlled.

Spastic colon: A synonym for irritable bowel syndrome.

Spasticity: A motor disorder characterized by an increase in muscle tone with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex.

Spectrum of activity: A qualitative term that describes the number of different bacterial species that are susceptible to an antimicrobial regimen. Generally, broad spectrum activity refers to regimens that possess activity against many bacterial species, whereas narrow-spectrum therapy refers to activity against a few bacterial species.

Sphincter of Oddi: Structure through which the common bile duct empties bile and pancreatic secretions into the duodenum.

Spirometry: Measurement by means of a spirometer of the air entering and leaving the lungs.

Sprain: An overstretching of supporting ligaments that results in a partial or complete tear of the ligament.

Stable disease: In cancer, neither sufficient shrinkage to qualify for partial response nor sufficient increase to qualify for progressive disease.

Stage: Estimate of tumor burden, which is not only of prognostic importance, but also has important implications regarding appropriate treatment options.

Status epilepticus: Continuous seizure activity lasting more than 5 minutes or two or more seizures without complete recovery of consciousness.

Steatohepatitis: A severe form of liver disease caused by fat deposition in the liver, characterized by hepatic inflammation that may rapidly progress to liver fibrosis and cirrhosis.

Steatorrhea: Excessive loss of fat in stool.

Steatosis: Infiltration of liver cells with fat.

Stenosis: Blockage of an artery.

Stenting: Placement of a stent to allow blood flow through an artery.

Stereotactic radiosurgery: A type of external radiation therapy that uses special equipment to position the patient and precisely give a single large dose of radiation to a tumor.

Stevens-Johnson syndrome: A severe expression of erythema multiforme (also known as erythema multiforme major). It typically involves the skin and the mucous membranes, with the potential for severe morbidity and even death.

Stimulant: Any amphetamine or amphetamine-like substance (methylphenidate) that causes an increase in dopaminergic and norepinephrine activity in the brain resulting in lessening of hyperactivity, impulsiveness, and/or inattentiveness.

Stomatitis: Inflammation of mucous membranes in the mouth.

Strain: Damage to the muscle fibers or tendon without tearing of the ligament.

Stricture: An abnormal narrowing of a body passage, especially a tube or a canal.

Stroke volume: The amount of blood ejected from the heart during systole.

ST-segment elevation myocardial infarction: A type of myocardial infarction that typically results in an injury that transects the thickness of the myocardial wall.

Subchondral: Situated beneath and supporting cartilage.

Substantia nigra: The area in the brainstem with highly pigmented cells that make dopamine.

Subtrochanteric: Below the trochanter (the bony protrusion at the end of the femur where the hip and thigh muscles attach).

Surgical site infection: Infections occurring at or near the surgical incision within 30 days of the operation; up to 1 year if a prosthesis is implanted.

Suspending agent: An additive used in the compounding of oral liquid medications to suspend drug particles throughout a liquid; enables resuspension of particles by agitation (e.g., shaking well).

Symptomatic epilepsies: A seizure disorder with an identifiable cause for the seizures, such as trauma or hypoxia.

Synechia: Adhesions or the abnormal attachment of the iris to another structure. Peripheral anterior synechia refers to occurrence of synechia with the trabecular meshwork.

Synergism: Interaction between two or more factors or substances that produces an effect greater than the sum of their individual effects.

Synovitis: Inflammation of the synovial membrane, often in combination with pain and swelling of the affected joint.

Synovium: The membrane lining the internal surfaces of joints.

Systolic dysfunction: An abnormal contraction of the ventricles during systole.

T2 weighted magnetic resonance imaging: A setting of the magnetic resonance imaging machine that shows water as a bright signal.

Tachycardia: An abnormally rapid heart rate.

Tachyphylaxis: A rapidly decreasing response to a drug following its initial administration.

Tachypnea: Faster than normal respiratory rate.

Tachysystole: More than five contractions in 10 minutes, averaged over a 30-minute window.

Tangentiality: Abandoning one’s ideational objective in pursuit of thoughts peripheral to the original goal. Used to describe a thought and speech pattern wherein the individual never gets to the point or answers the question.

Tardive dyskinesia: A chronic disorder of the nervous system characterized by involuntary jerky or writhing movements of the face, tongue, jaws, trunk, and limbs, usually developing as a late occurring side effect of prolonged treatment with antipsychotic drugs.

Targeted therapy: A type of treatment that uses drugs or other substances to identify and attack specific types of cancer cells with less harm to normal cells.

Tendinosis: Tendon degeneration without accompanying inflammation.

Tendonitis: Inflammation of the tendon.

Tenesmus: Difficulty with bowel evacuation despite the urgency to defecate.

Teratogenic: Causing malformations in a fetus.

Terminal secretions: The noise produced by the oscillatory movements of secretions in the upper airways in association with the inspiratory and expiratory phases of respiration. It is also known as “death rattle.”
Thelarche: Onset of breast development.

Third spacing: Fluid accumulation in the interstitial space disproportionate to the intracellular and extracellular fluid spaces.

Thoracentesis: Removal of fluid that is present in the pleural space. Common procedure to determine what caused the fluid accumulation.

Thought-blocking: Speech is halted, often in mid-sentence, and then picked up later, usually at another point in the thought process.

Thrombin: An enzyme formed from prothrombin which converts fibrinogen to fibrin. It is the principal driving force in the clotting cascade.

Thrombocytopenia: A condition whereby the number of circulating platelets are abnormally low due to decreased production of new cells, possibly secondary to medication toxicities.

Thrombocytosis: Increased number of platelets in the blood.

Thrombogenesis: The process of forming a blood clot.

Thrombolysis: The process of enzymatically dissolving or breaking apart a blood clot.

Thrombolytic: An enzyme that dissolves or breaks apart blood clots.

Thrombophlebitis: Inflammation of a blood vessel (e.g., vein) associated with the stimulations of clotting and formation of a thrombus (or blood clot).

Thromboplastin: A substance that triggers the coagulation cascade. Tissue factor is a naturally occurring thromboplastin and is used in the prothrombin time test.

Thrombosis: A condition in which blood changes from a liquid to a solid state and produces a blood clot.

Thrombotic thrombocytopenic purpura: Condition characterized by formation of small clots within the circulation resulting in the consumption of platelets and a low platelet count.

Thrombus: Blood clot attached to the vessel wall and consisting of platelets, fibrin, and clotting factors. A thrombus may partially or completely occlude the lumen of a blood vessel compromising blood flow and oxygen delivery to distal tissue.

Thyroglobulin: A thyroid hormone-containing protein, usually stored in the colloid within the thyroid follicles.

Thyroid peroxidase: Enzyme that catalyzes the organization and coupling steps of thyroid hormone synthesis.

Thyroiditis: Inflammation of the thyroid gland.

Thyrotoxicosis: State caused by excess amount of thyroid hormone.

Tocolytic: Medication used to suppress premature labor.

Tolerance: A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug’s effects over time.

Tonic-clonic seizure: A primary-generalized seizure characterized by a sudden loss of consciousness accompanied by tonic extension and rhythmic clonic contractions of all major muscle groups.

Tonometry: Method by which the cornea is indented or flattened by an instrument. The pressure required to achieve corneal indentation or flattening is a measure of intraocular pressure.

Tophi: Collections of monosodium urate crystals that develop in tissues and generally appear as firm nodules under the skin.

Topoisomerase-I: Enzymes that cut one of the two strands of double-stranded DNA, relax the strand, and reanneal the strand.

Torsade de pointes: Very rapid ventricular tachycardia characterized by a gradually changing QRS complex in the ECG; may change into ventricular fibrillation.

Toxic epidermal necrolysis: A life-threatening skin disorder characterized by blistering and peeling of the top layer of skin.

Toxoid: Bacterial toxin which has been inactivated.

Trained interventionist: Includes mostly health professionals such as registered dieticians, psychologists, exercise specialists, health counselors, and professionals in training who adhere to weight management protocols.

Transesophageal echocardiogram: Procedure used to generate an image of the heart via sound waves, via a probe introduced into the esophagus (rather than the traditional transthoracic view) in order to obtain a better image of the left atrium.

Transferrin saturation: The ratio of serum iron and total iron-binding capacity, multiplied by 100.

Transformation (conversion): Mutated cell becomes malignant.

Transient ischemic attack (TIA): A transient episode of neurological dysfunction caused by focal brain, spinal cord, or retinal ischemia without acute infarction. TIAs have a rapid onset and short duration, typically lasting less than 1 hour and often less than 30 minutes. The symptoms vary depending on the area of the brain affected; however, no deficit remains after the attack.

Translocation: Movement of bacteria and endotoxin from the intestinal lumen through the gut mucosa and into the lymphatic and systemic circulation.

Transmural: Existing or occurring across the entire wall of an organ or blood vessel.

Transsphenoidal pituitary microsurgery: Surgery through the nasal cavity to access the pituitary gland through the sphenoid bone.

Traveler’s diarrhea: An acute infectious diarrhea that afflicts travelers during or immediately upon return from visits to other countries.

Trigeminal neuralgia: A disorder of the fifth cranial (trigeminal) nerve characterized by excruciating paroxysms of pain in the face.

Troponin T or I: Proteins found predominately in the myocardium. Troponin I and T are released into the blood from the myocytes at the time of myocardial cell necrosis secondary to infarction. These biochemical markers become elevated and are used in the diagnosis of myocardial infarction.

Trouseau sign: Noted when a blood pressure cuff is applied to a patient’s upper arm and inflated.

Trypsin: A proteolytic enzyme formed in the small intestine from trypsinogen by the action of enteropeptidase, which once activated hydrolyzes peptides, amides, and esters.

Tuberoeruptive xanthomas: Small yellow-red raised papules usually presenting on the elbows, knees, back, and buttocks.

Tubulointerstitial: Involving the tubules or interstitial tissue of the kidneys.

Tumor lysis syndrome: A syndrome resulting from cytotoxic therapy, occurring generally in aggressive, rapidly proliferating lymphoproliferative disorders. It is characterized by combinations of hyperuricemia, lactic acidosis, hyperkalemia, hyperphosphatemia, and hypocalcemia.

Tumor suppressor genes: A gene that suppresses growth of cancer cells.

Tympanocentesis: Puncture of the tympanic membrane with a needle to aspirate middle ear fluid.

Tympanostomy tube: Small plastic or metal tube inserted in the eardrum to keep the middle ear aerated and improve hearing in patients with chronic middle ear effusion.

Uhthoff phenomenon: Acute worsening of multiple sclerosis symptoms on exposure to heat because high body temperatures
may exceed the capacitance of the demyelinated nerve and conduction may fail.

Ultrafiltration: The movement of plasma water across a semi-permeable membrane.

Uncomplicated acid-base disorder: See simple disorder.

Unstable angina: Pathogenically similar to non-ST segment myocardial infarction but without muscle damage, therefore, troponins are not elevated.

Uremia: A condition that results from accumulation of metabolic waste products and endogenous toxins in the body resulting from impaired kidney function. Symptoms of uremia include nausea, vomiting, weakness, loss of appetite, and mental confusion.

Urethral structure: Narrowing of the urethra.

Uricosuric: Pertaining to, characterized by, or promoting renal excretion of uric acid.

Urosepsis: Sepsis resulting from a urinary source.

Urticaria: Itchy, raised, swollen areas on the skin. Also known as hives.

Uveitis: An inflammation of the uvea. Uveal structures include the iris, the ciliary body, and the choroid.

Vagal maneuvers: Stimulate the activity of the parasympathetic nervous system, which inhibits atrioventricular nodal conduction. Examples of vagal maneuvers include cough, carotid sinus massage, and Valsalva.

Vagotomy: A surgical procedure that blocks vagal (cholinergic) stimulation to the stomach.

Valsalva maneuver: Vagal maneuver; patient bears down against a closed glottis, as if they were having a bowel movement.

Variceal bleeding: Varices are weak collateral blood vessels that are friable and rupture easily; often observed in the esophagus or stomach.

Vasculitis: Inflammation of the walls of blood vessels.

Vasomotor symptoms: Menopausal symptoms that include both hot flashes and night sweats.

Vasopressors: Medications that cause constriction of blood vessels, increase in vascular resistance, and increase in blood pressure.

Vasospasm: Narrowing (constriction) of a blood vessel causing a reduction in blood flow.

Ventilation/perfusion ratio (V/A/Q): A comparison of the proportion of lung tissue being ventilated by inhaled air to the rate of oxygenation of pulmonary blood.

Ventricular depolarization: Change in the membrane potential of a ventricular myocyte, resulting in loss of polarization. Under normal conditions, depolarization of ventricular myocytes is followed by ventricular contraction.

Vertigo: Sensation of spinning or feeling out of balance.

Vesicants: Chemotherapy drugs that cause significant tissue damage if extravasation occurs.

Virilization: Production or acquisition of virilism, which is masculine characteristics.

Volvulus: Twisting of the intestine causing obstruction and possible necrosis.

Vomiting: A reflexive rapid and forceful oral expulsion of upper gastrointestinal contents due to powerful and sustained contractions in the abdominal and thoracic musculature.

Waist circumference: A practical tool to measure the abdominal fat in patients with a BMI of less than 35.

Wernicke syndrome: Neurologic condition caused by thiamine deficiency and characterized by classic triad of symptoms (mental confusion, ataxia, and ophthalmoplegia).

Wheeze: A high-pitched whistling sound caused by air moving through narrowed airways. Wheezes are usually heard at the end of expiration but may be heard during inspiration and expiration in acute severe asthma.

White coat hypertension: A persistently elevated average office blood pressure of greater than 140/90 mm Hg and an average awake ambulatory reading of less than 135/85 mm Hg.

Wild-type virus: Refers to natural form of HIV virus without any genetic mutations.

Wilson disease: A disorder of copper metabolism, characterized by cirrhosis of the liver and neurological manifestations.

Xanthomas: Firm raised nodules composed of lipid-containing histocytes.

Xerostomia: Unusual dryness of the mouth.

ZAP-70 expression: An intracellular tyrosine kinase found in CLL B-cells.

Zymogen: An inactive protein precursor of an enzyme that is converted into an active form.
According to the International Monetary Systems (IMS) Health Report, 4 billion prescriptions were written and dispensed in the United States in 2011. This reflects a need for prescribers and dispensers to fully understand prescriptive privileges and rational prescribing. The following outlines principles of pharmacotherapy, including general considerations of prescribing, rational prescribing of medications, types of prescription orders, safe prescribing practices including the importance of handwriting, adverse event reporting, and medication education.

It is essential that the prescriber and dispenser familiarize themselves with the professional guidelines, state laws, and federal laws. In addition, they must also understand the components of rational prescribing. Table D–1 below provides key elements a prescriber should understand as well as useful resources.

### TYPES OF PRESCRIPTION ORDERS

Prescription orders can be provided in a variety of ways by authorized prescribers. Outpatient prescriptions may be written, verbally authorized by phone, faxed, or provided via electronic means. All outpatient prescriptions are subject to federal regulations and contain the same basic components. Laws and regulations for outpatient prescription requirements can vary from state to state, so prescribers should be knowledgeable of all applicable laws. The basic components of a prescription are listed below as well as numbered in Figure D–1.

1. Prescriber information: name, address, and phone number
2. Prescriber’s signature and prescriptive authority number or Drug Enforcement Administration (DEA) number (if applicable)
3. Patient information: full name and address, and weight and age if appropriate
4. Date the prescription was written
5. Superscription (Rx symbol), meaning “you take” or “recipe”
6. Inscription: medication being prescribed (name of medication, strength, and dose)
7. Signa, sig, or signature: directions to the patient (eg, take one tablet daily)
8. Subscription: dispensing instructions to the pharmacist (number, quantity, or volume to dispense)
9. Number of refills allowed
10. Generic substitution requirement: “DAW (dispense as written)” or “no substitution” if brand name medication only is desired

Further regulations are in place for prescriptions written for controlled substances. In addition to the aforementioned elements, prescriptions for controlled substances must also include the patient’s full name and address as well as the full name, address, and DEA number of the prescriber. Stricter regulations exist for Schedule II controlled substances compared with Schedule III-V. Schedule II prescriptions must be written and can only be provided orally in an emergency situation. Refills are prohibited with Schedule II prescriptions. Schedule II and IV prescriptions may be refilled up to five times within 6 months of when the prescription was issued.

Chart orders, orders written for hospital inpatients, are not considered prescriptions and are not subject to the same requirements. Typically chart orders include:

- Patient identifiers including name and account number
- Physician name
- Medication name, dose, route, and frequency of administration
- Date and time of order
- Physician signature
- If the order was given verbally, the person reducing the order to writing must sign the order and the ordering physician countersign

Electronic prescribing has become common practice because of government incentives aimed at moving health records to electronic databases. Principles discussed previously in regard to requirements of a prescription hold true for electronic orders; however, additional considerations must be taken to ensure safe prescribing habits occur. A brief list of potential barriers and benefits is summarized in Table D–2.

Electronic prescribing is no longer a projection of the future but instead is becoming the norm. With appropriate use of this technology, patients are provided ultimately with safer and more efficient care.

Omission of any of the earlier discussed elements on a prescription order can be considered erroneous and poses a danger to patient care. Responsibility lies with the prescriber as well as the pharmacist dispensing the medication to ensure the prescriptions are not only accurate but also appropriate for the given patient.

### SAFE PRESCRIBING PRACTICES

Safe prescribing should be a priority of all health care providers. To avoid inappropriate use of medications in patients, prescribers
### Table D–1

**Pharmacotherapy Principles**

<table>
<thead>
<tr>
<th>Pharmacotherapy Principle</th>
<th>Description</th>

</tr>
</thead>
<tbody>
<tr>
<td>Prescriptive privileges</td>
<td>Dictated by federal and state law. Scope of practice and formularies vary by profession. Physicians, nurse practitioners, physician assistants, and dentists all have varying scopes of practice, which may include formularies or supervising prescribers. Each provider must become familiar with his or her profession’s scope of practice. Pharmacology courses in program of study and Continuing Education required. Prescribing legend drugs requires board examination and National Provider Identifier (NPI). Prescribing controlled substances requires DEA registration number.</td>

should take careful consideration in writing clear and descriptive prescriptions. This ensures appropriate communication among all interdisciplinary health care providers.

A thorough understanding of the medication prescribed, including its expected risks and benefits, should be realized by the prescriber ensuring appropriate drug selection. Providers should be aware of common errors related to prescription writing. These errors include: sound-alike/look-alike medications and inappropriate use of shorthand language and abbreviations. The Joint Commission, as well as the Institute for Safe Medication Practices (ISMP), has collected common examples of these errors seen during the ordering process. Common examples are described in Tables D–3 and D–4.

Other abbreviations are commonly used medical abbreviations used in prescription writing can be found in Appendix B: Common Medical Abbreviations.

### Adverse Event Reporting

Adverse events may occur related to inappropriate prescribing, dispensing, or administering medications. Inappropriate prescribing may be avoided by ensuring care is taken to determine

[^ab]: For additional information, please see ISMP/Joint Commission List of Error-Prone Abbreviations.
all pertinent patient related issues are discussed during the encounter. Additionally, appropriate interdisciplinary care where multiple health care providers are evaluating the patient’s problem and its treatment may help avoid adverse events from occurring. Inappropriate dispensing and administration may be avoided through use of clear order entry that undergoes multiple checks by a variety of providers before it reaches the patient. Movement to electronic prescribing has helped eliminate many issues with misinterpreting hand written orders, however, should they still be encountered, providers should take care to very legibly write prescriptions. If any questions remain upon receipt of a questionable order should be verified with the writing provider by the dispensing pharmacist. If adverse events related to medication use are determined, the health care provider who discovers the event is responsible for reporting it. The Food and Drug Administration’s reporting system for such adverse events is MedWatch http://www.fda.gov/Safety/MedWatch/default.htm. This online database archives medication-related adverse events, and providers are able to report errors seen in clinical practice.

Medication Education
After a prescription has been written, counseling patients on newly prescribed therapies is an essential responsibility of the prescriber and pharmacist. The patient should be made aware of the rationale for drug use, the dose, route, and frequency at which they should administer the medication and expectations of the prescribed drug. Expectations should include risks and benefits to avoid patient confusion about side effects or efficacy measures. Thorough discussion of medication therapy selected with the patient may identify contraindications previously unknown or a patient history of failure or success with the selected agent in the past.

CONCLUSION
Multiple principles must be exercised for appropriate drug delivery from the bedside to the patient. As a health care provider, understanding these processes helps to ensure safe medication prescribing.

Apo B synthesis, 224–225
Apolipoprotein E, 452
Apomorphine
adverse effects of, 514
dosage of, 511t
in Parkinson disease, 511t, 514
Apoptosis, 68, 507
Apraclonidine in glaucoma, 926t, 930
Apriso in inflammatory bowel disease (IBD), 311
Aqueous humor in glaucoma, 922–923
Aqueous shunts in glaucoma, 925t
Arboviruses, in CNS infections, 1060
Arcuate scotoma, 924
Arformoterol, 265
Argatroban, 180
for HIT, 180
Arginine vasopressin and heart failure, 68
Aripiprazole
adverse effects of, 567, 569t
in bipolar disorder, 607t
dosage of, 567, 568t, 607t
in schizophrenia, 567, 568t
Armadoitin in narcolepsy, 636
Aromatase inhibitors (AI) in cancer, 1310
Arrhythmias, 137–159
adverse effects of drugs used to treat, 148t
case studies, 145, 146, 152
normal and abnormal cardiac conduction and electrophysiology, 137–140, 138
cardiac conduction system, 137–138
electrocardiogram (ECG), 139
Mechanisms of cardiac arrhythmias, 139–140
abnormal impulse conduction, 139–140, 140f
abnormal impulse initiation, 139
refractory periods, 139
Vaughan Williams classification of antiarrhythmic drugs, 140, 141t
ventricular action potential, 138–139
patient care process, 158–159
Arsenic trioxide, in cancer, 1304
Arteriovenous malformation, 158
Arthritis
and cystic fibrosis, 282
psoriatic, 965
Arthrocentesis, 905
Artificial tears
in allergic conjunctivitis, 939
dry eye, 946
viral conjunctivitis, 938
Ascariasis, 1160
Ascites, 349, 371
approaching patient with, 355f
in cirrhosis, 350, 356–357
development of, in cirrhosis, 352f
diagnosis of, 353
Asenapine
in bipolar disorder, 607t
dosage of, 607t
in schizophrenia, 568t, 569
1-Asparaginase, in cancer, 1304
Aspergillus, 276

**Asthma**

- special populations, 256–257
- quick relief medications in home settings, 257–258
- overview, 241
- outcome evaluation, 257–259
- long-term control medication in, 247–249, 248t–249t
- self-management, 254–256
- action plan, 256
- trigger avoidance in, 243–244
- Astrinents

### Common Laboratory Tests

The following table is an alphabetical listing of some common laboratory tests and their reference ranges for adults as measured in plasma or serum (unless otherwise indicated). Reference values differ among laboratories, so readers should refer to the published reference ranges used in each institution. For some tests, both the Système International Units and Conventional Units are reported.
